Some appetitive instrumental sexual responses are expressed without much prior experience (e.g., nose-pokes, digging, obstruction-box performance, crossing electrified grids), whereas others require some degree of training (maze learning or bar pressing). Those behaviors can be reduced following castration, indicating that gonadal steroid actions in the brain are necessary for their development and/or maintenance, or following lesions of certain steroid-concentrating brain regions, for example, basolateral amygdala. They can also be reduced after a devaluation of the sexual reward (e.g., switching from receptive female to no female, an extinction procedure), or following infusions of DA antagonists to the nucleus accumbens (NAcc). DA antagonists administered systemically to male rats reduce running speed in a runway that leads to a goal box containing a sexually receptive female, and microinjections to the mPOA disrupt maze learning for sexual reinforcement in the male rats. It is likely that different DA terminal regions play a role in different types of unconditioned and conditioned sexual activity. Female rats will bar-press for access to gonadally intact, sexually active males, and access to intromissions from a male that were made contingent on poking a lever with the nose increased the incidents of nose-poking in sexually receptive female rats. Contingent access to male bedding or emulsified preputial gland secretions did not support increases in behavior, indicating that the copulatory stimulation was rewarding. As noted above, paradigms which allow females to pace the rate of copulation result in sexual reward. Any imposition of an operant prior to copulatory stimulation, therefore, allows females to pace copulation at their own preferred rate. Although copulation in general increases DA release in the mPOA, NAcc, and striatum of male and female rats, such operant pacing of copulation increases DA release more in the striatum relative to

unpaced copulation. Consistent with this, lesions of the striatum reduce the ability of females to pace the copulatory interactions, whereas lesions of the NAcc result in females that avoid sexual contact.

Desire and Reward Inferred from Copulatory Behaviors

The strength of certain copulatory behaviors can be taken as measures of sexual motivation. In female rats, for example, such behaviors include solicitations, pacing, and the magnitude of lordosis. In male rats, such behaviors include the latency to mount, the number of intromissions before ejaculation, and the total number of ejaculations the male can achieve in a circumscribed test. Lesions of the mPOA in female rats abolish solicitations and other precopulatory indices of sexual motivation. Lesions of the mPOA in male rats abolish copulatory behavior altogether, although they leave bar-pressing for second-order sexual incentives intact. Systemic treatment with the DA agonist apomorphine increases solicitations and reduces pacing in females, a pattern of behavior indicative of a greater degree of sexual desire and time spent copulating with males. In males, apomorphine stimulates mounts, intromissions, and ejaculations, although at high doses this excitatory effect is overpowered by the psychomotor stimulating effects of the drug. Conversely, systemic treatment of female rats with DA antagonists, such as haloperidol, dramatically reduces solicitations, increases pacing, and makes females unable to disengage from lordosis once they have engaged in the posture. In males, DA antagonists increase the mount and intromission latencies, and reduce the number of ejaculations that males are capable of attaining. As mentioned above, DA release is increased in the mPOA, NAcc, and striatum of both female and male rats during copulation, and in males, DA release falls immediately after each ejaculation, and rises again prior to the initiation of copulation. The role of DA in the NAcc appears to play a role in attention toward sexual incentives, especially during appetitive phases of sexual behavior, whereas the role of DA in the striatum appears to enhance motor output, but especially if an operant is imposed. DA in the mPOA appears to modulate appetitive responses, perhaps by activating efferent connections to the ventral tegmental area (VTA) to drive sexual-incentive motivation.

Other neurotransmitter systems are also important for sexual desire. For example, melanocortin agonists, such as MT-II and bremelanotide, increase solicitations selectively in female rats. Both agonists induce this effect after microinfusions to the lateral ventricles or directly to the mPOA, but not the ventromedial nucleus of the hypothalamus (VMH). Interestingly, systemic administration of bremelanotide increases DA release selectively in the mPOA, and blockade of D1 receptors

in the mPOA can reverse the increase in solicitations induced by systemic bremelanotide treatment. This suggests that melanocortin receptors in the mPOA potentiate sexual desire in females by promoting DA release and subsequent binding to D1 receptors. Recent clinical trials with bremelanotide have confirmed that the drug administered intranasally stimulates sexual desire both in pre- and postmenopausal women with hypoactive sexual desire disorder. The VMH plays a key role in regulating lordosis by estrogens, perhaps through a disinhibitory process by which glutamate interneurons in the VMH (whose activation inhibits both appetitive and consummatory measures of female sexual behavior) are inhibited by the estrogenic stimulation of γ -aminobutyric acid (GABA) and/or other inhibitory transmitters directly onto glutamate neurons. In contrast, GABA transmission in the mPOA inhibits female sexual behavior, whereas nitric oxide-potentiated glutamate release in the mPOA stimulates DA release presynaptically to enhance male sexual behavior. This complex neurochemical interplay in hypothalamic regions appears to involve both excitation and disinhibition in the activation of sexual desire. In turn, hypothalamic outputs combine with more general motivational systems in limbic regions of the striatum, amygdala, and piriform cortex (and likely elsewhere) to focus attention on primary and conditioned-incentive sexual stimuli in the external environment and direct motor patterns that enable animals to seek out and act upon those incentives ([Figure 2](#)).

Sexual Inhibition

All behaviors have a beginning, middle, and end. The end typically comes with the attainment of reward large enough to activate mechanisms of satiety. In any motivational system, reward is a dynamic function with an inverted U-shaped relationship to ongoing behavior: Low rewards do not generally sustain behavior, moderate-to-ideal rewards do, and high rewards induce the inhibitory feedback that characterizes satiety. With regard to sexual behavior, rewards that sustain sexual arousal and desire might be considered low-to-moderate, whereas high rewards like orgasm might be those that induce a period of sexual refractoriness. Although sexual satiety decreases sexual responding in the short term, the reward associated with it in male and female rats is necessary for the conditioning of sexual preferences in the long term.

The notion of separate (but interactive) neural systems for behavioral excitation and inhibition goes back to the work of early neurophysiologists like Sechenov, Sherrington, and Pavlov, and more modern psychologists like Jeffrey Gray. It has important implications for motivation, in general, because it posits that behavior can commence either due to direct excitation or through a process of disinhibition.

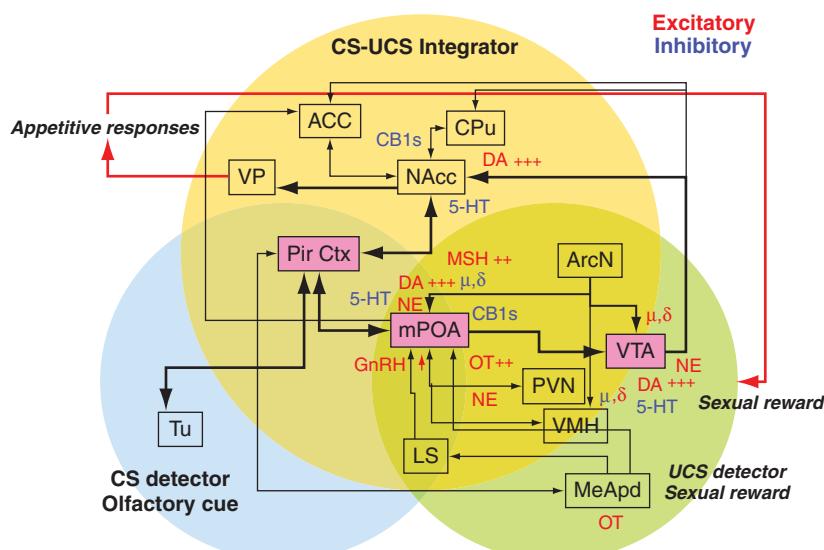

Figure 2 Neural systems which are critical for the display of conditioned olfactory preferences in the rat. Appetitive behaviors made toward conditioned stimuli lead to sexual reward that is processed by three interactive systems. Two systems process olfactory stimuli and sexual reward relatively independently, whereas a third – mesolimbic DA system – acts to integrate both the conditioned olfactory cue and its rewarding sexual outcome. Three common regions – the piriform cortex, mPOA, and VTA – are activated in male and female rats by conditioned olfactory stimuli. Opioid actions in the VTA potentiate mesolimbic DA activation, whereas opioid actions in the mPOA inhibit sexual arousal and desire. Neurotransmitter systems or their receptors in red are excitatory for sexual motivation whereas those in blue are inhibitory. Note that opioids can be excitatory in the VTA, inhibitory in the mPOA, or either in the VMH (depending on the receptor type). Abbreviations: ACC = anterior cingulate cortex; ArcN = arcuate nucleus of the hypothalamus; CB1 = cannabinoid Type 1 receptor; CPU = caudate-putamen (striatum); DA = dopamine; δ = delta opioid receptors; GnRH = gonadotropin-releasing hormone; LS = lateral septum; MeApd = posterior-dorsal nucleus of the medial amygdala; mPOA = medial preoptic area; MSH = melanocortin-stimulating hormone; μ = mu opioid receptors; NAcc = nucleus accumbens; NE = noradrenaline; OT = oxytocin; PirCtx = piriform cortex; PVN = paraventricular nucleus of the hypothalamus; Tu = olfactory tubercle; VMH = ventromedial nucleus of the hypothalamus; VP = ventral pallidum; VTA = ventral tegmental area; 5-HT = serotonin.

A Dual Control Model of sexual function has been advanced by researchers that posits excitatory and inhibitory mechanisms in the brain that interact to produce a level of sexual responsiveness in all individuals during all phases of the sexual response cycle. This model stresses the adaptive nature of both excitatory and inhibitory processes. For example, the adaptive nature of sexual excitement would drive individuals to seek out sexual partners for reproductive or reward purposes. The adaptive nature of sexual inhibition would guard against situations that threaten the individual, including chronically stressful life events. However, too little activation of the excitatory mechanisms, as might occur in hypogonadal individuals, or too much activation of the inhibitory mechanisms, would be expected to lead to decreased sexual motivation. The study of sexual inhibition is also critical if we are to understand how certain events or prosexual drugs (e.g., alcohol, cocaine) induce sexual disinhibition.

Sexual inhibition is most likely to occur in the presence of an obvious threat or a conditioned cultural proscription against the activity (complete with the possibility of getting caught). However, this raises some interesting issues with regard to the arousing nature of

inhibition. As mentioned above, central excitation and inhibition both activate the autonomic nervous system. A small degree of stress or threat (i.e., something naughty or even painful) can be arousing, especially for individuals with low levels of arousability. Translated to a sexual situation, such arousal could be transferred directed into sexual activity, perhaps to the point where, in some individuals, it becomes a necessary antecedent. Anger, fear, or even short-lived terror, can be preludes to sex because they stir passion or arousal. The stimuli that evoke excitation and inhibition may be different for different individuals and what inhibits one person may actually excite another.

Punishment and Stress

Although punishment with shock can suppress a variety of appetitive and consummatory behaviors in rats, such punishment has never been reported to induce sexual inhibition in males. In fact, shock, short-term pain (e.g., tail-pinch), or neutral stimuli paired with them, actually stimulate mounting in sexually sluggish or inactive male rats, and reduce the number of intromissions required for

ejaculation in sexually active males. As mentioned above, both male and female rats will readily cross electrified grids to gain access to sexually receptive partners, and arousal is a necessary antecedent to sexual activity and sexual reward in both male and female rats. However, more reliable methods of punishment exist. Rodents live in a predominantly olfactory world, and pairing estrous odors with gastrointestinal distress (induced by contingent injections of lithium chloride that make animals sick) induces a conditioned odor-aversion in male rats and hamsters that translates to avoidance of female vaginal secretions, increased mount and intromission latencies, decreased proportion of males that ejaculate, or avoidance of copulation altogether. This effect occurs if conditioning took place when the males were juveniles, and conditioned males utter distress vocalizations in the presence of vaginal secretions. Male rats can also learn to avoid copulation with sexually receptive females scented with odors that predict gastrointestinal distress, while copulating normally with unscented females.

When are animals in the wild exposed to circumstances in which they must inhibit their sexual responses? Dominance hierarchies are important in controlling copulation in the wild, and, in some primate species, subordinate males will not attempt to copulate with females in the presence of dominant males. Males of many species also inhibit their copulatory advances in the presence of sexually nonreceptive females. This is in marked contrast to laboratory settings in which male rats will attempt to copulate with nonreceptive females placed into chambers in which the males have copulated previously with sexually receptive females. However, training sexually active male rats to differentiate between sexually receptive and nonreceptive females on alternating test trials leads quickly to a substantial reduction in the proportion of males that attempt to copulate with nonreceptive females. The aversive stimuli provided by the nonreceptive females include a thwarting of attempted copulations due to the female's lack of receptivity, along with aggressive and defensive behaviors (e.g., boxing, biting, kicking) when the male attempts to mount. By virtue of the females being nonreceptive, these behaviors are paired with a lack of estrous odors. Males learn quickly to differentiate the presence of estrous odors with preceptive and receptive behaviors, and the lack of estrous odors with thwarted sexual advances and female aggression (which can be severe). In the wild, such conditioning may occur normally during adolescence. As juveniles, male and female rats mount almost anything, including one another. As the expression of this behavior transitions into adult forms, males likely attempt to mount adult females that are not in heat. Of course, those females teach the males not to try it again. Using this type of conditioned inhibition, researchers have shown that low-to-moderate doses of alcohol can release sexual behavior

from inhibition and compel male rats to attempt copulation with nonreceptive females. This finding is of interest for several reasons, most notably because alcohol intoxication figures in high-risk human sexual activity. A neutral odor paired with sexually nonreceptive females can also inhibit male sexual advances toward a sexually receptive female bearing the odor.

Refractoriness and Sexual Satiety

If male rats are allowed to copulate to sexual exhaustion, they display reduced responsiveness to female solicitations and many will not copulate to ejaculation for 24–48 h. This inhibition is due to neurochemical events that underlie sexual satiety, and can be partly or fully reversed with the α_2 -adrenergic receptor antagonist yohimbine (which increases noradrenergic tone), the 5-HT-1a agonist 8-OH-DPAT (which decreases serotonin release), and the opioid-receptor antagonists naloxone or naltrexone. This suggests that increased release of serotonin and endogenous opioids, and decreased release of noradrenaline, somewhere in the brain underlie the inhibitory state of sexual satiety. As with men, sexual inhibition in women can occur as a result of stress, lack of intimacy, sexual nonreward, or in the refractory state after orgasm that denotes satiety. Sexual inhibition in female rats has been explored rudimentarily in paradigms of estrus termination (in which sexual behavior is inhibited by a large amount of vaginocervical stimulation prior to testing), after subthreshold administration of ovarian hormones to ovariectomized rats (which stimulates a low level of lordosis but no appetitive behaviors), and following sexual nonreward (induced as noted above by naloxone treatment during the females' early sexual experience). Appetitive sexual behaviors like solicitation are the most sensitive to those treatments. As the intensity of the inhibition progresses, females display increases in pacing and defensive behaviors and a decrease in high-intensity lordosis.

Integration

Motivation imbues all aspects of sexual behavior. In all animals, sexual arousal, desire, reward, and inhibition are integrated along neural mechanisms of sexual excitation and inhibition. These mechanisms are set up by steroid hormone actions in the hypothalamus (notably the mPOA) and limbic system (notably the NAcc, amygdala, and cells in the VTA that give rise to the mesolimbic DA system) and altered conditionally (and continually) by interaction with sexual incentive stimuli that lead to sexual reward. Hormonal actions stimulate the synthesis of proteins that act as transmitter receptors, synthesizing enzymes, uptake mechanisms, etc., that create a different 'state' of neurotransmitter actions in hypothalamic,

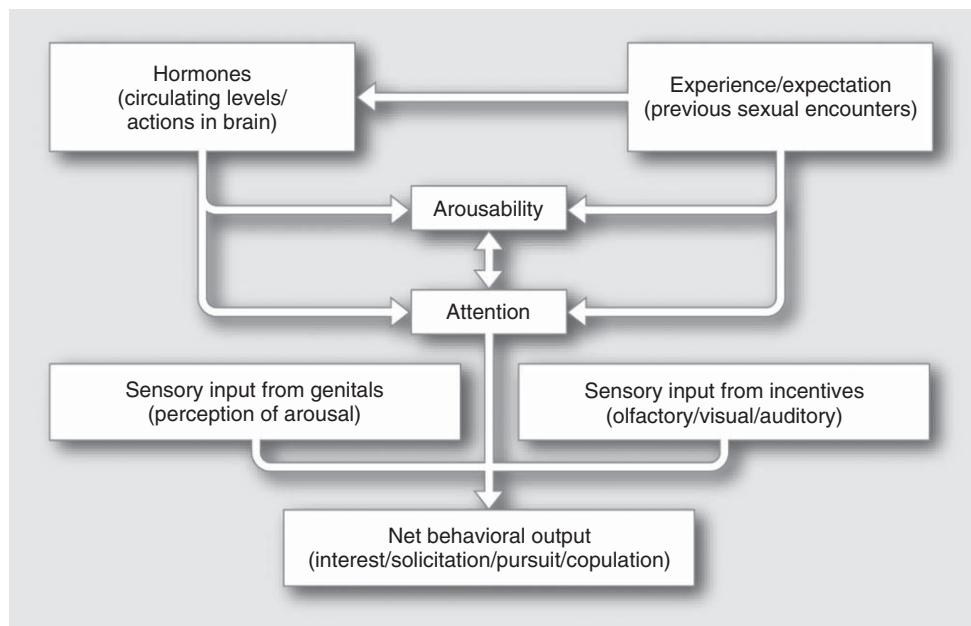

Figure 3 Hypothetical relationship between experience, hormonal activation, arousability, attention, and stimulus processing from genital sensations and external incentives on net sexual responding at any given time. Note that excitatory and inhibitory feedback can occur anywhere in this flowchart to strengthen or reduce responding. Such feedback provides moment-to-moment modulation of sexual motivation. limbic, and cortical sites to support sexual responding. The brain's excitatory and inhibitory systems for sexual behavior are likely in constant interaction. The excitatory system involves the coordinated activation of noradrenergic pathways for central and autonomic arousal, and mesolimbic, nigrostriatal, and hypothalamic DA pathways for attention toward external incentive stimuli and the activation of specific sexual responses. These systems are themselves modulated by certain neuropeptides, notably melanocortins, which activate DA release in the mPOA selectively and conditionally in response to sexual incentive stimuli, and may modulate oxytocin which selectively and conditionally activates genital blood flow. The inhibitory system involves the coordinated activation of opioid pathways that support sexual reward states and serotonergic pathways that induce feelings of satiety after orgasm or ejaculation. However, those systems may also be activated in response to stressors or environments in which sexual responding is dangerous or otherwise not in the organism's best interest. Some transmitter pathways feed-forward to sensitize mechanisms of bonding (e.g., oxytocin, vasopressin), activate reproduction and steroid hormone synthesis (e.g., gonadotropin-releasing hormone), and to sensitize mesolimbic and other DA pathways so that conditioned sexual incentives can prime the excitatory system into action. The sum of those influences (Figure 3) generates a net 'sexual motivation' that is either at a hypothetical zero, in the case where excitatory and inhibitory influences are equal, or is

enhanced or inhibited depending on the dominant influence at the time.

Glossary

Central pattern generators (CPGs) – Neuronal circuits located in the thoraco-lumbar spinal cord that generate the locomotor pattern. This pattern is inborn, is shaped by proprioceptive input, and is under the control of cortical and brainstem centers.

Electromyography (EMG) – A device used to record muscle activity by needle or surface electrodes. It reflects the activity of motoneurons within the spinal cord.

Monosynaptic stretch reflex – This reflex is the simplest reflex system. Muscle spindles within a muscle monitor changes in muscle length. The afferent discharge of the muscle spindles is mediated by fast-conducting afferents to the motoneurons of the muscle of origin (i.e., one synapse). The excitatory input leads to a discharge of the motoneurons. This again leads to a contraction of the muscle which becomes stretched. The delay between the stretch of the muscle and its contraction is therefore within a minimal range (e.g., latency for the lower leg muscle is around 40 ms). The monosynaptic stretch reflex plays a role in the neurological examination in order to recognize, for example, a spastic paresis.

Proprioception – Afferent information from the limbs (muscles, skin, and tendons) to the spinal cord. This information is used by spinal neuronal circuits to shape the locomotor pattern according to the actual requirements.

Propriospinal neurons – Neuronal circuits within the spinal cord. These circuits activate and control movements of the different limbs, for example, the coordination of upper and lower limbs during locomotion.

Clinical Relevance

The study of movement control has relevance to our general understanding of brain function; however, it also has implications for specific fields, such as neurology, cognitive neuroscience, rehabilitation medicine, and robotics. Our understanding of movement disorders and their appropriate treatment depends on knowledge of the

neuronal mechanisms that underlie normal functional movements. Movement disorders are the focus of one of the most rapidly expanding fields in medicine, leading to increasing costs of treatment and rehabilitation. There is increasing evidence that movement disorders, such as spasticity and Parkinson's disease, involve the defective use of afferent input in combination with secondary compensatory processes. This article focuses on the role of proprioception and a quadrupedal organization of human locomotion, which can serve as a paradigm for functional movements.

In a general sense, locomotion is representative of movement control. It is a subconsciously performed, everyday movement that is highly reproducible and is adapted automatically to existing conditions, such as ground irregularities, within a large safety margin. Furthermore, knowledge about the neuronal control of human locomotion is of wide interest for clinical reasons. Characteristic disorders of locomotion are often the first sign of a central or peripheral lesion of the motor system.

Neuronal Control of Locomotion

It is generally accepted that locomotion in mammals depends on neuronal circuits (networks of interneurons) in the spinal cord (the central pattern generator (CPG)) that can act in the absence of any afferent input. Afferent information influences the central (spinal) pattern and, conversely, the CPG selects appropriate afferent information according to external requirements. In addition, proprioceptive information provides the basis for a conscious representation of our body in space, which becomes severely disturbed in deafferented individuals. Both the spinal locomotor center (CPG) and the reflexes that mediate afferent input to the spinal cord are under the control of the brainstem. In addition, there is a phase-linked corticospinal control of locomotion in humans. Voluntary commands have to interact with the spinal locomotor generator to change, for example, the direction of gait or to avoid an obstacle. Any disturbance of this finely coordinated interaction between afferent inputs and pattern generation after a central lesion, such as stroke or spinal cord injury, leads to a movement disorder.

Irrespective of the conditions under which stance and gait are investigated, the neuronal pattern that is evoked

during a particular task is always directed to hold the body's center of mass over the base of support. All control mechanisms must therefore be considered and discussed in this respect. One consequence is that the selection of afferent input by central mechanisms must correspond to the requirement for body stabilization. Neuronal signals of muscle stretch or length are insufficient for the control of bipedal posture. Only a combination of afferent inputs can provide the information that is needed to control the body's equilibrium during locomotion.

The control of locomotion involves the use of afferent information from a variety of sources in the visual, vestibular, and proprioceptive systems. As a rule, spinal reflex pathways and descending pathways converge on common spinal interneurons to integrate these inputs. Furthermore, the amount of proprioceptive feedback from the legs during various locomotor activities determines the influence of vestibulospinal input on the stabilization of body movement. Conversely, somatosensory loss increases vestibulospinal sensitivity.

Reflex Mechanisms

The adaptation of the locomotor pattern to external demands is achieved by proprioceptive input that continuously modulates the programmed pattern during locomotion as per the information from peripheral sensors. Proprioceptors include receptors of the locomotor system that are located in the muscles and tendons, as well as other mechanoreceptors in the joints and the skin. The impulses of these receptors – which signal, for example, muscle stretch or tension – are conveyed to the spinal cord by afferent nerve fibers of different diameters, and

hence of different excitability and conduction velocity. On the basis of these differences, the input from various types of receptors can be separated into fiber types of group I to group IV (Table 1). For example, impulses from sensors of dynamic muscle length (spindles) are mediated by group Ia afferents, whereas those representing static muscle length are carried by group II fibers, and information about tension developed at the tendons (measured by Golgi organs) is transmitted by group Ib fibers to the spinal cord. Only the group Ia fibers have direct excitatory connections to the motoneurons of the same muscle – they are part of the monosynaptic stretch reflex, which has a characteristic short latency (~40 ms). The other afferent fibers converge on spinal interneurons that project in a more complex way to the motoneurons of leg muscles. Consequently, their afferent input usually leads to responses in synergistic muscle groups with a longer latency (starting at 70–80 ms). This pathway represents the polysynaptic, or long-latency, reflex mechanism.

For methodological reasons, there has been a bias toward the simplest reflex system, the monosynaptic stretch reflex, in experimental studies of the afferent sources that contribute to the regulation of human gait. Most studies have focused on the contribution of type Ia afferents using the H-reflex technique (which measures the monosynaptic reflex response of the muscle to low-intensity electrical stimulation of group Ia afferents). However, as discussed below, the contribution of this reflex system to the regulation of locomotion is limited. The significance of, for example, type Ib, II, or III afferents to locomotor movements has been underestimated for many years.

In fact, there is multisensory afferent input during locomotion both in the cat and in humans. This proprioceptive input arises from muscles, skin, joints, and

Table 1 Prorioceptive reflexes suggested to be involved in locomotion

Appropriate stimulus	Receptor pathway	Afferent connection	Reflex	Suggested function
Dynamic muscle stretch (small amplitude)	Muscle spindles (nuclear bag)	Group I	Monosynaptic stretch reflex	Compensation for ground irregularities; running/hopping (?)
Muscle stretch (large amplitude; static)	Muscle spindles (nuclear chain)	Group II (III)	Polysynaptic spinal reflex	Compensation for perturbations of gait
Change in body's center of mass	Golgi tendon organs	Group Ib	Polysynaptic; convergence spinal interneurons	Control of body's center of mass
Joint-movement position	Muscles around joint; mechano-sensors of joint capsule	Group I,II	Polysynaptic; convergence spinal interneurons	Influence on locomotor pattern (hip); local compensation (other leg joints)
Skin deformation	Mechanosensors of skin	Group II (III)	Polysynaptic; convergence spinal interneurons	Adaptation to actual ground conditions
Noxious stimulus; pressure	Free endings; Pacini corpuscles	Group III, IV	Spinal interneurons (CPG); flexor reflex	Withdrawal reflex

CPG, central pattern generator.

tendons. One of the primary functions of proprioceptors is to detect unexpected events and to initiate rapid compensatory electromyographic (EMG) responses. Recently, it has become clear that proprioceptors have further roles in the regulation of motor output during unperturbed movements. This is the case, for example, during the push-off phase of locomotion, running and hopping, and the control of the unperturbed step cycle (cf. **Figure 1**).

Monosynaptic Reflexes

The monosynaptic reflex represents the most extensively investigated proprioceptive reflex system. Monosynaptic reflex responses can be recognized clearly by the characteristic short-onset latency of the EMG responses, which alter muscle stretch in different motor conditions.

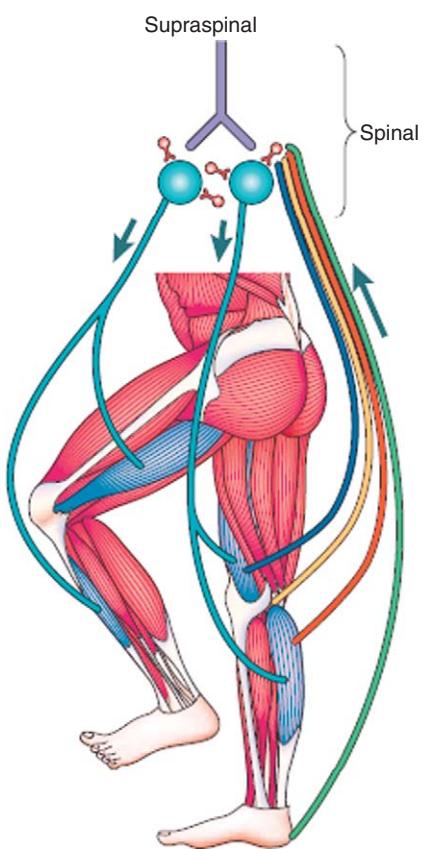

Figure 1 Schematic drawing of the neuronal mechanisms involved in human gait. Physiological condition. Leg muscles become activated by programmed pattern that is generated in spinal neuronal circuits (turquoise pathway). This pattern is modulated by multisensory afferent input, which adapts the pattern to meet existing requirements. Both the pattern and the reflex mechanisms are under supraspinal control. In addition, there is differential neuronal control of leg extensor and flexor muscles. Whereas extensors are mainly activated by proprioceptive feedback, the flexors are under central control. From Dietz V (2002) Proprioception and locomotor disorders. *Nature Reviews Neuroscience* 3: 781–790.

The potential significance to locomotion of group Ia afferent input lies in the fact that its gain can be modulated by presynaptic inhibition (i.e., type Ia excitatory input to the motoneurons can be attenuated, e.g., by supraspinal influences) and by changes in muscle-spindle sensitivity. This sensitivity is controlled by the fusimotor system, which can vary the strength of activation of intrafusal muscle fibers in muscle spindles by γ -motoneurons.

During locomotion, the threshold and amplitude of the soleus H-reflex is modulated over the entire step cycle. The functional implications of this modulation of group Ia afferent input during locomotion are suggested to be threefold: First, facilitation of the gastrocnemius/soleus stretch reflex at the end of the stance phase contributes to compensation for ground irregularities and assists during the push-off phase. Second, the depression of type Ia inputs to leg extensor motoneurons during the swing phase prevents the occurrence of the extensor stretch reflex during ankle dorsiflexion. Finally, type Ia afferents are proposed to have an important role in the continuous online control of joint movements.

Nevertheless, the functional significance of monosynaptic stretch reflexes during gait remains at part unclear, largely for reasons related to the properties of the monosynaptic stretch reflex itself. The monosynaptic reflex system is highly sensitive to small inputs, and its function during gait should, therefore, be restricted to compensation for small ground irregularities. This is consistent with the observation that leg muscle vibration, which excites type Ia afferent input, affects human locomotion only a little.

Cutaneous Reflexes

Muscle responses induced by electrical stimulation of a sensory nerve of a limb are mediated by cutaneous reflexes. These reflex responses appear in different muscles of the limb with a latency that is compatible with a spinal pathway. In human leg muscles, the task-dependency of cutaneous reflexes has been shown in standing versus running or walking, and in cycling versus static contraction. Cutaneous reflexes in leg muscles are sensitive to the specific motor task that is performed, and undergo profound modulation depending on the context in which they are evoked. Furthermore, cutaneous reflex modulation is nerve specific (i.e., it depends on the nerve that is stimulated), and this seems to be important functionally. Certain features of cutaneous-reflex modulation, such as task-dependency, have been suggested to include central-pattern-generating elements. Such influences of the CPG on rhythmical and cyclical leg movements would be parallel with observations made in the cat.

Polysynaptic Reflexes

It has been proposed that polysynaptic reflexes are mediated mainly by muscle proprioceptive input from group II afferent fibers (e.g., from static muscle spindles or skin) and possibly from group III fibers (carrying information mainly from joint capsules and ligaments). Polysynaptic spinal reflexes produce functionally useful compensatory responses during locomotion, which are more complex than simple stretch-reflex responses. As the pathway of this reflex system is polysynaptic, it allows the integration of inputs from muscle, joint, and cutaneous afferents, and convergence with commands from supraspinal centers to common spinal interneurons. In addition, this reflex system has excitatory and inhibitory connections to both extensors and flexors.

The sensory input determines the direction, velocity, and amplitude of the adjustment that is needed to restore the subject's center of gravity over the feet and to generate the required pattern of leg muscle activation. Consequently, this reflex system leads to functional activation of synergistic muscle groups of both legs, and it can clearly be separated from segmental stretch-reflex responses, which affect only individual muscles.

A polysynaptic pathway also mediates the effects of flexor-reflex afferent (FRA) fibers. Although the modulation of flexion reflexes has several similarities to the polysynaptic spinal reflexes discussed above, there are also distinct differences. First, in people with spinal cord lesions, there is a loss of polysynaptic spinal reflexes, but the flexor reflex can still be elicited. Second, the characteristic feature of the flexor reflex is to serve as a withdrawal reflex to noxious stimuli, which is released as a direct response by the CPG, rather than in modulating the locomotor pattern to adapt to irregularities of the ground. Finally, the activity of spinal polysynaptic reflexes depends on the presence of contact forces, whereas flexor-reflex responses can be elicited by tibial nerve stimulation independently of loading.

Two main sources of afferent input are probably integrated in the polysynaptic reflex system: load-related and joint-position-related information. Load receptors, or graviceptors, are thought to signal the influence of gravity on the body to the spinal cord. There is only indirect evidence for such receptors in humans. For many years, the question of how the position of the body's center of mass relative to the feet is signaled to the central nervous system (CNS) has been neglected in most studies of human locomotion. To achieve appropriate gain control of postural reflexes, information is needed that signals the influence of gravity on the body. This information is insufficiently provided by muscle stretch receptors and the vestibular system.

Essential Sources of Proprioception

During locomotion, multisensory proprioceptive feedback is continuously weighted and selected. This process depends on the requirements of a particular locomotor task and the availability of afferent input. Afferent inputs from load receptors and hip joints make essential contributions to the activation pattern of leg muscles during human locomotion. It has been proposed that proprioceptive input from extensor muscles, and probably also from mechanoreceptors in the sole of the foot, provides load information. The afferents that signal hip-joint position mainly come from muscles around the hip. The role of this afferent activity in rhythmic locomotion is to shape the pattern, to control phase transitions, and to reinforce ongoing activity. Simple stretch and cutaneous reflexes might be involved in compensating for irregularities and in adapting to ground irregularities.

Load-Related Afferent Input

Extensor load receptors are suggested to provide essential information about the body's center of gravity during locomotion in humans. Experiments in the cat indicate that these receptor signals might arise from Golgi tendon organs and be carried by type Ib afferents to the spinal locomotor generator. In humans, the influence of load receptors on the regulation of stance and gait became evident from studies of weightlessness induced in adult humans either during space flight or by water immersion. Furthermore, it became clear that body load has an effect on the magnitude of polysynaptic reflex responses. The effect of load-receptor input on leg extensor activation during the stance phase of gait might be reinforced by heteronymous reflexes from ankle dorsiflexors. In addition, extensor muscle activity is reinforced during the stance phase by positive feedback, which contributes to load compensation without leading to instability.

Joint-Position-Related Afferent Input

In the cat, there are two main sources of afferent input that lead to rhythm entrainment and/or resetting of locomotor activity. Such input can either block or induce a switch between the alternating flexor and extensor locomotor bursts. The first of the afferent sources that satisfy these criteria is related to load, whereas the second is related to hip position. The afferents that signal hip-joint position mainly come from muscles that act around the hip. It has been suggested that receptors of the hairy skin can also provide high-fidelity information about knee-joint movements in humans.

Quadrupedal Coordination of Bipedal Locomotion

For most of the basic mechanisms that underlie locomotion, there seems to be no fundamental difference between bipeds and quadrupeds. Essential spinal neuronal mechanisms, such as the afferent inputs that determine the locomotor pattern (including hip-joint-related and load-receptor-related inputs), are probably similar for quadrupedal and bipedal locomotion. The coordination of forelimb and hindlimb rhythmic activities is a main characteristic feature of quadrupedal locomotion. Specialized neural circuits located in the caudal spinal cord (CPG) organize hindlimb locomotor activity, whereas specialized circuits in the rostral spinal cord control forelimb movements. The coordination of both circuits is mediated by propriospinal neurons with long axons, which couple the cervical and lumbar enlargements of the spinal cord.

In many respects, bipedal and quadrupedal locomotion share common spinal neuronal control mechanisms. As in quadrupeds, long projecting propriospinal neurons couple the cervical and lumbar enlargements in humans. Furthermore, the coordination of limb movements during walking is similar in human infants, adults, and quadrupeds. Nevertheless, there are distinct differences also as the upper limb in primates has become specialized to perform skilled hand movements. The evolution of upright stance and gait, in association with a differentiation of hand movements, represents a basic requirement for human cultural development.

In humans there is a task-dependent switch, from a strong direct (i.e., monosynaptic) cortical–motoneuronal control during reaching and skilled hand and finger movements to a more indirect control by cervical propriospinal circuits during locomotion, as it appears to occur in the cat. The neuronal control of human locomotor activities is based on the coordination of the quadruped fore- and hindlimbs, and this phylogenetically older system coexists with the newly developed, direct cortical–motoneuronal control of skilled hand movements. A typical example for such an interlimb coordination in humans represents the alternated movements of the arms during locomotion and its impairment, for example, in Parkinson's disease.

Coordination of Arm and Leg Movements

There is some evidence that interlimb coordination is organized similarly in the lower and upper limbs during cyclic movements of humans and cats. This indicates that the neuronal coordination and patterns of reflex modulation are conserved within the human lumbar and cervical spinal cord. During human bipedal walking, a quadrupedal limb

coordination of upper and lower limb muscles occurs similar to that of fore- and hindlimbs in quadrupeds.

Evidence for Neuronal Coupling

Recent experiments have indicated that there is neuronal coupling of upper and lower limb muscles during various human locomotor activities. A linkage between the cervical and lumbar enlargement of the spinal cord by propriospinal neuronal circuits with long axons can also be inferred on the basis of H-reflex studies. For example, during rhythmic movements of one foot, a cyclic H-reflex modulation was observed in the upper limbs. According to recent studies using functional magnetic resonance imaging, the supplementary motor area might be involved in the supraspinal control of this coupling between upper and lower limb movements.

Task Dependency of Neuronal Coupling

Only during walking do mechanical impulses applied to one leg (in the middle or at the end of the stance phase) evoke distinct bilateral arm EMG responses. Similar interlimb reflex responses were obtained in arm muscles following electrical stimulation of the distal tibial nerve (a mixed nerve, which innervates plantar foot muscles and the skin of the sole) during walking. Correspondingly, arm muscle responses were absent when stimuli were applied either during standing with voluntary arm swing or sitting while writing (i.e., with a comparable background EMG activity). These observations indicate a flexible task-dependent neuronal coupling between upper and lower limbs. The pathway that couples upper and lower limb movements seems to become gated by the activity of the CPG during walking. It has been concluded that a stimulus applied to a leg can exert a direct influence not only on the compensatory leg muscle EMG activity but also, depending on the task, on the neuronal control of upper arm muscles of both sides. The range of movements in which such task-dependent neuronal coupling of upper and lower limb movements occurs has yet to be determined. The stronger impact of leg flexors in interlimb coordination is in line with the increasing evidence that leg flexor and leg extensor muscles are differentially controlled, both in animals and humans.

Recently, it has been shown that arm and leg muscle activity is well coordinated during walking, crawling on all fours, or swimming. In such conditions, arm and leg movements are locked with a fixed frequency-relationship. This indicates a coupling of the neuronal circuits controlling arm and leg movements, which is again under supraspinal control. The frequency relationship characterizing this coordination corresponds to that observed in well-defined biological systems consisting of coupled

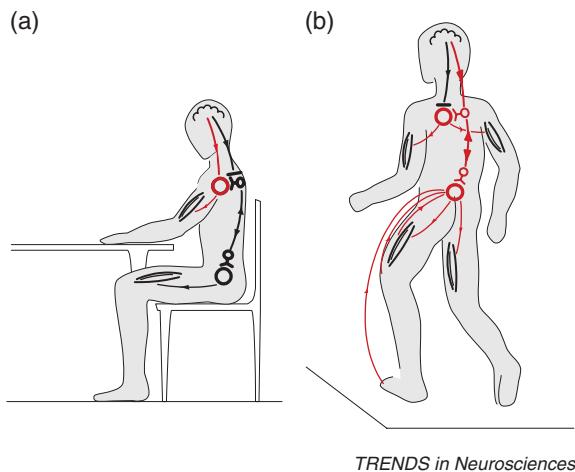

Figure 2 Movement control during different motor tasks. According to the research cited in this article, neuronal control of arm movement is task dependent. (a) During skilled hand movements, strong direct cortical-motoneuronal excitation is predominant (red lines) and the cervical propriospinal neuronal system is inhibited. (b) During locomotion, it is assumed that the brain command is predominantly mediated by interneurons. Cervical and thoraco-lumbar propriospinal systems become coupled and coordinate arm and leg movements (red lines). From Dietz V (2002) Do human bipeds use quadrupedal coordination? *Trends in Neurosciences* 25: 462–467.

oscillators. In addition, during gait, swinging of the arms serves to counteract torsion-related movements of the trunk. Therefore, swinging of the arms can be seen as an integral part of the dynamics of progression.

Differential Control of Upper Limb Movements

The task dependency of the neuronal coupling between upper and lower limbs might be based on a differential neuronal control of upper limbs during skilled hand movements and during locomotion. Direct cortical–motoneuronal connections to hand muscles are thought to determine the degree of dexterity in humans and nonhuman primates. It has been suggested that these phylogenetically new components are integrated into preexisting neuronal circuits. Indirect evidence indicates that propriospinal neuronal circuits corresponding to those described for cats persist, and most likely remain involved in the control of arm movement. It seems possible that there is an indirect corticospinal pathway to upper limb motoneuron pools, in addition to the well-documented direct cortical–motoneuronal pathway.

On the basis of the available evidence, the following hypothesis is put forward. Efficient corticospinal excitation of upper limb motoneurons via propriospinal neurons might occur during automatically performed movements, such as locomotion. By contrast, during skilled hand movements, strong cortical–motoneuronal

input dominates and transmission through the propriospinal system becomes suppressed.

Conclusions

It is proposed that a flexible coupling of thoraco-lumbar and cervical centers allows humans to use the upper limbs for manipulative and skilled movements or, alternatively, for locomotor tasks (Figure 2). This implicates a functional, task-dependent gating of neuronal pathways between the neuronal circuits controlling lower and upper limb muscles during walking, reflected in the arm swing as a residual function of quadrupedal locomotion. Therefore, propriospinal networks linking the thoraco-lumbar and cervical parts of the spinal cord can either function in a coupled way, for example, during locomotion, or an uncoupled mode during goal-directed voluntary movements.

Further studies are required to define more precisely the functions of evolutionarily older and evolutionarily newer neuronal control mechanisms in the broad variety of movements that can be carried out by humans.

Glossary

Bromodeoxyuridine (BrdU) – A synthetic thymidine analog that becomes incorporated into a cell's DNA during the S-phase of the cell cycle. BrdU is commonly used to detect proliferating cells in the brain.

Dentate gyrus – Part of the hippocampal formation and one of the select brain structures currently known to have high rates of adult neurogenesis in mammals.

Hypothalamic-pituitary-adrenal (HPA) axis – The combined system of direct and feedback projections between the hypothalamus, the pituitary gland, and the adrenal glands, which is ultimately involved in regulating stress-related homeostasis.

Irradiation – The use of radiation, which is a technique that can be used to block hippocampal neurogenesis.

Neurogenesis – The creation of new neurons.

Environmental influences play a key role in refining the neural circuitry required for normal adult brain function. The hippocampus is a brain region that undergoes structural changes throughout life. The dentate gyrus of the hippocampus has a great capacity to produce new neurons in adulthood. New neurons are produced from progenitor cells residing in the dentate gyrus within the subgranular zone, a region on the border of the granule cell layer and hilus (see **Figure 1**). These cells divide, producing mostly new neurons and a lesser percentage of non-neuronal cells. The new neurons differentiate into granule cells and become functionally integrated into the preexisting neuronal network. The hippocampus may be especially sensitive to environmental perturbations due to a high degree of structural plasticity in this brain region. This article reviews environmental influences on adult neurogenesis in the dentate gyrus with a specific emphasis on the effects of stress.

Stress Effects on Adult Neurogenesis

Although the hippocampus is primarily associated with learning and memory, this structure has also been implicated in the stress response. The hippocampus contains a high concentration of glucocorticoid receptors and stress throughout life has been shown to influence hippocampal biochemistry and function. Likewise, stress during

prenatal, postnatal, and adult life can alter adult neurogenesis in the dentate gyrus.

Prenatal Environment

Prenatal stress predisposes offspring to psychiatric disorders in adulthood. Since adult neurogenesis has been linked to mood disorders, understanding the influence of early aversive experiences on the production of new neurons may shed light on the mechanisms that underlie psychopathology.

Rat offspring exposed to prenatal stress demonstrate permanent behavioral and neurobiological changes. Maternal stress during the last week of pregnancy alters adult neurogenesis in offspring. Regardless of the stressor (repetitive restraint stress; various unpredictable stressors), both male and female offspring showed decreased proliferating cells in adulthood following prenatal stress. The changes in bromodeoxyuridine (BrdU)-labeled cells reflect changes in cell proliferation, as confirmed by a significant reduction in Ki67-labeled cells, an endogenous cell cycle marker, in the dentate gyrus of prenatally stressed rats. Yet, one study only found a significant reduction in hippocampal granule cell neurons among animals exposed to stress at the end of gestation. These different results are likely due to inconsistencies in stress paradigms and methodologies used to visualize and measure neurogenesis.

This finding has been further extended into primates, investigating whether the timing of maternal stress alters postnatal neurogenesis in offspring. Pregnant rhesus monkeys were subjected to 6 weeks of acoustic startle stress, 5 days a week, during early or late gestation. These time periods corresponded with two distinct stages of cell growth and synaptogenesis in the fetal monkey cortex. Both early and late fetal disturbances dramatically decreased the density of new cells in the dentate gyrus of juvenile monkeys, compared to controls. Collectively, these findings indicate that prenatal stress can have lasting negative effects on the rodent and primate brain, including the suppression of neurogenesis later in life. The mechanisms that induce persistent inhibition of postnatal neurogenesis following developmental stress remain unknown, but glucocorticoids are likely to play some role.

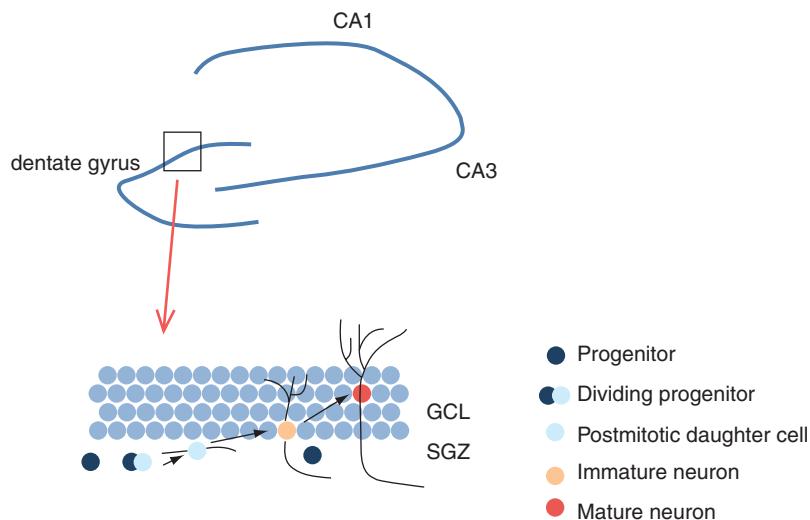

Figure 1 Adult neurogenesis in the dentate gyrus. New neurons develop from progenitor cells in the subgranular zone (SGZ), which divide to form postmitotic daughter cells. The remaining progenitor cell stays in the SGZ and continues to proliferate. Daughter cells migrate into the granule cell layer (GCL) and differentiate into immature neurons. These neurons develop dendrites that reach through the GCL into the molecular layer, and axons that reach into area CA3. New granule cells mature, develop neuronal properties, such as complex dendritic morphology, and become integrated into the existing neuronal circuitry.

Neonatal Environment

While maternal experience is critical to fetal brain development, environmental influences during the postnatal period have equally profound consequences. Early-life stressors activate the hypothalamic–pituitary–adrenal (HPA) axis; this activation can later impact some hippocampal functions, such as learning and anxiety regulation (see below), increase susceptibility to psychopathology, and have lasting effects on adult neurogenesis.

Rats subjected to prolonged maternal separation from postnatal day 1 to postnatal day 14 have significantly fewer proliferating cells and immature neurons in the dentate gyrus in adulthood, compared to control or handled rats (those that experienced a shorter duration of maternal separation). This reduction is similar to cell proliferation effects observed after exposure to an acute stressor. Given that a shorter duration of maternal separation does not alter adult neurogenesis, this suggests that only very extreme changes in mother–pup contact result in alterations to the dentate gyrus. However, the effects of maternal separation on cell proliferation and immature neuron production do not have a permanent effect on the number of new neurons. By 3 weeks after mitosis, the number of new neurons in maternally-separated rats is similar to that of controls, suggesting that compensatory factors may result in a greater proportion of surviving new cells. Interestingly, in mice, maternal separation-induced deficits in adult neurogenesis have also been observed, but following only one 24 hour period of separation on postnatal day 9, suggesting that species differences may play a role in the impact that a single bout of maternal separation can have on adult neurogenesis.

Adult Environment

In adulthood, the hormonal stress response is a critical reaction to demands in the environment that disrupt homeostasis. Activation of the HPA axis, and an increase in the production of glucocorticoids, is associated with both physical and psychological stressors. Both acute and chronic stress paradigms, including subordination, resident–intruder, footshock, restraint, isolation, cold immobilization, cold swim, and predator odor, decrease cell proliferation and neurogenesis in the dentate gyrus. This effect has been shown in at least four species: mice, rats, tree shrews, and marmosets. A single exposure to predator odor decreases cell proliferation in the adult rat, while a single exposure to the resident–intruder paradigm reduces cell proliferation and neurogenesis in the adult tree shrew and marmoset. Similar results have been found with a chronic psychosocial stress paradigm – prolonged social defeat decreases cell proliferation in the adult rat and tree shrew.

It is likely that the effects of stress on cell proliferation are partly related to an increase in glucocorticoids. Glucocorticoid manipulations have many structural effects on the hippocampus, including dendritic architecture, synaptic plasticity, and the rate of cell proliferation and survival. Removal of circulating adrenal steroids by adrenalectomy increases the proliferation of granule cell precursors and the production of new neurons. Furthermore, increased exogenous corticosterone suppresses cell proliferation and cell survival. Since aversive stressors and elevated glucocorticoids have similar effects on adult neurogenesis, it is likely that glucocorticoids are one of the main mediators of these

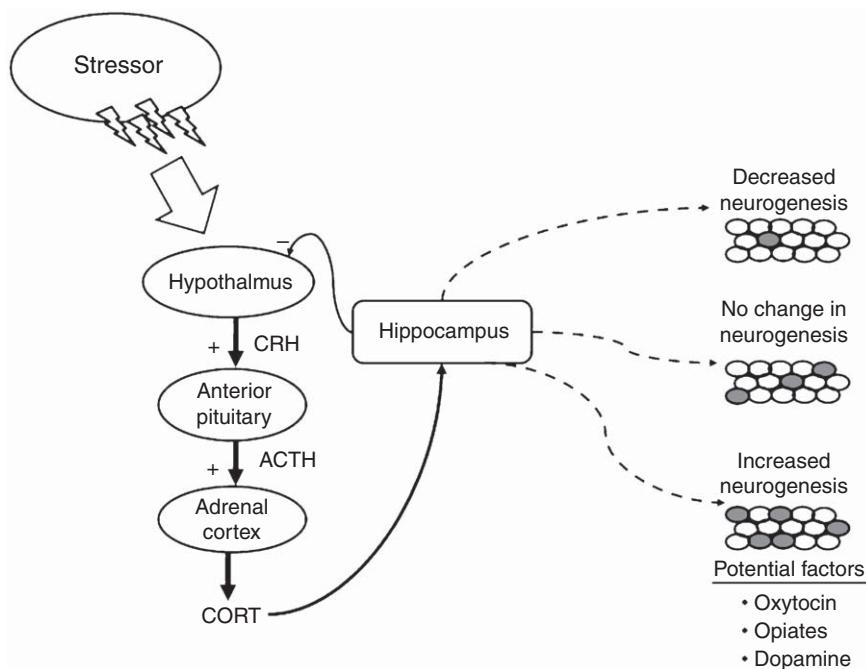

Figure 2 Possible glucocorticoid effects on adult neurogenesis in the hippocampus. Stressors activate the hypothalamic–pituitary–adrenal (HPA) axis, resulting in the release of a cascade of hormones, ultimately ensuring the release of glucocorticoids, such as corticosterone (CORT) in many rodent species. Corticosterones, or glucocorticoids, differentially alter cell proliferation and survival in the dentate gyrus of the hippocampus. It is commonly thought that stress inhibits adult neurogenesis as a result of increased glucocorticoids; however, in some instances, an enhancement in glucocorticoids does not alter adult neurogenesis. Paradoxically, some stressors, such as voluntary exercise and sexual experience, increase circulating glucocorticoids while also enhancing adult neurogenesis. The social or emotional valence of these stressors may play a role in the observed outcomes, as well as potential factors such as oxytocin, opiates, and dopamine.

stress effects. Preventing the stress-induced rise in glucocorticoids has been shown to eliminate the suppression of cell proliferation caused by stress.

Although a clear negative relationship exists between glucocorticoid levels and adult neurogenesis, a broader look at the literature suggests that this relationship is more complex. Some experiences that elevate glucocorticoid levels have no effect on adult neurogenesis, while other stressful experiences increase adult neurogenesis (see **Figure 2**). Active shock avoidance training increases glucocorticoid levels, but has no effect on cell proliferation or survival.

Voluntary exercise and sexual experience increase circulating glucocorticoid levels and enhance adult neurogenesis. Even long-term running has been shown to buffer the negative effects of certain stressors, such as social isolation (see below). Training in certain learning paradigms also increases the number of new neurons, despite elevated corticosterone concentrations. However, extensive training in learning paradigms, such as spatial reference or working memory maze tasks, can increase glucocorticoids and reduce adult neurogenesis. This reduction in the production of new neurons may be due to the intensity of the learning paradigm and the duration of training. The number of training trials has

been shown to determine whether adult neurogenesis is enhanced or diminished by learning. Future studies would be helpful to differentiate between the different phases of learning, such as acquisition and retrieval, when examining the effect of learning tasks on neurogenesis.

While much is known about the effects of stress on adult neurogenesis, there are still many questions that remain unanswered. Predictability and controllability of stress can decrease the negative impacts on neurogenesis. For example, active avoidance learning is a controllable stressor that has no effect on cell proliferation. This raises questions about whether the emotional valence of stressful situations can mitigate the stressors' negative effects on cell proliferation.

Environmental Influences and Neurogenesis

Social Stimulation

Housing

Across laboratories, standard housing conditions can vary. However, what usually remains consistent is the presence of a cage lined with bedding and *ad libitum* access to food

and water. It is also typical that same-sex animals will be group housed. Occasionally single, or isolation, housing is defined as ‘standard housing.’ However, some have found that isolation can have negative consequences on behavior, such as decreased spatial memory and increased aggression.

Four or 8 weeks of isolation housing decreases the number of newly dividing cells in both mice and rats, compared to animals housed in groups; however, the effect of isolation housing on adult neurogenesis is prevented by repeated antidepressant treatment (i.e., fluoxetine) and subsequent group housing. Isolation housing in guinea pigs also reduces the number of proliferating cells in the dentate gyrus, with a smaller percentage of new cells migrating into the granule cell layer.

It has been hypothesized that group housing or social support can interact with stress to ameliorate stress-induced alterations in both brain and behavior. Isolation housing renders the hippocampus more susceptible to the suppressive actions of glucocorticoids on adult neurogenesis; however, the interaction between housing and stress effects on the survival of proliferating cells in the dentate gyrus is dependent on the sex of the animal. Chronic exposure to inescapable footshock differentially affects individually-housed male and female Sprague-Dawley rats. A reduction in cell survival was observed among male rats, an effect mitigated by grouped housing, whereas females were not affected by either the chronic stressor of inescapable footshock or the housing condition. The lack of a chronic stress-induced deficit in cell survival does not indicate that females are not affected by chronic stress. Other indices of stress, such as behavioral alterations, adrenal hypertrophy, and c-fos expression, have been reported following chronic stress in females.

Social dominance

Many animals will develop a dominance hierarchy, particularly when living with conspecifics of the same sex, along with limited resources. Tree shrews, when paired with an animal of the same sex, will rapidly establish a dominant/subordinate relationship that is very stressful to the subordinate animal. The production of cells in the dentate gyrus can be rapidly modulated by subordination – decreased cell proliferation occurs within hours in subordinates, compared to controls. Similarly, rats housed in an apparatus called “the visible burrow system” will quickly establish a dominance hierarchy, characterized by individual differences in offensive and defensive behavior. These behavioral differences, resulting from time spent in the visible burrow system, alter adult neurogenesis in the dentate gyrus. Dominant rats in the visible burrow system demonstrated enhanced survival of new neurons in the dentate gyrus, compared to cage controls and subordinates. This effect persisted even when access to multiple burrows and tunnels was removed, indicating that the effect of dominance on cell survival was not contingent on the complexity of the environment. This

divergence was not due to substantial differences in circulating corticosterone levels in dominant and subordinate rats, which raises the likelihood that mechanisms other than stress may be responsible for the changes in dentate gyrus neurogenesis. One possibility is that dominants produce more new neurons because they have more opportunities for sexual experience, which has also been shown to increase adult neurogenesis.

Exercise

Running is a universally motivating behavior in rodents. Animals housed in cages with access to running wheels engage in a considerable amount of running, up to 4km a night. Although physical exercise is associated with numerous health benefits, some physiological changes that accompany running are indicative of stress, such as increased HPA axis activity. Despite the elevations in glucocorticoid levels, voluntary exercise is associated with positive influences on brain and behavior. Running enhances the number of new neurons in the dentate gyrus of adult rodents, which appears to be a paradox since elevated glucocorticoids have been associated with suppressed neurogenesis.

Most studies examine voluntary exercise in group-housed animals; therefore the social context in which voluntary exercise is experienced may buffer the negative effects of elevated glucocorticoids. Social isolation precludes the positive effects of short-term exercise on adult neurogenesis in the dentate gyrus. Individually-housed runners eventually show an enhancement in adult neurogenesis, but only after a considerably longer period of running, compared to group-housed runners. Therefore, the social context is important when examining the effects of voluntary exercise on adult neurogenesis.

The type of voluntary exercise may influence its effects on adult hippocampal neurogenesis. In studies investigating the effects of water maze training on neurogenesis, yoked controls swam for the same amount of time as animals undergoing water maze training; however, yoked controls did not experience enhanced neurogenesis. Further analysis of these data revealed that due to the short duration of swimming, it could not be concluded that swimming was less efficient than running in augmenting adult neurogenesis in the dentate gyrus. Nevertheless, voluntary exercise has remained one of the best studied paradigms of physical exercise in rodents, in respect to its effects on adult neurogenesis. The effects of voluntary exercise on hippocampal neurogenesis are even transmissible from the exercising pregnant mouse to her offspring.

Unlike voluntary wheel running, where animals can freely run when they so desire, forced or treadmill running only allows animals to run for a limited period of time each day. However, much the same as voluntary wheel running, forced exercise increases neurogenesis in the dentate gyrus. The intensity of forced exercise can alter the effects that treadmill running may have on adult neurogenesis. Low-intensity

forced running increases short-term cell survival more so than moderate- or high-intensity running, although all 3 groups significantly increased cell survival, compared to controls. The effects of forced running intensity on cell survival have produced conflicting results. One study found that only low-intensity exercise on a treadmill resulted in greater neurogenesis in the dentate gyrus, compared to moderate- and high-intensity exercise. Both moderate- and high-intensity treadmill running produced similar numbers of BrdU-labeled cells as controls. Here, the discrepancies most likely revolve around the duration of running and the definition of low-, moderate-, and high-intensity forced running.

Environmental Enrichment

Environmental enrichment refers to various housing conditions, either in the home cage or in exploratory chambers, that increase sensory, motor, and cognitive stimulation, compared to standard housing conditions. Most environmental enrichment paradigms also include more animals per cage, compared to the control setting.

Enriched environments enhance neurogenesis, an effect observed in many species, such as rats and mice. Unlike voluntary exercise, which is able to increase both cell proliferation and cell survival, enriched environments only increase the survival of newly born cells. Although enrichment paradigms vary among laboratories, the effects on adult neurogenesis remain consistent – nearly all enrichment protocols result in enhanced hippocampal neurogenesis. Due to differences in species, gender, standard housing conditions, objects used for enrichment, access to running wheels (see the section on voluntary exercise above), use of food treats, and so on, it is difficult to come to a consensus on which environmental enrichment paradigm is ideal (see **Table 1**). Numerous studies use female mice in enrichment paradigms instead of male mice. Given the tendencies for male mice to become highly aggressive when group-housed, male mice may not be ideal rodents to use in enrichment paradigms. What is clear is that the complexity of the environment, via sensory and motor stimulation, is able to significantly increase adult neurogenesis in the hippocampus.

Parenting

Motherhood is a very enriching experience, accompanied by changes in many nonreproductive functions, such as learning, memory, anxiety, and stress regulation. Lactation suppresses the number of proliferating cells in the dentate gyrus of primiparous and multiparous female rats, compared to nulliparous controls, with this effect lasting until the time of weaning. The effect of lactation on adult neurogenesis is transient – by 2 weeks post-BrdU injection, at a time when most newly born cells have matured, no difference are detectable among groups.

The diminished cell proliferation accompanied by lactation was resultant of elevated glucocorticoids – once pups were removed, basal glucocorticoid levels returned, resulting in no differences in BrdU-labeled cells compared to nonlactating females. Interestingly, nulliparous female rats briefly exposed to pups displayed enhanced cell proliferation in the dentate gyrus. Taken together, these results suggest that reproductive experience and exposure to offspring can significantly alter adult neurogenesis.

Functional Consequences of Adult Neurogenesis

One of the most important and, as of yet, unanswered questions in the field of adult neurogenesis is the functional significance of newly born neurons. Do new neurons replace mature neurons that have died, or do they have a unique function that could not be accomplished by existing mature neurons? For instance, new neurons may be used for processing novel stimuli or for temporary memory storage. While their function remains unclear, there is much evidence that adult-born neurons are involved in certain types of learning and memory, and possibly involved in regulation of anxiety and mood.

Learning and Memory

Not only do many learning paradigms increase adult neurogenesis, but there is also evidence that adult-generated neurons within the hippocampus are important for certain types of learning and memory. For instance, differences between mouse strains in their amount of baseline neurogenesis parallel their learning abilities in spatial navigation tasks; mice with the fewest new neurons performed worse in the Morris water maze. However, no such strain difference has been reported in rats. Experiences that increase adult neurogenesis, like enriched environments and voluntary exercise, also improve learning. Conversely, many of the same factors that decrease neurogenesis, like aversive stress and pharmacological manipulation of glucocorticoids, also impair learning.

There are several methods used to increase or decrease neurogenesis in order to examine the subsequent effects on learning and memory. Because voluntary exercise is known to increase the production of new neurons in the adult dentate gyrus, many studies use running to examine the effects of increased neurogenesis on learning and memory tasks, when compared to sedentary animals. Running-induced increases in neurogenesis enhance performance on learning tasks, such as improved memory acquisition and retrieval in the Y-maze and Morris water

Table 1 Representative selection of environmental enrichment paradigms

<i>Species</i>	<i>Gender</i>	<i>EE conditions</i>	<i>Age; duration of EE</i>	<i>Control housing</i>
C57/Bl6 mice	Female	Housed 10 per cage in large stainless steel cages ($42 \times 50 \times 20$ cm) with activity wheel and swing; toys and bedding changed every 2 days	3 months of age; 8 weeks in EE	Housed 3 per cage in clear plexiglas cages ($20 \times 22 \times 20$ cm)
		Housed 14 per cage (86×76 cm) with toys, tunnels, and running wheels	3 months of age; 2 or 5 weeks in EE	Housed 3–4 per cage in standard cages
		Housed 15 per cage in a 1 m^2 floor space with plastic tubes, a small running wheel, nesting material, and toys	10 months of age; 10 months in EE	Housed 15 per cage in standard cages
129Sv/Ev mice	Female	Housed 8 per cage in two clear plastic cages adjoined by a tube; cages contained a wooden house, hollow wooden log, paper tube, plastic igloo, and paper towels	10 weeks of age; 100 days in EE	Housed 4 per cage in clear plastic cages ($29.2 \times 19 \times 12.7$ cm)
Wistar rats	Male	Housed 5 per cage in a cage with 0.5 m^2 area with plastic tubes, tunnels, bridges, wheels, and food treats all changed daily	6 weeks of age; 11 or 28 days in EE	Housed 1 per cage in cages measuring $45 \times 22 \times 18$ cm
		Housed 8 per cage in a cage ($120 \times 100 \times 60$ cm) containing running wheels, rearrangeable plastic tunnels, an elevated platform, and toys changed every 3–4 days	2 and 25 months of age; 8 weeks in EE	Housed 1 per cage in wire mesh cages
Sprague-Dawley rats	Male	Housed 4–6 per cage in a large box ($1.5 \times 0.8 \times 0.8$ m) with toys (rearranged daily), wooden blocks, climbing platforms, plastic tubes, and small houses	$220\text{--}250\text{g}$; 3 h day^{-1} for 14 days in EE	Housed 2 per cage in standard laboratory cages
Long Evans rats	Both	Housed 4–5 pups plus parents per cage in a large clear plexiglass box ($1 \times 1 \times 1$ m) with a can, piece of wood, plexiglass tube, colored light bulbs, a towel, and a metal lamp shade	15 days of age; 6 or 12 days in EE	Housed 4–5 pups plus parents per cage in a standard laboratory cage of clear acrylic ($30 \times 50 \times 15$ cm)
Mongolian gerbils	Male	Housed 15–20 per cage in two storied cages ($30 \times 20 \times 30$ m) with tunnels, running wheels, and toys. New objects introduced every week and object locations changed $2 \times$ per week	2 months of age; 2 months in EE	Housed 3 per cage in conventional rat cages

EE = Enriched environment.

maze, as well as enhanced freezing response and consolidation in contextual fear conditioning paradigm. Exercise also mitigates the negative effects of hippocampal lesions on learning and memory tasks.

Irradiation, the administration of antimitotic agents, and transgenic knockdown of adult neurogenesis are three techniques used to block the production of new neurons in rodents. Rats and mice with reduced neurogenesis in the dentate gyrus caused by one of these methods exhibit performance deficits in several learning paradigms, such as trace conditioning and delayed non-matching to sample tests, although inconsistencies exist within the literature. In C57BL/6J mice, exercise-induced hippocampal neurogenesis is necessary for enhanced spatial learning, but not motor performance or contextual fear learning. In rats, treatment with the

antimitotic agent, methylazoxymethanol acetate (MAM), caused impaired trace conditioning, but had no effect on spatial learning in the water maze, even though both of these tasks are considered hippocampal dependent. Transgenic mice with ablation of adult-born hippocampal neurons were tested on several spatial tasks of varying complexities: detection of new environments, spatial navigation, and contextual conditioning. Mice with decreased neurogenesis showed impairments in spatial relational memory, but not in simpler forms of spatial knowledge.

All of the methods currently used to reduce adult neurogenesis have possible confounds, including lack of specificity and unwanted side effects. Because irradiation causes inflammation in the brain, the activation of microglia must be monitored to assess whether inflammation,

rather than reduced neurogenesis, is affecting cognition. Administration of MAM at a dose high enough to prevent adult neurogenesis induces physical illness in rats, characterized by weight loss, decreased locomotor activity, and degradation fur degradation. Transgenic knockdowns require long-term treatment with drugs in order to reduce the production of new neurons, causing a lack of temporal resolution. The time period that elapses between treatment and testing associated with these methods is long enough to allow neural reorganization to occur, therefore complicating the interpretation of the results.

Besides methodological problems, other possible explanations for the inconsistencies in the literature include differences in species, gender, timing of BrdU injections, and variations in particular paradigms and training schedules. Although studies often show a correlation between adult neurogenesis and learning and memory tasks, it is difficult to make statements about causation. In order to elucidate this relationship, it will be necessary to use a method that cleanly reduces adult neurogenesis with greater temporal resolution.

Mood Disorders

The hippocampus is implicated in the pathology and treatment of many mood disorders. Stress and animal models of depression cause a decrease in the number of neurons in this structure, as well as reductions in its overall volume. Reduced adult neurogenesis elicits anxiety or depressive-like behaviors in several species. While aversive stress is generally associated with a reduction in adult neurogenesis (see above sections for exceptions), administration of antidepressant drugs increases cell proliferation and neurogenesis. Behavioral studies indicate a possible role of adult neurogenesis in depression, as antidepressants may be able to reverse or prevent stress-induced deficits in neurogenesis. This effect has been shown with a variety of antidepressants, including a selective serotonin reuptake inhibitor (fluoxetine), a specific norepinephrine reuptake inhibitor (reboxetine), a monoamine oxidase inhibitor (tranylcypromine), and a phosphodiesterase-IV inhibitor (rolipram).

Acute antidepressant treatment does not alter cell proliferation, whereas treatment for 14 or 21 days results in the production of new cells. The delayed onset in antidepressant-induced neurogenesis in rodents parallels the chronic administration necessary to obtain therapeutic results in humans, as well as the time point when most newly born cells have matured and integrated into the preexisting hippocampal circuitry.

Although the adult neurogenesis hypothesis of depression has gained momentum in recent years, there are also studies that contradict this hypothesis. In 129/Sv mice, blocking antidepressant-induced neurogenesis through irradiation abolishes the behavioral responses to

antidepressant treatment. However, blocking neurogenesis did not decrease antidepressant effectiveness or the animals' sensitivity to unpredictable chronic mild stress in BALB/c mice. Focal hippocampal irradiation did not prevent the antidepressant-like actions of a corticotrophin releasing factor antagonist or vasopressin 1b antagonist. These inconsistencies could result from the specific type of antidepressant, the length or dosage of drug administration, and inherent strain differences.

Most studies investigate whether antidepressants increase adult neurogenesis in nonstressed animals, but it may be more useful to examine animals undergoing stressful situations to see whether these drugs can reverse or prevent the negative effects of stress. Two commonly used animal models of depression are chronic subordination and learned helplessness, both of which have been associated with reduced adult neurogenesis. Treatment with antidepressants can prevent the decrease in cell proliferation caused by chronic exposure to psychosocial stress. Moreover, inescapable shock (a learned helplessness paradigm) decreases cell proliferation, and leads to behavioral deficits, both of which can be prevented or reversed with antidepressants.

Not only do antidepressants prevent stress-induced reductions in neurogenesis, but they also decrease anxiety-like behavior in animal models. Approach-avoidance tests, including elevated plus maze, novelty-induced hypophagia, novelty-suppressed feeding, and the open field, are often used to measure anxiety. Anxious rodents reduce exploratory behavior due to an inherent fear of open areas. Antidepressant administration decreases anxiety in these tasks, possibly as a result of enhanced neurogenesis. There is suggestive evidence that enhanced neurogenesis may play a role in the therapeutic efficacy of antidepressants, but there is also evidence contradicting this theory. More studies are needed, particularly in humans, to assess the potential links among depression, anxiety, and adult neurogenesis.

Neurodegenerative Disorders

Stroke, the most frequent cause of acute neurodegeneration, affects millions of people per year and has become one of the leading causes of death. Current treatments, such as the use of thrombolytic agents, have had limited impact, as they are only effective within a small temporal window. There are many chronic neurodegenerative diseases, including Parkinson's disease, Huntington's disease, Alzheimer's disease, and amyotrophic lateral sclerosis (ALS). Each is associated with a gradual loss of neurons in certain areas of the nervous system. Except for Parkinson's disease, effective therapies are not readily available to reduce symptoms and restore lost function. Even in the case of Parkinson's disease, pharmacological

interventions are typically only useful for a limited period of time – after their therapeutic window closes, patients often resort to experimental treatments like deep brain stimulation. Given that there is restricted cell loss in many neurodegenerative disorders, restorative therapies are of high interest and worth pursuing.

Toward this end, the ability for the environment to stimulate adult neurogenesis should be considered. Understanding the molecular and cellular effects of the environment on adult neurogenesis may not only provide insight into the pathogenesis of disorders affecting the nervous system, but will also open the door to novel therapeutics that may mimic the effects of environmental enrichment on adult neurogenesis.

Glossary

Adult neurogenesis – The set of events leading to the production of new neurons in the adult brain, from precursor cell division to functionally integrated survival.

Bromo-deoxyuridine (BrdU) – A thymidine analog incorporated into dividing cells that are in the DNA synthetic phase (S-phase) of the cell cycle. BrdU incorporation can be visualized immunocytochemically. BrdU labeling can be used for quantitative stereological analysis of new cell number. In addition, BrdU labeling can be combined with immunohistological markers for neurons or glia to determine the phenotype of the newly generated cells.

Dentate gyrus – Neurogenic brain region that is one of the three subfields of the hippocampus. The dentate gyrus contains densely packed granule cell bodies in the granule cell layer. The granule cell axons, which are called mossy fibers, project to hilar interneurons and the hippocampal CA3 subfield. The dendritic tree of the dentate gyrus granule cells is contained in the molecular layer.

Growth factors – Neuropeptides that play a role in the following processes: cell proliferation, survival, differentiation, connectivity, and synaptic plasticity.

Long-term potentiation (LTP) – An enduring increase in the amplitude of excitatory postsynaptic potentials as a result of high-frequency (tetanic) stimulation of afferent pathways, considered to be the cellular basis for memory formation.

Progenitor cell – A mitotic cell with a fast cell-division cycle that retains the ability to proliferate and to give rise to terminally differentiated cells but that is not capable of indefinite self-renewal.

Retrovirus – RNA virus that uses reverse transcriptase to convert its RNA into DNA. It consists of *gag*, *pol* and *env* genes, which are translated as polyprotein precursors and are later processed to yield internal structural proteins, enzymes, and the envelope glycoproteins, respectively. The Moloney MLV retrovirus only infects dividing cells, can be made to express a fluorescent reporter, and is used to label stem and progenitor cells *in vitro* and *in vivo*.

Stem cells – Cells that have both the capacity to self-renew (make more stem cells by cell division) as well as to differentiate into mature, specialized cells.

Adult Neurogenesis

Traditionally, genesis of new neurons was considered to be restricted development. However, it is now established that neurogenesis occurs in two brain areas: the subventricular zone of the lateral ventricles/olfactory bulb and the dentate gyrus of the hippocampus (Figure 1). In initial studies in the 1960s, using tritiated thymidine autoradiography, continued cell division in the postnatal and adult brain was observed. This work was largely ignored due to lack of proof that the adult-generated cells were neurons. In the mid-1980s, it was discovered that neurogenesis occurs in the bird brain in areas that mediate song-learning and seed-storing behavior. The avian results and the isolation of cells with stem cell properties from the adult mouse brain led to a revived interest in adult mammalian neurogenesis. Subsequent work using the thymidine analog 5-bromo-2'-deoxyuridine (BrdU), in combination with specific neural markers, showed that newborn cells could become neurons in the rodent and human hippocampus. Conclusive evidence that the new neurons are functionally integrated into the hippocampal circuitry was obtained by injecting retrovirus specific for dividing cells and express green fluorescent protein (GFP) into the dentate gyrus. This approach revealed the morphology and electrophysiological characteristics of newly born neurons in the adult rodent hippocampus (Figure 1).

The process of proliferation, migration, differentiation, and survival of new neurons *in vivo* has become well-defined in recent years. Two types of neural stem cells have been identified in the subgranular zone of the dentate gyrus. Type 1 cells have a long radial process and express nestin and glial fibrillary acidic protein (GFAP), even though they are not astrocytes. Type 2 cells have short processes, can self-renew, as well as proliferate and differentiate into new neurons. Type 2 cells go through a series of developmental steps, beginning with axonal and dendritic growth, followed by spine formation and maturation over the course of 2 months. These cells express a sequential series of markers during maturation, starting with nestin, doublecortin, and finally the mature neuronal marker Neun. Similar to newborn neurons in the embryonic brain, new granule cells in the mature brain are initially depolarized by γ -aminobutyric acid (GABA). The transmitter becomes hyperpolarizing at about 2–4 weeks after cell genesis, concurrent with the development of dendritic spines and glutamatergic activity. Although the newborn neurons

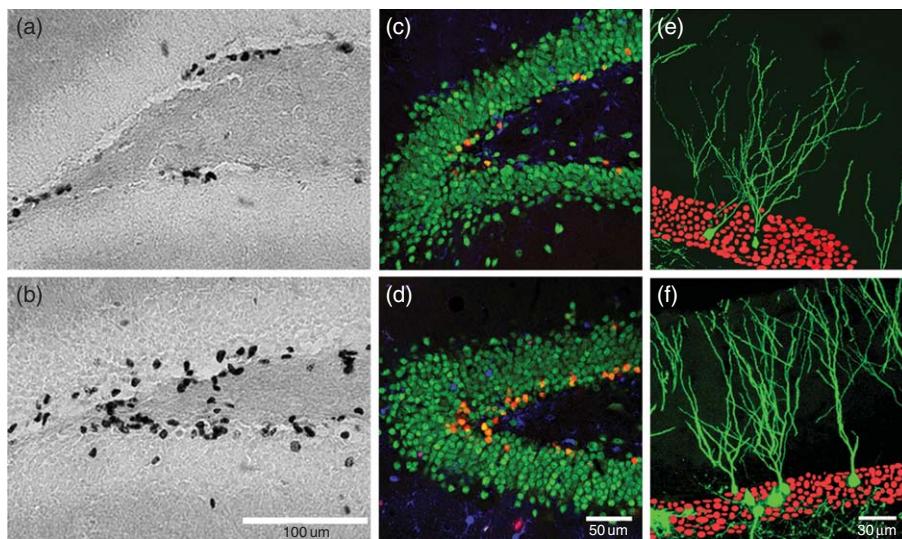

Figure 1 Regulation of cell proliferation and neurogenesis by exercise. (a, b) Photomicrographs of BrdU+ cells 1 day after the last of a series of 12 BrdU injections (50 mg kg^{-1} per day). Mice housed with a running wheel (b) have more BrdU+ cells than sedentary mice (a), showing that running increases cell proliferation. (c, d) Confocal images of sections that were immunofluorescently triple-labeled for BrdU (red), NeuN-indicating neuronal phenotype (green), and S100 β -selective for glial phenotype. BrdU+ neurons are orange (red + green). These images demonstrate that the survival and neuronal differentiation of the cells are enhanced 4 weeks after the last BrdU injection in runners (d) relative to control (c) mice. (e, f) Retroviral labeling of new neurons. Retrovirus-expressing green fluorescent protein (GFP) was injected into the dentate gyrus of sedentary (e) and running (f) mice. Confocal images show more GFP+ new neurons in running than in sedentary mice 4 weeks after virus injection. The red ovals (e, f) were added to illustrate the location of the granule cell layer.

are similar to mature granule cells in their basic physiological properties, they continue to mature for several months and show transiently enhanced synaptic plasticity between 4 and 8 weeks of age.

Exercise and Hippocampal Neurogenesis

Adult neurogenesis has been shown to be highly regulatable by both extrinsic and intrinsic, genetic and epigenetic factors. In general, an enhancement of cell genesis has been correlated with improved learning and memory, whereas decreased neurogenesis is associated with aging, stress, and depression. The initial study that showed enhancement of adult neurogenesis used environmental enrichment. In an enriched environment, mice are housed in a larger cage with toys, running wheels, and more opportunity for social interaction. The mice were housed in enriched or control conditions for 40 days and given a series of daily BrdU injections for the first 12 days. Animals were sacrificed either immediately after the last injection to study cell proliferation, or 1 month later to investigate cell survival. It was found that cell neurogenesis and survival were enhanced, but not cell proliferation. Mice were also tested in a spatial memory task, the Morris water maze, in which mice are trained to find a platform hidden under the surface of a pool using visual cues on the walls of the room. The enriched mice learned faster

than controls, raising the possibility that the new neurons contribute to enhanced cognition.

In a subsequent study, it was determined which aspect of the environment—increased opportunity for learning, socialization, or physical activity—may mediate the neurogenic effect. The avian literature at the time indicated that neurogenesis was correlated with food storing, and therefore learning was considered to be an essential factor of enrichment. However, to represent all aspects of the enriched environment, mice were tested in five different conditions: water maze learning, yoked swim controls, wheel running, enrichment (positive control), or standard housing (negative control). Surprisingly, voluntary exercise in a running wheel enhanced both proliferation and survival of newborn neurons in the dentate gyrus, indicating that physical activity was the critical neurogenic factor. Physical activity also improved hippocampus-dependent memory function. The strong correlation between increased neurogenesis and learning following exercise, suggested that the new neurons might play an important role in cognition.

Exercise, Neurogenesis, and Brain Function

Enhancement of hippocampal neurogenesis by running is a robust phenomenon that has been replicated by many different laboratories. The onset of the effect is rapid

regardless of whether the animals are housed individually or in groups. Running induced cell proliferation peaked after 3 days of running and was still significantly enhanced at 10 days. After 32 days of running, the proliferative effect had returned to baseline. Interestingly, the number of new neurons continued to increase. Recent research has shown that the benefits of exercise for new neurons are also qualitative. Using a retroviral labeling strategy (**Figure 1**), it was shown that exercise enhances the maturation of newborn neurons. Specifically, the density of mushroom spines is enhanced and spine motility is decreased during development of new neurons in the adult brain, even though the total number of dendritic protrusions does not change.

Synaptic Plasticity

Exercise-induced increase in cell genesis is associated with enhanced hippocampal synaptic plasticity. In particular, long-term potentiation (LTP), a physiological model of certain forms of learning and memory, is influenced by physical activity. In an initial study, field excitatory postsynaptic potential (fEPSP) amplitudes, as well as LTP, were compared in hippocampal slices from running and control mice. The fEPSPs were unchanged in both groups. However, LTP amplitude was enhanced in the dentate gyrus in slices from running mice as compared with controls. Recordings from another hippocampal subfield, area CA1, showed no change in LTP in response to running. In subsequent studies, dentate gyrus LTP was studied *in vivo* in anesthetized rats that had been housed with a running wheel or given forced treadmill exercise. In both voluntary and forced exercise conditions, LTP was increased.

Changes in synaptic plasticity associated with exercise occurred in the same region where neurogenesis was stimulated by running, suggesting that newborn cells have a functional role in this process. Although the new cells are a small percentage of the granule cell layer, several studies have indicated that they have greater plasticity than do mature cells. Indeed, in immature rats, dentate gyrus LTP lasts longer than in adults. In another study, properties of granule cells from the inner and outer layers of the dentate gyrus were compared. Inner layer cells were considered to be young cells and the outer layer to be old cells. It was found that putative young cells had a lower threshold for LTP and were unaffected by γ -aminobutyric acid-A (GABA_A) inhibition, indicating enhanced plasticity in the young cells. In a subsequent investigation, recordings were made from young neurons identified by electrophysiological criteria established during early postnatal development of dentate gyrus neurons, immunoreactivity for immature neuronal markers, and developing dendritic morphology. It was shown that LTP could be induced more easily in young neurons than

in mature neurons under identical conditions. Recently, using retroviral labeling, it was reported that individual new neurons have increased LTP amplitude and decreased induction threshold between 1 and 1.5 months of newborn neuron age. A proposed mechanism is increased dependence of LTP on N-methyl-D-aspartic acid (NMDA) NR2B receptors during this critical developmental period.

Cognition/Learning and Memory

The enhanced synaptic plasticity of individual newborn neurons and the exercise-associated increase in the number of new dentate granule cells may mediate some of the beneficial effects of exercise on learning and memory in humans and animals. Indeed, exercise has been shown to improve learning in human subjects and is correlated with an increase in hippocampal volume. In rodents, both voluntary wheel running and forced treadmill training have been shown to enhance spatial learning using different types of mazes (water maze, y- and radial arm maze). Running also improves performance in other hippocampus-dependent tasks, such as contextual fear conditioning and novel object recognition.

The correlation between neurogenesis, exercise, and cognitive function is maintained during normal aging. Physical activity has been shown to protect against age-related cognitive decline and brain atrophy in aging adults. Neurogenesis declines to low levels with aging in rodents as well as in nonhuman primates and has been associated with cognitive deficits. The age-dependent reduction in cell genesis can be partially prevented when animals are housed with running wheels over a 6-month period. In addition, the decline in neurogenesis and cognition associated with normal aging can be reversed in part by the onset of wheel running late in life. In a recent study, normal aged mice that had been sedentary until they were 18 months of age were housed in a cage with a running wheel for 1 month and tested for spatial memory using the Morris water maze. It was found that exercise significantly improved neurogenesis as well as acquisition and retention of the water maze task in aged runners.

Mechanisms Underlying Exercise-Induced Neurogenesis

Adult neurogenesis in the hippocampus is an extremely dynamic process, and the neurogenic effects of exercise add a level of complexity to the molecular mechanisms mediating this phenomenon. Dentate granule cells receive inputs from many areas of the brain and from the periphery through different neurotransmitters, neural

peptides, and growth factors. Therefore, the complexity of the circuitry and factors in the neurogenic niche must be taken into account for an accurate description of the regulation of cell genesis by exercise.

Neurotransmitters

Acetylcholine

Exercise influences the firing rate and theta rhythm in hippocampal cells through a cholinergic mechanism. In addition, lesion studies in rodents have shown that acetylcholine is required for the proliferation and survival of new neurons. Lesions of the forebrain cholinergic input in rats reduced dentate gyrus neurogenesis. Systemic administration of the cholinergic agonist physostigmine increased neurogenesis. Furthermore, mice lacking the β -2 subunit of the neural nicotinic acetylcholine receptor have significantly decreased cell proliferation in the hippocampus.

Glutamate

The NMDA receptor (NMDA-R) subtype of glutamate receptors also plays a key role in regulation of adult hippocampal neurogenesis. Under exercise conditions, it was found that after 3 days of running both NR2A and NR2B subunits of the NMDA receptor were elevated, and that after 7 days of running only NR2A gene expression remained elevated. It was also shown that exercise leads to an increase in NR2B subunit mRNA levels. Both low- and moderate-intensity treadmill running was proven to enhance NMDA receptor 1 (NMDAR1) mRNA levels. These results are also supported by the lack of exercise-induced neurogenesis in NMDAR1 knockout mice. Interestingly, transgenic mice that overexpress NR2B subunits show enhanced LTP and increased performance on learning and memory tasks. There does not appear to be any significant functional expression of NMDA-R on early adult progenitor cells. However, NR1 has been indicated as important for the survival of young newborn neurons.

γ -Aminobutyric acid (GABA)

GABAergic inputs onto hippocampal progenitor cells have been shown to promote activity-dependent differentiation of progenitor cells in culture. GABA also promotes the synaptic integration of newly generated neurons in the adult brain. The release of GABA from hippocampal interneurons is regulated by a number of other neurotransmitters, including 5-hydroxytryptamine (5-HT; serotonin) and cannabinoids. It was shown that embryonic and adult hippocampal neural precursor cells are immunoreactive for cannabinoid receptors 1 (CB1). Indeed, chronic administration of cannabinoids has been shown to promote neurogenesis in the dentate gyrus of adult rats. These findings are in agreement with other studies showing that

mice lacking the CB1 receptor have significantly decreased neurogenesis.

Monoamines

Monoamines such as noradrenaline and 5-hydroxytryptamine (5-HT; serotonin) are activated by exercise. The dentate gyrus is enriched with 5-hydroxytryptamine (5-HT; serotonin) 1A (5-HT1A) receptors and receives serotonergic innervations from the brainstem. A considerable amount of evidence suggests that 5-HT may stimulate the production of neurons; antidepressants such as selective serotonin re-uptake inhibitors (SSRIs) and 5-HT1A receptor agonists stimulate adult hippocampal neurogenesis, whereas lesions of serotonergic projections from the raphe nuclei (RN) significantly reduced the accumulation of new hippocampal neurons. Inhibition of serotonin synthesis is associated with a decreased number of newly generated cells in the dentate gyrus. 5-HT can also promote the survival of neurons in the adult brain, as demonstrated by the ability of a 5-HT receptor agonist to protect neurons against excitotoxic and ischemic injury. The proposed mechanism is that exercise can elevate the levels of tryptophan hydroxylase, the enzyme involved in the rate-limiting step for the synthesis of 5HT in the RN. Projections from the RN to the hippocampus can influence hippocampal activity. The altered expression of the 5-HT precursor tryptophan may lead to increased serotonin synthesis.

Opiates

Exercise enhances endogenous levels of the opioid systems. For example, in humans, it was shown that the level of β -endorphins increases after exercise. In fact, β -endorphins are a candidate mechanism to explain why people become addicted to running. Recent studies have shown that an increase in cell proliferation can be produced by the direct infusion of opiates, and that opiate receptor antagonists decrease cell proliferation in the dentate gyrus. Interestingly, endorphins and enkephalins stimulate cell genesis *in vitro*. Moreover, administration of the mu receptor antagonist naltrexone decreased running-induced cell proliferation.

Although these neuromodulatory signals trigger proliferation, the direct mitogenic stimulus to the progenitor cells appears to be mediated through growth factors.

Growth Factors

Running wheel exercise increases both central and peripheral levels of key growth factors. In the periphery, trophic factors are released predominantly from muscle tissue during exercise. Growth factors provide important extracellular signals regulating proliferation and differentiation of stem and progenitor cells. Trophic factors that influence adult neurogenesis include brain-derived

neurotrophic factor (BDNF), basic fibroblast growth factor (bFGF-2), epidermal growth factor (EGF), insulin-like growth factor I (IGF-I), and vascular endothelial growth factor (VEGF).

BDNF

BDNF fits particularly well into the concept of function-dependent regulation of adult neurogenesis, because stress and glucocorticoids, which decrease adult hippocampal neurogenesis, also downregulate BDNF, whereas physical activity upregulates BDNF and neurogenesis in the hippocampus. It is known that BDNF supports the survival and growth of many neuronal subtypes, including glutamatergic neurons. With exercise, levels of BDNF mRNA in the hippocampus increased rapidly and remained elevated for weeks. Specifically, it was shown that several days of voluntary wheel running increased levels of BDNF mRNA in the hippocampus, particularly in neurons of the dentate gyrus, hilus, and CA3. Researchers found that 4 weeks of wheel running increase hippocampal BDNF mRNA levels in rats aged 2, 15, or 24 months; the highest level of BDNF was found in 2-month-old rats. BDNF protein levels also increased with running.

BDNF heterozygous mutant mice exhibited a 20% reduction in hippocampal stem cell proliferation. In addition, in BDNF knockout mice, no enhancement of hippocampal neurogenesis following environmental enrichment was observed. It was also shown that knockout of one BDNF allele leads to severe deficits in both LTP and experience-dependent synaptogenesis. Interestingly, selective knockout of the tropomyosin receptor kinase B (trkB) in the hippocampal neural progenitor cells prevented the exercise-induced increase in neurogenesis. Furthermore, intracerebral infusion of BDNF increased cell genesis in the dentate gyrus, but not in the subventricular zone, consistent with data showing that the neurogenic effect of exercise is limited to the hippocampus. BDNF may therefore have a key role in bridging the effects of complex environments from the molecular scale to the level of cellular plasticity. Altogether, these data suggest that exercise might be an effective method for increasing BDNF, which, in turn, can enhance the survival of newborn cells in the hippocampus.

FGF-2 and EGF

Growth factors such as FGF-2 and EGF are also potent factors for the maintenance of adult neural stem cells. FGF-2 was the first molecule identified to promote the proliferation of adult neural progenitor cells, because it was necessary for expansion in culture. These *in vitro* mitogenic effects of FGF-2 are mirrored *in vivo*. FGF-2 mRNA levels are upregulated in the hippocampus following exercise. *In vivo* FGF-2 appears to promote proliferation and differentiation of neural stem cells.

Intracerebroventricular (ICV) infusion of FGF-2 and EGF results in increased neurogenesis in the subventricular zone (SVZ) and in the dentate gyrus. The rate of hippocampal neurogenesis declines with age and intracerebroventricular (ICV) FGF-2 infusion counteracts this reduced neurogenesis.

IGF-1 and VEGF

In recent years, there has been a growing interest in the relationship between angiogenic factors and neurogenesis. In the dentate gyrus, new cells are clustered close to the blood vessels and proliferate in response to vascular growth factors. These observations lead to the hypothesis that neural progenitor cells are associated with a vascular niche and that neurogenesis and angiogenesis are closely correlated. Vasculature changes associated with exercise have been shown to occur in the brain and may be mediated by IGF-1 and VEGF.

Running enhances IGF-1 gene expression and protein levels in the hippocampus, and serum levels of both IGF-1 and VEGF. IGF-1 is a polypeptide hormone that induces neurogenesis in the adult mammalian brain both *in vivo* and *in vitro*. Peripheral infusion of IGF-1 increased adult neurogenesis and reversed the aging-related reduction in new neuron production. Blockade of peripheral IGF-1, on the other hand, inhibited the exercise-induced increase in hippocampal neurogenesis.

VEGF links exercise and adult hippocampal neurogenesis. An increase in levels of VEGF can be measured in exercising individuals. In experiments using local perfusion into the brain, VEGF has been shown to increase neurogenesis in the dentate gyrus. VEGF has also been shown to stimulate neuronal precursors in murine cerebral cortical neurons and *in vivo* in adult rat brain. The trophic factor primarily increased cell proliferation, whereas no alterations in cell survival were observed. Hippocampal gene transfer of VEGF in adult rats resulted in approximately doubling of the number of new neurons in the dentate gyrus and improved cognition. When VEGF is secreted into the blood, it can stimulate the formation of new blood vessels. Therefore, VEGF seems like an ideal trophic factor to induce the changes in angiogenesis and cell proliferation that occur with exercise. Indeed, peripheral blockade of VEGF by use of soluble VEGF receptor led to an inhibition of the effect of running on neurogenesis in the adult dentate gyrus. Similar findings were reported for IGF-1.

It is interesting that exercise increased cell proliferation in the hippocampus, but both exercise and environmental enrichment increased cell survival. The reason might be that exercise induces cell proliferation due to the action of IGF-1 and FGF-2, the expression of which is not altered following environmental enrichment.

Intracellular Pathways

A variety of intracellular mechanisms has been implicated in the regulation of adult neurogenesis. Among these, several transcription factors have been shown to play critical roles in postnatal neurogenesis. TLX, an orphan nuclear receptor, and Bmi-1 are required for the maintenance of adult forebrain neural stem cells. Interestingly, in an inducible knock-out model of TLX, which showed a marked reduction in BrdU-positive cells, voluntary exercise still stimulated cell proliferation. Another transcription factor, Pax6 promotes neuronal differentiation of SVZ progenitors, whereas Olig2 has an opposite effect. In addition, genes involved in cell-cycle regulation, DNA repair, and chromosome stability are required for the proper functioning of adult neural progenitors. The early process of adult neurogenesis might also be influenced by somatic gene insertions, such as the retrotransposon long interspersed nuclear element-1 (*LINE-1*), which is expressed in adult hippocampal neural progenitors *in vivo*, and upregulated by physical activity.

Exercise activates the intracellular pathways that were thought to play a role in cell survival. BDNF, IGF-1, and NGF activate the inositol trisphosphate (IP₃) and the mitogen-activated protein kinase (MAPK) pathways, and the former pathway appears to be essential for cell survival. A common downstream effector of the IP₃ pathways is a serine-threonine kinase, Akt, which has been shown to be activated by exercise and is instrumental in BDNF and IGF-1-induced cell survival. Therefore, exercise might augment the activity of Akt to promote cell survival through NGF.

Glossary

Bromodeoxyuridine (BrdU) – An analog of thymidine, which may be dissolved in saline and injected into animals. It crosses the blood–brain barrier and is incorporated into cells that are in the S-phase of mitosis at time of injection. *Postmortem*, cells containing BrdU are visualized using immunohistochemistry techniques.

Delay conditioning – The conditioned and unconditioned stimulus overlap and co-terminate in time. Learning this task neither requires an intact hippocampus nor rescues new cells from death.

Eyeblink conditioning – A form of classical conditioning in which stimulation of the eyelid, or unconditioned stimulus, occurs at the same time as an auditory tone, or conditioned stimulus. The unconditioned response in this learning model is closing the eyelid. After many trials, the subject learns to accurately time the closing of the eyelid. The precisely timed eyeblink is the conditioned response.

Morris water maze – A spatial navigation task that is widely used for rats and mice. A tank is filled with water which is made opaque with nontoxic paint. A platform is submerged just below the surface of the water. Animals are placed in the tank from various starting points. They use external cues in the room to find their way to the platform. The time it takes the animal to reach the platform, referred to as escape latency, is used as a measure of learning.

Trace eyeblink conditioning – A 500-ms stimulus-free interval occurs after the conditioned stimulus (auditory tone) and before the unconditioned stimulus (eyelid stimulation) is presented. Learning this task requires an intact hippocampus and rescues 1-week-old hippocampal cells from death.

Introduction

The production of a new neuron involves multiple stages and is regulated by several exogenous and endogenous factors. In the broadest sense, neurogenesis, or the generation of new neurons, includes two processes: (1) proliferation, where the number of new cells increases as they undergo repeated cell divisions, and (2) survival, the

fate of a single cell to either develop into a mature neuron or instead to become apoptotic and die. In the adult mammalian brain, one of the most active regions of neurogenesis is found in the dentate gyrus of the hippocampal formation. The hippocampal formation is critical for learning and memory processes. Humans with damage in this brain region exhibit severe and specific deficits in certain types of learning. In animals as well, learning tasks can be categorized as hippocampal dependent or not. In 1999, it was discovered that hippocampal-dependent learning enhances the probability that a newly generated neuron in the hippocampus will survive.

Adult Neurogenesis in the Hippocampal Formation

Newly generated neurons in the adult brain have been identified in several brain regions including the amygdala, hypothalamus, and neocortex, with much larger populations along the wall of the lateral ventricle (subventricular zone), the olfactory bulbs, and the hippocampal formation. The dentate gyrus of the hippocampal formation is among the most active neurogenic regions. These neurons arise from the border between the granule cell layer and the hilus. The precise cell lineage of hippocampal cells is not entirely clear; however, evidence suggests that these neurons arise from a constitutively active population of radial glial cells. Data are derived from a combination of techniques, including retroviral labeling and immunohistochemistry, to selectively label newly generated cells, and laser and electron microscopy to visualize morphological changes across development. When proliferating hippocampal cells were selectively destroyed, the first new cell type to arise was glial fibrillary acidic protein (GFAP)-expressing cells which later expressed neuron-specific proteins. GFAP is used to identify glial cells. While glial cells, or GFAP-expressing progenitors, represent one putative source of new neurons, other possibilities exist. For instance, when a cluster of new neurons is identified, there is often an increased density of blood vessels nearby. A positive correlation between neurogenesis and angiogenesis, the birth of new vasculature, occurs in both mice and humans. Furthermore, running, which increases cerebral blood flow, in turn, increases cell proliferation quite

dramatically. An intriguing possibility is that bidirectional communication between blood and nerve cells leads to the synthesis of neural progenitor cells *de novo*. Indeed, the angiogenic protein, vascular endothelial growth factor (VEGF), promotes the growth of vascular endothelial cells and also stimulates the growth of neuronal precursors both *in vitro* and *in vivo*. Although speculative, perhaps the delivery of lipids, proteins, and carbohydrates across blood and nerve cell membranes provide the building blocks of a new cell or otherwise contribute to adult neurogenesis in the hippocampus. Regardless of the mechanism for synthesis, newly generated cells that give rise to neurons in the adult hippocampus are found in the dentate gyrus of the hippocampal formation.

Newly generated hippocampal cells exhibit significant growth between 4 weeks and 4 months. Throughout this period, the size of the soma, total dendritic length, dendritic branching, and spine density all increase by about 60%. During the first 3 days after mitosis, apical dendrites extend through the granule cell layer at a rate of $10 \mu\text{m day}^{-1}$. When the cells are 4 and 5 days old, the dendrites double in length each day as they continue to extend toward the molecular layer. Between 6 and 10 days after mitosis, new granule cells extend axons to the CA3 layer of the hippocampal formation; just as the existing, fully mature dentate granule cells do. Basal dendrites appear early in cell development but are no longer apparent as the cell matures, a feature also observed in the young, developing brain. Another property of new cells in the adult brain, which is also observed in the young brain, is the manner in which they respond to the amino acid neurotransmitter, γ -aminobutyric acid (GABA). Initially, diffuse, tonic GABA surrounding the cell is adequate to induce intracellular changes in the new cell. As the cell develops, it is no longer responsive to ambient GABA, rather it requires synaptic-mediated input. It depolarizes in response to the binding of GABA, then as the cell matures, it hyperpolarizes in response to the binding of GABA. This is the same stereotypical pattern observed in development, and in both cases, it is attributed to the sequential expression of chloride transporters. Ultimately, newly generated cells in the dentate gyrus of the adult brain are completely integrated into the hippocampal network. They form functional synapses and are capable of firing action potentials.

Identifying New Neurons

The ability to label newly dividing cells and track their survival *in vivo* is critical to understanding the role of neurogenesis in memory. The most widely used technique to do this is immunohistochemistry with a synthetic thymidine analog. Bromodeoxyuridine (BrdU) is the thymidine analog most frequently used. It is incorporated into DNA during the S-phase of the cell cycle, during

which DNA is single stranded and BrdU can bind to the thymidine base pair, adenine. As this only occurs during a fraction of the cell cycle, BrdU only labels a fraction of mitotic cells. BrdU is dissolved in saline, is injected into the intraperitoneal cavity (i.p.), crosses the blood–brain barrier, and can label mitotic cells which are in S-phase for up to 2 h after injection. Once incorporated inside cells of the adult brain, BrdU remains there for several cell divisions without substantial dilution. This is different from the postnatal brain, where cell division of neurons occurs at an exponential rate and therefore, substantial dilution occurs in a relatively short amount of time. After animals are euthanized, brain tissue is fixed with paraformaldehyde. The brain is then cut into thin sections and mounted onto glass slides. Cells containing BrdU are visualized using standard immunohistochemical techniques. Essentially, the tissue is treated with an antibody that was created to bind specifically to BrdU. The antibody complex is then reacted with a peroxidase which gives a cell containing BrdU a distinct brown color (**Figure 1**). Alternatively, a BrdU-containing cell is labeled with a fluorescent secondary antibody (**Figure 2**). Fluorescent immunohistochemical techniques are beneficial because they allow for labeling of more than one antigen inside of a single cell. Several methods for labeling new neurons are becoming increasingly available. For instance, additional thymidine analogs, such as iododeoxyuridine and chlorodeoxyuridine, may also be used. In addition, new cells may be selectively labeled using a retroviral vector that expresses green fluorescent protein. In this case, the vector is typically injected into the brain using stereotaxic procedures. This approach has been critical in demonstrating that newly generated neurons *in vivo* possess electrophysiological properties, such as the firing of action potentials, which are similar to those of mature granule neurons.

Learning-Sensitive Period during Cell Development

The age of the cell at the start of the training experience appears to be a critical factor for learning-induced survival. Majority of new neurons in the adult hippocampus begin to die about 1–2 weeks after they are generated. If animals are exposed to a hippocampal-dependent task, or to an enriched environment, at the time when these cells normally die, then the fate of these cells is altered and they survive. Recent data indicate that nearly all of the cells that are available at the onset of training are rescued from death, provided that the animal learns and learns well; once rescued, they remain in the hippocampus for at least 2 months after training. These findings indicate that learning increases the number of surviving neurons in the hippocampus and thereby alters the existing circuitry of the hippocampal formation.

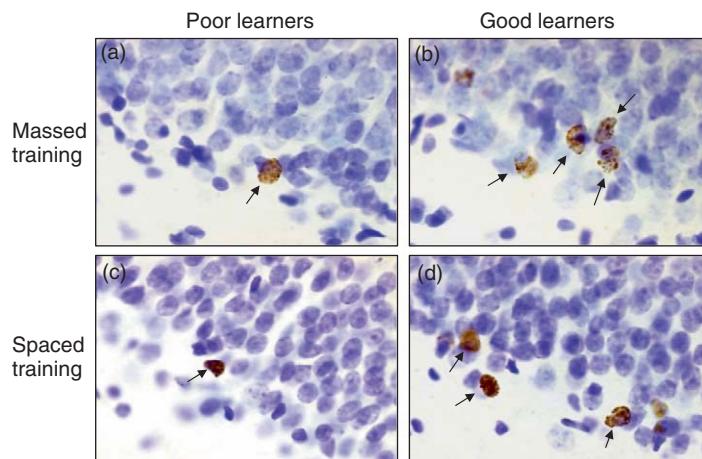

Figure 1 Mitotic cells that were in the S-phase at the time of injection incorporate BrdU. After the brains are dissected, immunohistochemical procedures are used to change the color of cells that contain BrdU. In this image, BrdU-labeled cells are brown. Purple cells were stained with cresyl violet; these are mature cells, as well as cells that may have been synthesized two or more hours after injection with BrdU. Number of BrdU-labeled cells in the dentate gyrus depends on how well the animal learned. An example of an animal trained with massed trials that learned poorly (a), massed trials that learned well (b), spaced trials that learned poorly (c), and spaced trials that learned well (d). With permission from Sisti HM, Glass AL, and Shors TJ (2007) Neurogenesis and the spacing effect: Trials distributed over time enhance memory and cell survival. Learning and Memory 14(5): 368–375.

Learning and New Neurons

In general, the term ‘learning’ is used to imply a change in cognitive state or behavior as a result of acquiring new information. The primary distinction between learning and memory is a temporal one. That is, learning is the acquisition of a new task or skill, whereas memory is the retention and retrieval of that newly acquired information. Learning processes engage different brain regions to varying degrees depending on the type of task: (1) learning that involves fearful and threatening situations is highly dependent on amygdala activity; (2) learning that involves associations between overlapping and discrete sensory stimuli, as occurs in the conventional delay eyeblink conditioning task, depends on an intact cerebellum; and (3) learning that involves trace associations or spatial tasks depends on the hippocampus. As the hippocampus is among the most active neurogenic regions in the adult brain, it was hypothesized that learning that involves the hippocampus could rescue newly generated cells from death.

Learning processes that require the hippocampus tend toward those that require considerable effort and cognitive engagement. Some of these processes include: learning to associate events across time (trace conditioning); learning to navigate and remember locations in three-dimensional space without any obvious visual or olfactory cues (spatial learning); learning the sequence of events (relational learning); and learning to associate the environment with an event (contextual learning). To be explicit, learning is dependent on the hippocampus if

lesions to all of the neurons within it prevent or severely retard learning; learning is not dependent on the hippocampus if learning still occurs even though all the neurons within the hippocampus do not exist (both old and new neurons).

To determine whether hippocampal-dependent learning could rescue new cells from death, animals were trained with two tasks: spatial learning using the Morris water maze and associative learning using eyeblink conditioning. For each task, a hippocampal-dependent and hippocampal-independent version was used. In the Morris water maze, when the platform is hidden just below the surface of the water, the hippocampus is needed; however, when the platform is made visible, the hippocampus is not needed. That is, animals with a damaged hippocampus can navigate toward the visible platform just as well as control animals with no hippocampal damage. For eyeblink conditioning, both trace (hippocampal-dependent) and delay (hippocampal-independent) tasks were used. In delay conditioning, the conditioned stimulus (CS), usually an auditory cue, overlaps and co-terminates with the unconditioned stimulus (US), an airpuff to the eye. Thus, the two stimuli are contiguous in time. In the trace version of this task, the conditioned and (USs) are separated by a stimulus-free interval, for example, the stimuli are discontiguous. Acquisition of the trace task depends on an intact hippocampus. Hippocampal-lesioned animals can learn the delay task as well as controls, but they are unable to learn the trace task, even after many trials. Animals were injected with BrdU 7 days before the start of training.

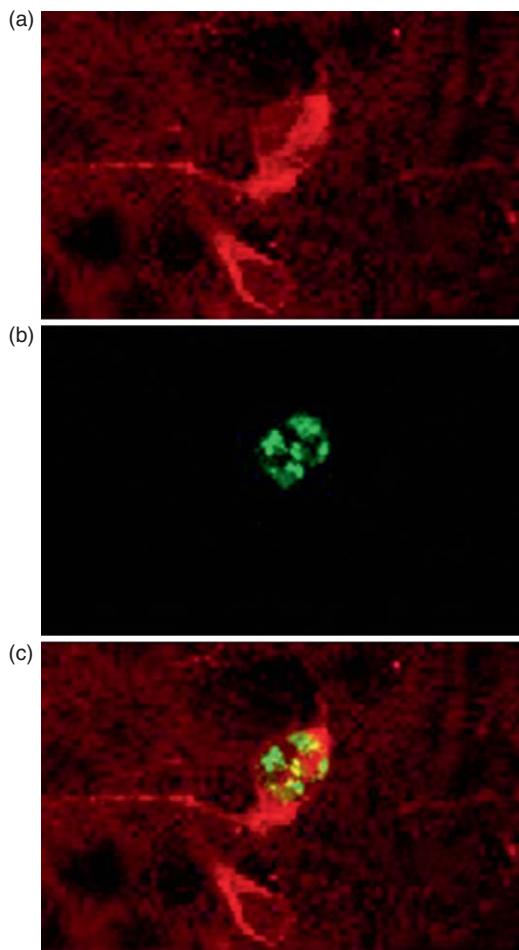

Figure 2 Newly generated cells may be visualized using fluorescent immunohistochemistry and confocal microscopy. Here, the BrdU-labeled cell is green (a). The cells in red express doublecortin (b). The cell expressing both DCX and BrdU is a new neuron, whereas the cell expressing only doublecortin (red only) is a new neuron that was synthesized outside the 2 hour time-window of BrdU injection (c). With permission from Sisti HM, Glass AL, and Shors TJ (2007) Neurogenesis and the spacing effect: Trials distributed over time enhance memory and cell survival. Learning and Memory 14(5): 368–375.

Learning which requires the hippocampus, regardless of whether it was spatial or associative, enhanced the probability that new neurons would survive. Animals trained using the hippocampal-dependent version of either the Morris water maze or eyeblink conditioning had higher numbers of BrdU-labeled cells compared to hippocampal-independent versions of both tasks. Animals trained with the visible platform or with delay conditioning had similar number of new neurons as animals that received no training. Thus, if animals are exposed to a hippocampal-dependent learning task at the time when new cells would normally die, then their fate is altered and the new cells survive. In other words, learning can rescue newly generated neurons from death.

Learning versus Performance

In addition to hippocampal activation, in order to rescue new neurons from death it is important that new learning indeed occurs. Merely exposing animals to a task and all relevant training stimuli is not sufficient to rescue new neurons from death. For instance, for over a century it has been recognized that memory is longer lasting when the new information is learned over time compared with the same amount of information learned in a very brief period of time. This phenomenon has been known alternatively as the ‘spacing effect,’ ‘distribution of practice,’ or colloquially as ‘cramming.’ The role of new neurons in the spacing effect was investigated using a spatial learning task. One group of animals was trained with 16 trials distributed, or spaced, across 4 days. A second group was trained with 16 trials all in 1 day (massed training). Generally, animals trained with spaced trials learned better and had a longer-lasting memory compared with animals trained with massed trials. However, a few animals in the spaced condition learned poorly compared to those in the massed condition, despite having an advantageous training protocol. When the number of BrdU-labeled cells was measured, good learners retained more 1-week-old cells than poor learners, regardless of training condition (Figure 1).

The importance of learning *per se* in rescuing 1-week-old neurons from death also occurs in associative learning tasks. Trace conditioning, which enhances cell survival, was compared with another task, contiguous trace conditioning (CTC). This task is similar to trace except that the CS, or tone, is presented a second time during which it coincides with the US. Unlike the trace conditioning task, the CS and US are presented contiguously. Only when the CS and US are presented simultaneously, animals generally learn poorly. When the number of learned responses was compared between animals trained with either trace or CTC, there were both good and poor learners in each training condition. Animals that learned well had higher numbers of new cells than those that learned poorly, regardless of the training condition.

Task Difficulty

Generally, tasks are considered more difficult to learn if more training trials are necessary to reliably and accurately express a learned response. For example, learning to emit an eyeblink response during delay conditioning (which does not depend on the hippocampus) requires many fewer trials than learning to emit a similar eyeblink response during trace conditioning, which does depend on the hippocampus. If a typical delay conditioning task is rendered more difficult, as in very long delay conditioning, learning this new task will rescue new neurons from death. In contrast, if a trace conditioning task, which is

usually quite difficult to learn, is made easier to learn, learning the new task does not increase the number of surviving cells. In the end, it appears that tasks that are more difficult to learn are also more likely to rescue new neurons from death. However, as stated previously, it is also important that the animals actually learn. That is, animals that learn best tend to possess more cells after training than those that are trained but do not learn or do not learn very well.

Are New Neurons Necessary for Learning?

Eliminating new neurons induces deficits in some types of learning tasks, while leaving most types of learning intact. To test if new neurons are necessary to learn a given task, newly generated cells must be selectively destroyed before animals begin training. It is somewhat challenging to prevent new cell proliferation *in vivo* without any other detrimental consequences; however, pharmacological agents and focused irradiation have been successfully used. For instance, a drug used to treat cancer patients, methylazoxymethanol acetate (MAM), blocks neurogenesis without obvious debilitating side effects in animals. Animals injected with MAM were tested for pain sensitivity, motor activity, stress hormone levels, hippocampal volume, and excitatory postsynaptic potentials in CA1 of the hippocampal formation. On all measures, MAM-treated animals were similar to saline-treated controls. They were then trained on either a hippocampal-dependent (trace eyeblink conditioning) or a hippocampal-independent (delay eyeblink conditioning) task. Both groups could learn the delay task. However, when number of learned responses on the trace task was compared, animals with relatively few new cells could not learn the trace task. The MAM-treated animals emitted few learned responses compared with saline controls. Furthermore, when MAM treatment was stopped, the ability to learn trace conditioning was recovered.

Focused irradiation selectively reduces ongoing neurogenesis in the dentate gyrus without any detectable damage to mature neurons or reduced cell proliferation in the subventricular zone. Low-dose irradiation has been used to inhibit hippocampal cell proliferation of animals which were then tested on the Morris water maze. Training began 4 weeks after irradiation treatment, so that new neurons 4 weeks or younger were not available during training. Animals could learn the task and even remember it when tested 1 week later. However, when tested 2 and 4 weeks later, irradiation-treated animals had no memory of the platform location, whereas controls did. Therefore, new neurons were not necessary in spatial learning or short-term memory of the platform location; however, new neurons were necessary for long-term retrieval of the spatial memory. This is consistent with previous experiments in which MAM-treated rats could

learn the location of a hidden platform in the Morris water maze as well as control animals. Spatial learning is not the only task that can be performed well without neurogenesis. Learning simple associations between aversive events and contextual or environmental cues also does not require new neurons.

There has been much speculation about what the new cells do once they become incorporated as mature neurons into the hippocampus. Some argue that the numbers are too few to matter. This may be the case, but most of the cells that remain in the hippocampus after learning are still there 2 months later. Within that time period, each neuron can develop thousands of spines. If tens of thousands of new neurons are generated each week, the number of potential connections could increase dramatically over a relatively short period of time. In addition, the new cells are located in a prime location – at the first major synapse in the hippocampal formation. Additional neurons will impact neuronal activity within the dentate gyrus, not to mention efferent synapses and other brain regions. Whether these neurons are then used to retrieve the memory of the task by which they were rescued seems unlikely. The hippocampus is mostly involved in learning and only temporarily involved in the retention of most memories. Within weeks of learning, animals without a hippocampus can clearly remember the context in which an aversive event occurred, and they readily express a memory for the trace interval. If the hippocampus is not required to express these types of memory, then new neurons within the hippocampus cannot be necessary either, irrespective of any effect that learning may have on them. Most likely, learning-induced cell survival represents a way in which this brain region is rewired to encode new information. The phenomenon is specific to the type of learning and to the brain regions involved and seems to occur in an activity-dependent manner.

Potential Mechanism of Action

While several theories have been put forth regarding the mechanism by which new learning rescues cells from death, the precise cascade of events remains to be determined. Generally, it is likely that neural progenitor cells of the dentate gyrus receive either mitogenic or anti-apoptotic signals from adjacent mature granule cells as new hippocampal-dependent learning occurs. If the animal has already learned the task, or if the task is very easy to learn, then such signals simply may not be expressed. However, when learning is sufficiently difficult, then the neural mechanisms implicated in learning may result in the induction of specific pathways that lead to the neuronal differentiation of newly generated cells. The most likely candidates in regulating learning-induced cell survival may be found in those pathways which are critical for

both hippocampal-dependent learning and neuronal differentiation. For instance, the acquisition of the conditioned eyeblink response depends on activation of *N*-methyl-D-aspartic acid (NMDA)-receptors and NMDA receptors are critical in regulating adult neurogenesis. NMDA receptors have been localized on newly generated neurons. When glutamate, the excitatory amino acid which activates NMDA receptors, is applied to hippocampal neural progenitor cells *in vitro*, the proportion of cells that differentiate into neurons is increased. Regardless of the mechanism by which new neurons are rescued from death, new learning can predict cell survival.

Conclusions

The ability of learning to rescue new neurons from death has important implications for both the healthy and diseased brain. Even throughout adulthood, the brain continues to generate new neurons.

Current evidence suggests that patients with dementia continue to produce new neurons in their hippocampus, but the numbers are few and most do not mature. It is perhaps paradoxical that even the few new neurons patients produce may not survive simply because the individuals are not able to learn. Determining precisely how learning rescues new neurons from death will be an important advancement in behavioral neuroscience and may translate to widespread therapeutic interventions in the damaged brain.

Glossary

Accommodation – A neuronal response to a sustained depolarizing stimulus where the neuron accommodates to the depolarization and stops or reduces its action potential generation (firing). It is also referred to as ‘spike-frequency adaptation.’

Afterhyperpolarization – Membrane hyperpolarization, mediated mainly by calcium-dependent potassium currents, that follows a train of action potentials, acting to reduce a neuron’s propensity to fire.

Calcium-dependent potassium current – An outward current triggered by elevation of calcium ions in the cytosol of the neuron that causes membrane hyperpolarization mediated by potassium ions leaving the neuron and thus reducing its membrane potential.

Conditioned stimulus (CS) – A neutral stimulus used in learning paradigms that does not elicit the reflexive behavior (measured to reflect learning and memory) prior to training.

Eyeblink conditioning – A classical or Pavlovian learning task designed around the reflexive closure of the eyelid. The subject learns to associate a CS with an unconditioned stimulus (US), with repeated pairings, to anticipate the US after the onset of the CS. After conditioning, the subject closes the eyelid prior to the onset of the US. A simple, yet powerful learning task first used with humans, it has been used extensively to examine the role of the cerebellum and the forebrain, including the hippocampus, in learning and memory storage.

Fear conditioning – A task in which the subject learns to associate a neutral CS with a fear evoking US. This paradigm has been extensively used to examine the learning-related changes in the amygdala, the hippocampus, and the prefrontal cortex.

Hippocampus – A portion of the ancient cortex buried in the medial temporal lobe that was brought to scientific prominence by a landmark study reported by William Scoville and Brenda Milner in 1957. They described profound memory impairments caused by bilateral removal of the hippocampus and surrounding areas in patients with intractable seizure, depression, or paranoid schizophrenia.

Memory consolidation – A stage in the temporal progression of memory formation. The hippocampus and its associated areas are critical when declarative learning (knowing that) is taking place and memories are

initially being formed. Once formed, the memory is distributed and hypothesized to be stored in the neocortical regions.

Unconditioned stimulus (US) – A stimulus used in learning paradigms that evokes a reflexive behavior, for example, an eyeblink response to a puff of air on the eye. After pairing with the neutral CS, the learned conditioned response (CR) has components of the reflexive behavior caused by the US.

What happens when you learn something and it becomes part of your memory? What and where are the changes that must take place in your brain for learning to occur? An alteration in the strength of synaptic contacts between neurons which has been postulated by Donald Hebb is commonly thought to occur with learning. Neuronal excitability, an intrinsic property of neurons, also changes during learning and is our focus. Pyramidal neurons in a portion of the ancient cortex buried in the temporal lobe, the hippocampus, show alterations in the postburst afterhyperpolarization (commonly referred to as AHP) as memories are formed and stored.

Before delving into the learning-related alterations in the AHP, a brief discussion of the well-defined learning tasks used to analyze these changes with a systematic experimental approach is necessary.

The Morris water maze and fear-conditioning tasks are two behavioral assays used by numerous laboratories. The water maze tests the spatial navigation learning ability of rodents that relies on the proper function of the hippocampus. In this task, the animal learns that a hidden platform for getting out of the water in which it is swimming is located in a fixed location in the pool. By learning the location of the platform relative to the visual cues around the water maze, the animal quickly escapes the water in the pool by swimming directly to and climbing onto the escape platform. The fear-conditioning task relies on the proper function of the amygdala and the neocortex. It can also be hippocampus dependent by having the rodents learn the context (the spatial cues) of the fear training environment, or by introducing a temporal gap between the offset of the conditioning cue and the onset of the mild, aversive shock, such as the case in the trace fear-conditioning task.

Eyeblink conditioning is a simple, yet powerful tool to assess the proper function of the various neural networks

involved in learning this task. The subject has to learn to associate a conditioned stimulus (usually a tone) that precedes the airpuff unconditioned stimulus to the eye that causes the reflexive response of eyelid closure. After learning, presentation of the tone causes eyeblinks that occur prior to or even without the air puff. Due to its similarity to Pavlov's experiments with dogs (ringing the bell before giving food reward), eyeblink conditioning is often called a Pavlovian learning task. This remarkably simple sounding task can be made challenging by inserting a temporal gap between the tone (the predictor) and the airpuff (the reinforcer): the resulting paradigm is called 'trace eyeblink conditioning' because it requires that a short-term memory trace be formed to allow the correct prediction of when the airpuff will occur. Many studies, including those from our laboratory, have demonstrated that trace eyeblink conditioning relies on the proper function of the hippocampus and is sensitive to aging. More importantly, results from animal experiments with trace eyeblink conditioning are directly applicable to humans, because results from human experiments on trace eyeblink conditioning are similar to those found with animals: humans with hippocampus damage (and thus amnesia) and the elderly are impaired in learning the association between the tone and the airpuff. Most of the experiments that illustrate the learning-related AHP reductions observed in hippocampal pyramidal neurons are from animal studies using trace eyeblink conditioning.

The Postburst AHP

In the brain and the spinal cord, relay of information from one neuron to another is achieved by action potentials (APs) (Figure 1). In most neurons, especially pyramidal neurons, an AP is followed by a hyperpolarization (commonly referred to as 'the refractory period') that makes it difficult for the neuron to fire another AP in quick succession. However, when a neuron fires a burst of APs, the result is a prolonged, postburst AHP that increases in size with increasing number and frequency of APs in the burst (Figure 1). Thus, the AHP plays a central role in determining whether or not a neuron will relay a message to other neurons within and between the cortical neural networks.

Three Phases of AHP: Fast, Medium, and Slow

The fast AHP

The fast AHP is part of the repolarizing phase of an AP (Figure 1). Comprised of multiple potassium currents (I_{C} , I_{M} , and I_{A}), it plays a significant role in shaping the AP. When these potassium currents are active, the repolarization of the membrane is accelerated, and as a consequence, it limits the influx of calcium ions (Ca^{2+})

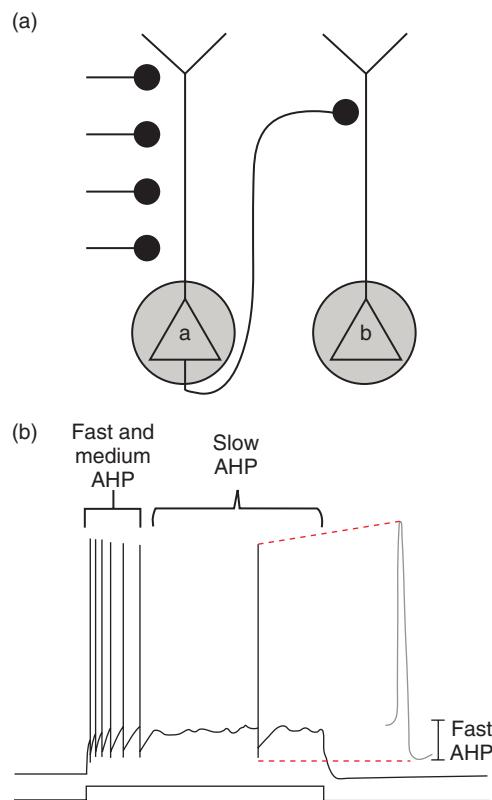

Figure 1 The postburst AHP plays a critical role in determining transmission of information from one neuron to the next. (a) Highly simplified diagram of two neurons that are in a neural circuit. Neuron 'a' receives synaptic input from various sources in the neural circuit and integrates it in the soma (triangle). When the synaptic inputs exceed the threshold for the neuron, an action potential (AP) is generated in the axon initial segment, and information is relayed to the next neuron 'b'. The hypothesized location of the slow AHP channels is the shaded circle around the soma. Due to its localization, the size of the slow AHP plays a critical gatekeeper role in determining whether or not an AP will be generated. A large slow AHP can shunt depolarizing inputs arriving to the soma from the dendrites and effectively prevent these depolarizing signals from being passed on to the axon initial segment. (b) An example of CA1 pyramidal neuron's response to a prolonged depolarizing input is illustrated. The neuron initially responds with a number of APs. With time, the frequency of the APs reduces, to a point where there is a cessation of AP for a long duration. This reduction of APs is called 'spike-frequency adaption', or simply 'accommodation', and has been found to be highly correlated to the size of the slow AHP. The fast and medium AHPs dictate the frequency of APs that can be generated during the initial depolarization. The slow AHP dictates the neuronal response to the sustained depolarization. The inset illustrates where the fast AHP is measured after an AP.

into the cell by removing the depolarization necessary for the voltage-gated calcium channels (VGCCs) to work. Conversely, when the fast AHP is reduced or inhibited, the AP becomes broader and allows Ca^{2+} influx through the VGCCs. By having a large fast AHP, the membrane potential is repolarized to a point further away from AP threshold and prevents the neuron from firing

immediately after repolarization. When the fast AHP is reduced or inhibited, the membrane potential is near the AP threshold upon repolarization, and the neuron can subsequently generate another AP with a depolarizing stimulus. It is this balancing act of regulating the rate and degree of membrane repolarization after an AP that allows the fast AHP to help determine the frequency of AP generation.

The medium AHP

The medium AHP, I_{AHP} , is a calcium-dependent, but not voltage-dependent, potassium current that results from a burst of APs and lasts for 50–125 ms during which the peak of the AHP occurs. Originally identified by its sensitivity to a neurotoxin from bee venom, apamin, it is generally accepted that the medium AHP is mediated by SK2 channels in most cortical neurons, including hippocampal pyramidal neurons. However, contrary data reported by Johan Storm and colleagues suggest that an apamin-sensitive AHP does not exist in hippocampal pyramidal neurons and that the medium AHP reflects activation of I_M and I_h in these neurons.

The slow AHP

The slow AHP, sI_{AHP} , is mainly a calcium-dependent, voltage-independent, potassium current that can last for seconds after a burst of APs and that is modulated by a wide variety of neurotransmitters and peptides. It is hypothesized that the channels mediating the slow AHP are located on the soma and the dendrites near the soma of pyramidal neurons; however, the channel identity has yet to be discovered. Due to its proposed location and long-lasting duration, the slow AHP plays an important role in signal transduction and plays a role akin to a gatekeeper. When the slow AHP is large, the region surrounding, and including, the soma is at a hyperpolarized state far away from AP threshold. Thus, unless the neuron is bombarded with synaptic signals that can significantly depolarize the cell, the large slow AHP will prevent further relay of synaptic information that arrives at the cell. On the flip side, when the slow AHP is small, the soma and its surrounding region will be less hyperpolarized and in a state closer to AP threshold. Thus, synaptic information that arrives at the cell will more likely be relayed to the next neuron in the neural circuit ([Figure 1](#)).

Learning-Related Alterations in the AHP

Daniel Alkon and colleagues demonstrated a learning-related alteration of an intrinsic membrane property of a neuron in invertebrates. They showed that I_A and a calcium-dependent potassium current were significantly reduced in isolated type B photoreceptors from

Hermissenda crassicornis trained to avoid a lighted area: *Hermissenda* normally move toward light. The resulting reduction in these AHP currents led to increase in excitability of the type B photoreceptors after training.

Disterhoft, Coulter, and Alkon reported that an intrinsic neuronal property, the postburst AHP, is altered by associative learning in vertebrates. They demonstrated that learning the classic, delay eyeblink conditioning task is correlated with an increase in neuronal excitability resulting from a reduction in the postburst AHP in CA1 hippocampal pyramidal neurons in brain slices taken from rabbits. The AHP reduction was an alteration in the intrinsic membrane property as the learning-related AHP reduction was still evident after synaptic transmission in the hippocampal slice was blocked. More importantly, the AHP reduction was a learning-specific phenomenon as the postburst AHPs in neurons from control animals given unpaired delay eyeblink training were not different, and nearly identical, to that measured in neurons from naive, untrained animals. However, all these observations were made in CA1 hippocampal pyramidal neurons after the animals learned the delay eyeblink conditioning task; which engages the hippocampus, but can be learned without it.

Building upon these initial findings, several studies have demonstrated that the postburst AHP is reduced in pyramidal neurons in various cortical regions that are necessary for learning a specific task. The postburst AHP and the currents mediating it (I_{AHP} and sI_{AHP}) are reduced in dorsal CA1 hippocampal pyramidal neurons after spatial water maze learning in rats ([Figure 2](#)). Learning trace eyeblink conditioning task is correlated with smaller postburst AHP in hippocampal pyramidal neurons of rats and rabbits ([Figure 3](#)). Recently, Elizabeth Matthews in our laboratory demonstrated a learning-related reduction in I_C (BK channel-mediated fast AHP) in hippocampal CA1 pyramidal neurons after rats learned the trace eyeblink conditioning task. Smaller postburst AHP in piriform cortical neurons after odor discrimination learning in rats has been demonstrated by Edi Barkai and colleagues. All of these learning-related AHP reductions lead to enhanced neuronal excitability of the neurons.

However, reduced AHP and the resulting increase in neuronal excitability are not always appropriate for all learning tasks. Proper modulation of the postburst AHP is essential for learning to take place. Recent work by James Porter and colleagues demonstrate this point. In their experiments, rats are trained on auditory fear conditioning. This task relies on the proper function of the amygdala and the prefrontal cortex for the rats to learn that a tone will be followed by a shock. In a naive state, the activity in the amygdala is repressed or kept in check by efferent activity of the prefrontal cortical neurons that act to inhibit

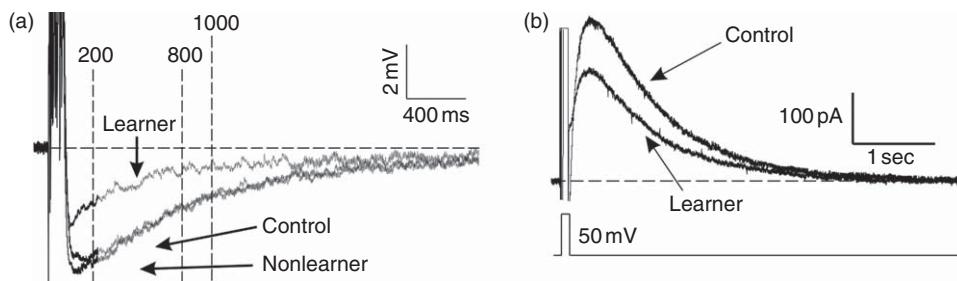

Figure 2 The postburst AHP and the currents underlying it were reduced in CA1 pyramidal neurons from rats that learned the hidden platform location. (a) Typical examples of the postburst AHP from dorsal CA1 neurons of learner, nonlearner, and controls are illustrated. These neurons were current clamped to near -68 mV (horizontal dashed line). The vertical dashed lines illustrate the time points of AHP measurements at 200, 800, and 1000 ms after the pulse offset. (b) Examples of isolated I_{AHP} - S/I_{AHP} currents from dorsal CA1 neurons of a learner and a control rat are illustrated. The horizontal dashed line indicate the holding current used to hold the neurons at -55 mV ; that is, the relative zero for the measurements. Reproduced with permission from Oh MM, Kuo AG, Wu WW, Sametsky EA, and Disterhoft JF (2003) Watermaze learning enhances excitability of CA1 Pyramidal neurons. *Journal of Neurophysiology* 90: 2171–2179, copyright The American Physiological Society.

amygdala neuron firing rate. However, for fear learning to take place, the activity in the amygdala increases as a result of reduced activity in the prefrontal pyramidal neurons. Porter and colleagues observed a significant reduction of activity in infralimbic pyramidal neurons of the prefrontal cortex in rats trained on the fear-conditioning task that was mediated by an enlargement of the postburst AHP in these neurons. Subsequently, they observed that the postburst AHP in these infralimbic neurons was reduced and restored to a naive-like (pretraining) state when the auditory fear memory was extinguished in the trained rats: that is, the increased activity resulting from the decreased AHP in the prefrontal cortex keeps the amygdala in check to prevent expression of the fear memory. Thus, the proper modulation of the postburst AHP is essential for expression of the appropriately learned behavior.

This leads to the question of where memory is stored. Experimental evidence points to the neocortex as the site for permanent memory storage. However, memory for even the simplest learned event appears to be distributed throughout the cortex. What we do know is that memory for a learned association, such as trace eyeblink conditioning, is not stored permanently in the hippocampus as demonstrated by two important studies.

First, in a series of experiments by Moyer, Thompson, and Disterhoft, the transient nature of the learning-related postburst AHP reduction was demonstrated in hippocampal pyramidal neurons after trace eyeblink conditioning in rabbits. The significantly smaller postburst AHPs in the pyramidal neurons were maintained for about a week after the animals learned the task (Figure 3). This does not mean that the rabbits forgot the learned association. Once the rabbits learned the trace eyeblink conditioning task, the

memory of the conditioned stimulus–unconditioned stimulus association is maintained for months after the last training session; although experimentally untested, the memory may last the lifetime of the subject. More importantly, the learning-related postburst AHP reduction is not merely a by-product of sensory experience during training. To demonstrate this, the rabbits were trained to a learning criterion and left undisturbed in their home cages for 2 weeks, after which they were given another training session. As expected, these rabbits showed excellent retention of the learned trace eyeblink conditioning response. However, the biophysical properties, including the postburst AHP, of the pyramidal neurons from these rabbits were no different than those from neurons in naive and control rabbits (Figure 3). Apparently, hippocampal neurons show AHP reductions early in training when the association is being acquired and initially consolidated or stored in neocortex. After the neocortical storage has occurred, the conditioned response is demonstrated independent of the hippocampus and neurons there do not show AHP reduction after further training sessions.

In another series of experiments, Kim, Clark, and Thompson demonstrated the critical time window of hippocampal engagement for learning and retaining the memory for the trace eyeblink conditioning task. Briefly, they trained rabbits on the trace eyeblink conditioning task and chose two different times to remove the hippocampus bilaterally. In one group of rabbits, they removed the hippocampus 1 day after the rabbits achieved a learning criterion. These animals failed to recall the learned behavior and failed to relearn the trace eyeblink conditioning task. Notably, these rabbits did learn the cerebellum dependent but hippocampus independent, delay eyeblink conditioning task. In another group of

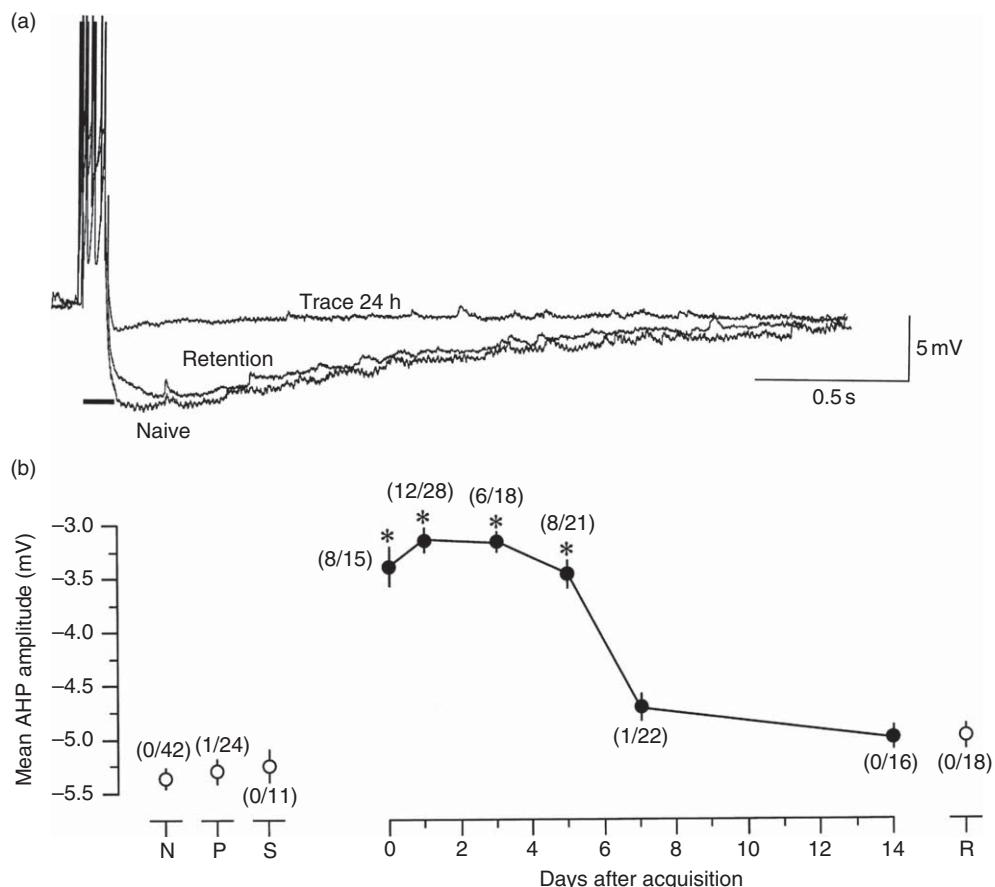

Figure 3 The postburst AHP was transiently reduced in CA1 pyramidal neurons while performance remained persistent after learning trace eyeblink conditioning in young adult rabbits. (a) Voltage trace shows an overlay of recordings of the postburst AHPs in CA1 neurons from a naive rabbit (naive) and from trace-conditioned rabbits studied 24 h after initial learning (trace 24 h) or 24 h after receiving an additional training session given 14 days after initial learning (retention). The resting membrane potentials for these cells were approximately -66 mV, with APs truncated for visualization of the AHP. The AHP was measured for 5 s beginning after a 100 ms depolarizing current injection (solid black line), with minimal current (~ 0.6 nA) required to reliably evoke a burst of four APs. (b) Learning-related reductions of the AHP amplitude were transient, lasting ~ 1 week in slices prepared at various times after learning [1 hr (0 d), 1 d, 3 d, 5 d, 7 d, or 14 d]. Such changes were not observed in: N, naive; P, pseudoconditioned; or S, slow-learning control rabbits. Numbers in parentheses indicate the ratio of individual cells with reduced AHPs to number of cells studied in that group. Slow learners were defined as rabbits that did not reach criterion within 15 training sessions, and that exhibited $<30\%$ conditioned responses on the last training session. R, retention rabbits received an additional 80-trial training session on the 14th day after initial learning. Asterisks indicate data significantly different from all three control groups: $*p < 0.001$. Reprinted with permission from Moyer JR, Jr., Thompson LT, and Disterhoft JF (1996) Trace eyeblink conditioning increases CA1 excitability in a transient and learning-specific manner. *Journal of Neuroscience* 16: 5536–5546, copyright The Society for Neuroscience.

rabbits, Thompson and colleagues removed the hippocampus 1 month after the rabbits met the learning criterion. These rabbits were able to produce the learned trace eyeblink responses at a high level without their hippocampus.

The results from the studies by Disterhoft and Thompson and colleagues provide further evidence that the hippocampus and the learning-related modification of the postburst AHP play a critical role in learning and consolidation of associative tasks. Importantly, the learning and memory detriment observed with hippocampal lesions 1 day after the rabbits learned the task coincides with the time point when

maximal learning-related postburst AHP reduction is observed after training. The lack of the learning-related postburst AHP change when measured 2 weeks after learning and the lack of behavioral consequence of hippocampal removal a month after learning provide further evidence that the hippocampus is necessary to learn the associative task, but is not the site of memory storage. These findings in animals are consistent with neuropsychological observations of hippocampus lesioned amnesic subjects, with HM being the most famous case study, who cannot store new declarative memories but have access to information stored prior to their amnesic insult.

Does Size Matter?

Considerable evidence for the postburst AHP in hippocampal pyramidal neurons suggests that AHP size is an important determinant of hippocampal function. This can be illustrated by examining the relationship between the size of the postburst AHP and learning with normal aging.

The postburst AHP in CA1 hippocampal pyramidal neurons is significantly enlarged with normal aging, as first reported by Landfield and Pitler (1984) and later replicated by others including our laboratory. The channel that mediates the slow AHP has not been identified; so much attention has been focused on alterations of calcium with aging, because the postburst AHP is mainly a calcium-dependent potassium current. This attention also arises from the calcium hypothesis of aging. From many studies that examined the alteration of potential sources of calcium with aging, it has been shown that there is an enhancement of calcium influx into neurons via the L-type voltage-gated calcium channels and an increase in calcium-induced calcium release from the endoplasmic reticulum with normal aging. Both of

these phenomena contribute to the enlarged postburst AHP observed in hippocampal pyramidal neurons from aged animals.

Learning various associative tasks has been shown to be progressively more difficult with normal aging. Specifically, spatial learning in the water maze and temporal eyeblink conditioning have been used extensively to demonstrate that aging subjects, including humans, have impaired learning. For example, studies in our laboratory have demonstrated that nearly half of the aging rabbits and rats fail to learn the trace eyeblink conditioning task. For those subjects that do meet the learning criterion, it takes them many more trials to do so as compared to the young.

The surprising observation concerns the size of the postburst AHP in CA1 pyramidal neurons from aging animals that successfully learn the trace eyeblink conditioning task. The CA1 neurons from aging learners had significantly smaller postburst AHPs as compared to those from aging animals that failed to learn (**Figure 4**). The animals that failed to learn the task had enlarged postburst AHPs-like those in neurons from naïve or control aging subjects. The size of the

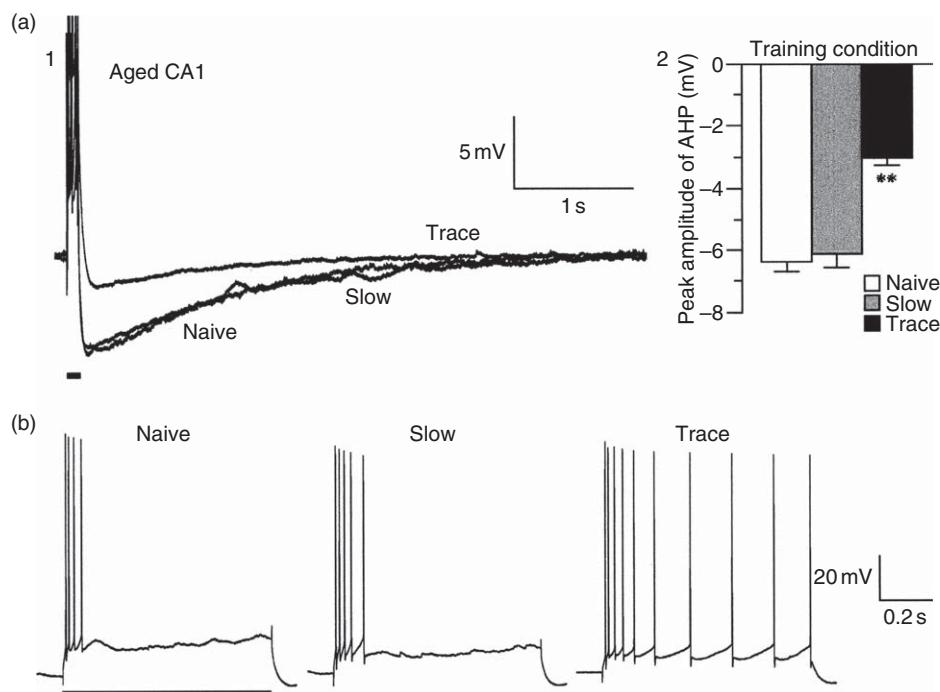

Figure 4 Acquisition of hippocampus-dependent trace EBC increased excitability of aging rabbit hippocampal CA1 pyramidal neurons. (a) Effects of trace conditioning on the size of the postburst AHP. (1) Overlay of voltage recordings of the postburst AHP in CA1 neurons from an aging naïve rabbit (naive), an aging rabbit that showed <15% conditioned responses after 15 sessions (slow), and an aging trace-conditioned rabbit (trace). Duration of current injection is indicated by the bar below the trace. (2) Mean effects of trace EBC on postburst AHP amplitude in aging rabbit CA1 neurons. Notice that after learning the AHP was significantly reduced compared with naïve and slow-learning aging controls. (b) Typical examples of accommodation responses in CA1 pyramidal cells from aging naïve, aging slow-learning and aging trace-conditioned rabbits. Reproduced with permission from Moyer JR, Jr., Power JM, Thompson LT, and Disterhoft JF (2000) Increased excitability of aged rabbit CA1 neurons after trace eyeblink conditioning. *Journal of Neuroscience* 20: 5476–5482, copyright the Society for Neuroscience.

postburst AHPs from the aging subjects that did learn were nearly identical to that found in CA1 neurons from young animals that learned the task. These findings strongly suggest that proper modulation of the intrinsic neuronal properties, mainly those that control the postburst AHP, may be a key to successfully learning associative tasks.

Cause or Result

Thus far, we have reviewed experimental results that illustrate a correlation between successful learning and alteration in the postburst AHP. However, it remains to be determined if the alteration in the postburst AHP leads to successful learning, or if learning leads to the change in the postburst AHP.

In an attempt to address this question, Tombaugh, Rowe, and Rose designed a set of experiments that took advantage of the heterogeneity of learning ability in aging rats. They separated the aged rats into two groups after spatial water maze training: those that learned the location of the hidden platform; and those that failed to learn. After the behavioral assay, they allowed the aged rats to remain in their home cages for at least 2 weeks to ensure that any learning-related alteration in the postburst AHP will return to a pretraining level, based on the timeline identified by Moyer, Thompson, and Disterhoft (**Figure 3**). They observed that the postburst slow AHPs of CA1 pyramidal neurons from aged animals that successfully learned the water maze task were nearly identical to that found in young rats, while the learning impaired rats had CA1 neurons with large AHPs (**Figure 5**). More importantly, they found an inverse relationship between the size of the slow AHP and performance on the water maze task: better performers had smaller postburst AHP.

Thus, a cascade of events that may underlie the age-related learning impairment of hippocampus-dependent tasks is as follows. Increase in the postburst AHP of hippocampal pyramidal neurons is part of the normal aging process. This increase in the AHP leads to significantly reduced excitability of the pyramidal neurons. The reduced excitability of the pyramidal neurons prevents them from participating in the neural network involved in learning. AHPs from those aging animals able to learn, even after more training trials, show reductions similar to those from young animals.

If the pyramidal neurons need to be in a young-like state to participate in the neural network for successful learning, are there interventions that allow this state be achieved?

We have addressed this issue with pharmacological experiments using potential therapeutic compounds developed to ameliorate the cognitive deficits observed

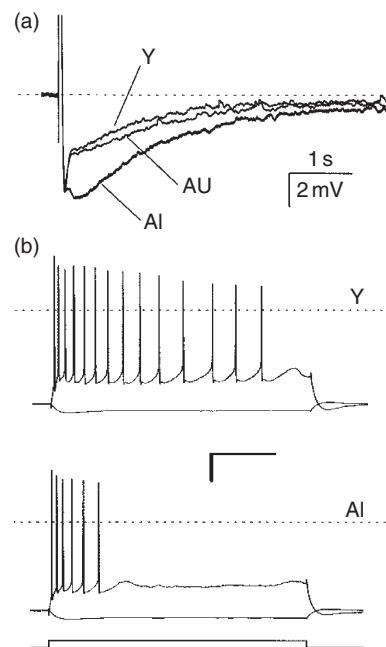

Figure 5 Aged rats that are impaired in learning the spatial water maze task have greater AHP and accommodation in CA1 neurons than do young rats and aged rats that learned the task successfully. (a) Representative waveforms taken from a Y, young rat; AU, an aged unimpaired rat; and AI, an aged impaired rat. In each case, the AHP was evoked with a 50 ms current pulse sufficient to trigger four APs. The broken line indicates holding potential. (b) Representative recordings from young and aged impaired CA1 neurons during tonic current injection. The broken lines represent 0 mV. Scale bar: 20 mV and 0.2 s. Reproduced with permission from Tombaugh GC, Rowe WB, and Rose GM (2005) The slow afterhyperpolarization in hippocampal CA1 neurons covaries with spatial learning ability in aged Fisher 344 rats. *Journal of Neuroscience* 25: 2609–2616, copyright the Society for Neuroscience.

in Alzheimer's disease. As an example, we have tested the impact of a cholinesterase inhibitor, metrifonate, on aging rabbits. Metrifonate significantly ameliorated the learning impairments on trace eyeblink conditioning in aging rabbits. Importantly, when we pretreated another group of aging rabbits with metrifonate and examined the biophysical properties of neurons from these subjects, we found that metrifonate treatment significantly increased the neuronal excitability of CA1 neurons from these aging naive animals. The basal activity level of the CA1 neurons from these metrifonate treated, naive aging rabbits was similar to that found in naive young rabbits. Thus, metrifonate treatment restored the aging CA1 neurons to a young-like state. We hypothesize that it is this rejuvenation of hippocampal pyramidal neurons with the various potential therapeutics (cholinesterase inhibitors, L-type calcium channel blocker, and muscarinic agonist) that we have tested which ameliorated the age-related learning impairments on the trace eyeblink conditioning task in aging rabbits.

Thus, our current working hypothesis is that the modulation of the postburst AHP (depending on the neural circuit, the AHP will need to be enhanced or reduced) precedes and is a prerequisite for learning to occur in young and aging subjects. In addition, further potential modification of the postburst AHP may also occur as learning occurs.

Potential Mechanism for Learning-Related AHP Reduction

The postburst AHP of hippocampal pyramidal neurons is reduced by nearly all known neuromodulators and neurotransmitters that, for the majority, act via second messengers involving activation of protein kinases. Notably, activation of the same kinases (e.g., protein kinase A, PKA) that reduce the AHP also activates various signaling cascades that lead to activation of cAMP response element binding (CREB) and gene transcription that lead to altered synaptic connectivity during learning. Barco and colleagues have demonstrated that activation of CREB also results in a reduction of the postburst AHP in CA1 pyramidal neurons.

Recently, we examined the potential role of PKA and another kinase, protein kinase C (PKC), in mediating the learning-related AHP reduction observed in CA1 pyramidal neurons after trace eyeblink conditioning in young adult rats. One day after the rats met our learning criterion; we prepared hippocampal slices and measured the postburst AHP in CA1 neurons. As previously reported and reviewed in this article, we observed a learning-related AHP reduction in CA1 neurons from rats that learned the trace eyeblink task. When the recorded neurons were challenged with a PKA activator, we found that the postburst AHP was only reduced in CA1 neurons from control animals, but not in neurons from animals that learned the task. Thus, learning-related AHP reduction occluded the PKA effect on the AHP in CA1 neurons from animals that learned. Contrary to the results observed with PKA, when the recorded neurons were challenged with a PKC activator, the postburst AHP in CA1 neurons from both trained and control animals was significantly reduced. While not ruling out the involvement of PKC during initial stages of learning, these data suggest that the activity of PKA maintains the learning-related AHP reduction observed in CA1 neurons at a time point after successful learning.

Conclusion

In this article, we have reviewed the learning-related alteration in the intrinsic membrane property of pyramidal neurons, the postburst AHP, mainly by using

examples from our studies examining hippocampal pyramidal neurons after trace eyeblink conditioning. We have also reviewed the fact that this learning-related AHP modulation is observed in other brain regions (such as the prefrontal and piriform cortices) after a subject has learned a task. But the story does not end here. Much more needs to be done to understand the biological mechanisms of learning. For example, using the new technologies of multiphoton imaging and gene silencing with siRNAs, questions regarding the role and sources of calcium that may also be altered by learning can be addressed. Furthermore, learning-induced intracellular signaling cascades involved in gene transcription and translation that lead to alterations in the intrinsic membrane properties of the neuron have yet to be fully explored. No matter where these studies lead, it is clear now that alteration in intrinsic neuron excitability is most certainly one cellular fingerprint of learning.

Neurotransmitters and Neuromodulators Regulating Sleep and Wakefulness

Glossary

Electroencephalogram (EEG) – The electrical activity of the cerebral cortex measured by placing electrodes on the skull. The different stages of sleep are defined, in part, by the characteristic pattern of cortical electrical activity.

Gamma-aminobutyric acid (GABA) – The major inhibitory neurotransmitter in the brain. The binding of GABA to its receptor on the surface of a neuron reduces the probability that the neuron will discharge.

Laterodorsal and pedunculopontine tegmental nuclei (LDT/PPT) – Brainstem nuclei located at the border between the midbrain and pons which contain cholinergic neurons that play an important role in the generation of REM sleep.

Non-rapid eye movement (NREM) – The majority of sleep time is spent in NREM sleep, which is divided into four stages. Stages 1 and 2 are lighter states of sleep, whereas stages 3 and 4 are deeper and more restorative. Stages 3 and 4 together are also called slow-wave sleep because the cortical electroencephalogram is characterized by slow-frequency (0.5–4 Hz) waves. Normal sleep is characterized by an orderly progression from stage 1 to 4 and then back up to stage 2, from which REM sleep is entered.

Pontine, an adjective of the term pons – It is normally used to describe neurons that are located in the part of the brainstem called the pons.

Pontine reticular formation (PRF) – A group of brainstem neurons that forms the pontine component of the ascending reticular activating system.

Rapid eye movement (REM) – A state of sleep characterized by skeletal muscle atonia punctuated by phasic bursts of muscle activity, an activated cortical electroencephalogram, rapid phasic eye movements, autonomic dysregulation, and vivid dreaming.

made since the discovery of rapid eye movement (REM) sleep in 1953 by Eugene Aserinsky and Nathaniel Kleitman. A mechanistic understanding is emerging from studies that have identified sleep-related brain regions, neurotransmitters, and receptors. This article highlights some of the key neurotransmitters involved in the process of sleep-cycle control, with an emphasis on sleep-state-dependent changes in neurotransmitter release. **Figure 1** shows the location of the neurons that synthesize these neurotransmitters, and schematizes some of their projection pathways relevant for sleep.

Acetylcholine

Acetylcholine (ACh) was the first neurotransmitter discovered and is an important mediator of wakefulness, REM sleep, motor control, and the autonomic system. The brain contains two major cholinergic projection systems, both of which play a role in generating states of sleep and wakefulness. ACh-containing neurons in the basal forebrain project to the neocortex and hippocampus, where acetylcholine functions to activate the electroencephalogram (EEG), mediate focused attention, and consolidate memories. Cholinergic neurons in the basal forebrain fire fastest during wakefulness and REM sleep, and discharge more slowly during non-REM (NREM) sleep. This discharge pattern of basal forebrain cholinergic neurons is consistent with the ACh release pattern measured in the cerebral cortex (**Table 1**). The degeneration of basal forebrain cholinergic neurons that occurs in Alzheimer's disease contributes to memory loss, daytime sleepiness, and disrupted nighttime sleep in these patients. A second group of ACh-containing neurons is found in the laterodorsal and pedunculopontine tegmental nuclei (LDT/PPT) of the brainstem. LDT/PPT neurons project up to the thalamus, hypothalamus, and basal forebrain, as well as down to numerous brainstem nuclei, including the pontine reticular formation. One group of cholinergic LDT/PPT neurons discharges selectively during REM sleep, consistent with the finding that ACh release in the pontine reticular formation is greatest during REM sleep (**Table 1**). A second group of LDT/PPT neurons fires fastest during wakefulness and REM sleep, consistent with the pattern of relatively high ACh release in the thalamus during wakefulness and REM sleep and relatively low thalamic ACh release during NREM sleep (**Table 1**).

Neurotransmitters and Neuromodulators Regulating Sleep

Sleep neurobiology aims to elucidate the mechanisms by which states of sleep and wakefulness are generated by the brain. Great progress in achieving this aim has been

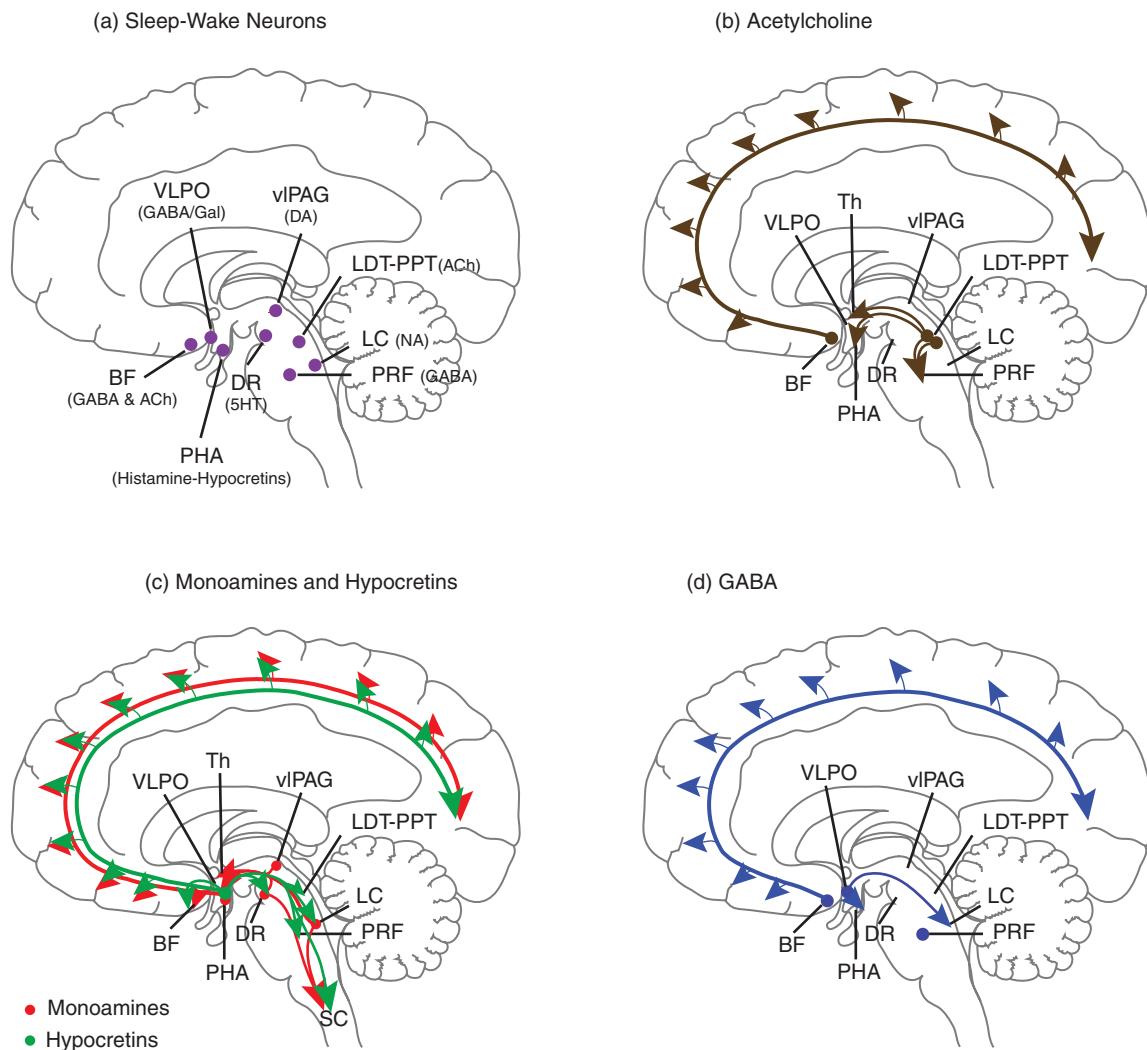

Figure 1 Localization of the major neuronal groups and pathways regulating sleep and wakefulness on a drawing of the human brain. (a) shows the major sleep–wake related neurons and their neurotransmitters. (b) indicates cholinergic projections from the basal forebrain and the brainstem. (c) schematizes the monoaminergic and hypocretinergic wakefulness-promoting neurons and their projections. (d) draws the projections from GABAergic neurons in the basal forebrain and preoptic area. ACh, acetylcholine; BF, basal forebrain; DR, dorsal raphe nucleus; DA, dopamine; Gal, galanin; LC, locus coeruleus; LDT-PPT, laterodorsal and pedunculopontine tegmental nucleus; NA, noradrenaline; PHA, posterior hypothalamic area; SC, spinal cord; 5-HT, serotonin; Th, thalamus; vIPAG, ventrolateral periaqueductal gray; VLPO, ventrolateral preoptic area. We thank Dr. Giancarlo Vanini for contributing this figure.

Although ACh release during sleep and wakefulness differs according to brain region, one consistent finding is that in all of the brain regions analyzed, ACh levels are greatest when the EEG is activated, such as during REM sleep and wakefulness. During NREM sleep when the EEG is deactivated, ACh release is at its lowest (**Table 1**).

ACh exerts its effects by activating two major classes of receptors called nicotinic and muscarinic. Nicotinic receptors are ligand-gated ion channels and exist as 17 subtypes. Activating nicotinic receptors in the thalamus contributes to cortical activation by suppressing slow-

wave activity characteristic of NREM sleep. There are five muscarinic receptor subtypes. M₁, M₃, and M₅ receptors are coupled to excitatory G proteins, whereas M₂ and M₄ receptors are coupled to inhibitory G proteins. Acetylcholinesterase hydrolyzes ACh to choline and acetic acid. Nerve gases inhibit acetylcholinesterase to increase ACh levels, which leads to muscle paralysis and death.

Additional insights concerning the endogenous neurotransmitter regulating sleep have come from administering drugs into specific brain regions of experimental animals while recording sleep and wakefulness.

Delivering drugs into the brain is possible, in part, because the brain has no pain receptors. Thus, sleep can be studied humanely in animals following drug administration into specific brain regions. These types of studies provide insights into the sleep-related functions of specific brain regions and receptor subtypes localized within those brain regions. For example, in the pontine reticular formation, microinjection of drugs that mimic the effects of ACh causes an increase in REM sleep. These data fit well with the observation that ACh release in the pontine reticular formation is increased during REM sleep (Table 1). In the pontine reticular formation, drugs that are effective for increasing REM sleep include those that inhibit the breakdown of endogenous ACh and drugs that activate M2 muscarinic cholinergic receptors. Studies in humans have shown that administering low doses of acetylcholinesterase inhibitors also causes an increase in REM sleep. Taken together, these data support the interpretation that the cholinergic transmission in the pontine reticular formation contributes to the generation of REM sleep.

Serotonin

Serotonin is a monoamine neurotransmitter that contributes to the regulation of appetite, emotion, vascular smooth muscle tone, and wakefulness. Serotonin is

synthesized by the raphé nuclei of the brainstem and these nuclei project widely to the rest of the brain. The dorsal raphé nucleus has been most thoroughly studied with respect to sleep and wakefulness. The firing rate of serotonergic dorsal raphé neurons is fastest during wakefulness, slower during NREM sleep, and slowest during REM sleep, suggesting that serotonin promotes wakefulness and is inhibitory to REM sleep. Fourteen serotonin receptor subtypes have been identified, and are expressed throughout the brain and periphery. Clinically, serotonin receptor agonists are used for treating migraine, headache, and preventing nausea. Serotonin reuptake inhibitors, which block uptake of serotonin from the synapse to increase serotonin levels, are used to treat depression. A consistent finding across most brain regions studied to date is that serotonin levels are highest during wakefulness, lower during NREM sleep, and lowest during REM sleep (Table 2). These measures of serotonin release support the interpretation that high serotonin levels are important for wakefulness, and that a decrease in serotonin release promotes sleep.

Norepinephrine

Norepinephrine promotes wakefulness and is an important mediator of autonomic function and muscle tone.

PRF, pontine reticular formation; PPT, pedunculopontine tegmental nucleus.

Neurons that synthesize norepinephrine are concentrated in the brainstem nucleus called the locus coeruleus. These neurons project rostrally to the forebrain and cerebral cortex, as well as caudally to the brainstem and spinal cord. Similar to the serotonergic neurons described above, noradrenergic neurons fire at their fastest rates during wakefulness, slow their discharge during NREM sleep, and cease firing during REM sleep. This ‘wake-on/REM-off’ discharge pattern is unique to monoaminergic neurons and is consistent with the wakefulness-promoting role of norepinephrine. As a result of the unique state-dependent discharge pattern, norepinephrine release is higher during wakefulness than during sleep in all brain regions studied (**Table 3**).

Clinically, norepinephrine has many uses including the treatment of shock because it acts as a vasoconstrictor. Norepinephrine binds to and activates α and β receptors. There are two α noradrenergic receptors, $\alpha 1$ and $\alpha 2$. The $\alpha 2$ receptors function as autoreceptors to regulate the release of norepinephrine. The $\alpha 2$ receptor agonist dexmedetomidine is used frequently in the intensive care unit setting to provide sedation. Xylazine is an $\alpha 2$ receptor agonist used clinically in veterinary practice for sedation. Preclinical studies have shown that dexmedetomidine inhibits the firing of wakefulness-promoting locus coeruleus neurons.

Histamine

Histamine is a monoamine synthesized in the tubero-mammillary nucleus of the posterior hypothalamus. These neurons send projections throughout the brain, including the sleep-promoting anterior hypothalamus, the arousal-promoting LDT/PPT, and the neocortex. Similar to the other monoamines serotonin and norepinephrine, histaminergic neurons fire with a wake-on/REM-off discharge pattern and function to promote

wakefulness. Histamine also modulates the immune system and gastric acid secretion. Histamine is synthesized by the enzyme histidine decarboxylase. Knock-out mice lacking the gene responsible for histamine synthesis show slow frequencies in the EEG during wakefulness, suggesting that they are less alert than control mice. In addition, mice that cannot synthesize histamine do not show the normal increased wakefulness in response to a novel environment.

There are three known subtypes of histamine receptors, H1–H3, which are coupled to G proteins. H1 and H2 receptor antagonists are used clinically to block allergic responses and gastric acid secretions, respectively. First-generation antihistamines cause drowsiness, and H1-receptor knock-out mice show a decreased waking response to the arousal-promoting peptide hypocretin (orexin). Less is known about H3-receptor subtype function except that it is an autoreceptor and modulates the release of histamine. Histamine release has only been studied in a few brain regions during sleep and is highest during wakefulness, similar to serotonin and norepinephrine (**Table 4**).

Inhibiting tubero-mammillary neurons with the GABA_A receptor agonist muscimol causes a decrease in wakefulness and an increase in sleep, consistent with a wakefulness-promoting role for histamine and a sleep-promoting role for GABA. Microinjection of an H1-receptor agonist into the LDT also causes an increase in wakefulness, as does administering histamine into the basal forebrain. Consistent with these findings are data showing that increasing histamine levels in the tubero-mammillary nucleus by blocking the enzymatic degradation of histamine also increases wakefulness and decreases both NREM sleep and REM sleep. In general, the wakefulness-promoting effects of histamine are mediated by the H1 receptor, whereas increases in sleep are produced by drugs that activate H2 or H3 receptors.

Dopamine

Dopamine is the precursor of norepinephrine and mediates mood, motor activity, addiction, and the secretion of prolactin. The D1 family (D1, D5) of dopamine receptors is coupled to stimulatory G proteins to activate adenylcyclase. The D2 family (D2, D3, D4) of dopamine receptors is coupled to inhibitory G proteins that inhibit adenylcyclase. Similar to norepinephrine, dopamine is used clinically to treat shock. Dopamine neurons of the substantia nigra selectively degenerate in Parkinson's disease, which is characterized by excessive daytime sleepiness and disrupted nighttime sleep. Dopamine-receptor agonists are widely used to treat Parkinson's disease. The firing rates of dopaminergic neurons in the ventral tegmental area and substantia pars compacta do not vary across sleep–wake states. However, dopamine levels do vary across sleep–wake states in the frontal cortex, nucleus accumbens, and spinal cord (Table 5). The locus coeruleus does not appear to be a target region for dopaminergic regulation of arousal state as dopamine levels do not show state-specific changes.

Hypocretins

Hypocretins (also known as orexins) are neuropeptides discovered by separate groups in 1998 and play diverse roles in physiology by regulating arousal, feeding, nociception, energy homeostasis, neuroendocrine, and cardiovascular functions. The two subtypes of hypocretins, hypocretin-1 (orexin A) and hypocretin-2 (orexin B) are synthesized in the lateral, posterior, and perifornical hypothalamus and project widely throughout the brain. There are two receptor subtypes, hypocretin receptor-1 and hypocretin receptor-2. Hypocretin receptor-2 binds both peptides equally, whereas hypocretin receptor-1 is selective for hypocretin-1. Hypocretin deficiency underlies the sleep disorder narcolepsy, which is characterized

by excessive daytime sleepiness and disrupted nighttime sleep, and can be accompanied by cataplexy, or the sudden loss of muscle tone.

One normal, physiological role of the hypocretins is the promotion of wakefulness. Hypocretin levels are greater in the hypothalamus and the basal forebrain during wakefulness and REM sleep (when the EEG is activated) when compared to NREM sleep (Table 6). These data fit nicely with the increase in firing rate of basal forebrain neurons observed during wakefulness and the increase in activity seen from PET imaging in the basal forebrain. Hypocretinergic neurons in the lateral hypothalamic area also increase firing rate during wakefulness. Interestingly, hypocretin levels in locus coeruleus (wakefulness-promoting region) do not vary across sleep–wake states even though this is where the greatest number of hypocretin-1 receptors are located. Hypocretin levels are greater during wakefulness than during sleep in the lateral hypothalamus and medial thalamus (Table 6).

Microdialysis studies suggest a causal relationship between neuromodulator levels and states of wakefulness, NREM sleep, and REM sleep. Pharmacological approaches further describe the sleep-related roles of these sleep modulators in different brain regions. Understanding the interactions between sleep modulatory neurochemical systems in different brain regions as well as deciphering the effects of specific neurotransmitter receptor subtype on sleep–wake states will pave the way for better pharmacological therapeutics for disorders of sleep and mental health.

GABA

GABA is the major inhibitory neurotransmitter in the brain and is synthesized from glutamate. Unlike the neurotransmitters discussed above, GABA is released from glial cells as well as from neurons. These glial cells, or

astrocytes, are in close proximity to synapses and modulate synaptic transmission. Furthermore, GABA transporters reside on both neurons and astrocytes; so GABA is taken up into astrocytes.

GABA binds to three types of receptors, GABA_A, GABA_B, and GABA_C. GABA_A and GABA_C receptors are ligand-gated ion channels and GABA_B is a G protein-coupled receptor. The GABA_A receptor has binding sites for a variety of molecules that produce sedation, sleep, or general anesthesia. Benzodiazepines also act via the GABA_A receptor to reduce anxiety. Almost all brain regions contain GABAergic interneurons. The basal forebrain also contains GABAergic projection neurons, which provide input to the cerebral cortex. GABA levels in the cortex during sleep and wakefulness have not been measured. GABAergic neurons in the anterior hypothalamus send projections to the wakefulness-promoting monoaminergic neurons in the posterior hypothalamus, locus coeruleus, and dorsal raphe, as well as the cholinergic LDT/PPT neurons. GABA levels in the dorsal raphe, locus coeruleus, and posterior hypothalamus are higher during sleep than during wakefulness (Table 7). GABA levels in the LDT/PPT have not been measured during sleep and wakefulness, but GABAergic interneurons in the LDT/PPT are active during REM sleep. The GABA_A-receptor agonist muscimol causes sleep when microinjected directly into the posterior hypothalamus, but causes wakefulness when delivered directly into the anterior hypothalamus. These findings are consistent with the interpretation that GABA in these brain areas contributes to sleep generation by inhibiting wakefulness-promoting neurons.

GABA levels in the pontine reticular formation are greater during wakefulness than during NREM sleep, REM sleep, or general anesthesia. These data indicate that GABA in the pontine reticular formation contributes to the generation of wakefulness. A wakefulness-promoting role for GABA is also supported by data showing that wakefulness is either increased or decreased by drugs that either increase or decrease, respectively, pontine reticular formation GABAergic transmission. GABA and ACh interact in the pontine reticular formation to regulate REM sleep. Activation of GABA_A receptors in the pontine reticular formation decreases REM sleep, in part, by decreasing ACh release. Similarly, blocking GABA_A

receptors in the pontine reticular formation increases ACh release and increases REM sleep. In summary, GABAergic inhibition either inhibits or promotes wakefulness, depending upon the brain region. In brain regions that promote wakefulness, GABAergic inhibition functions to increase sleep. In brain regions that promote sleep, GABAergic inhibition contributes to an increase in wakefulness.

Glutamate

Glutamate is the major excitatory neurotransmitter in the brain and is the precursor to GABA. Similar to GABA, glutamate is synthesized and released from neurons and glial cells. Glutamate exhibits its actions by activating ionotropic NMDA, AMPA, or kainate receptors and metabotropic glutamatergic receptors. Little is known about the role of glutamate in sleep-cycle control. Glutamate is excitatory, and in most brain areas, glutamate levels are highest during wakefulness or REM sleep, both of which are activated brain states (Table 8).

The results from studies that have microinjected glutamatergic drugs into the brain and quantified the effects on sleep and wakefulness have shown that glutamate promotes either wakefulness or REM sleep, depending on the brain region where glutamate is administered. Glutamate at lower doses, delivered directly into the PPT, causes REM sleep and at higher doses, causes wakefulness. The increase in REM sleep is mediated by kainate receptors and the increase in wakefulness results from activating NMDA receptors. Furthermore, activating the metabotropic glutamate subtype II receptor decreases wakefulness and increases NREM sleep. These data demonstrate that endogenous glutamate is an important regulator of arousal and suggest that in the PPT, activation of kainate and NMDA receptors is important for inducing sleep whereas activating metabotropic subtype II receptors is important for inducing wakefulness. Administration of glutamate to the dorsal raphe or basal forebrain increases wakefulness and decreases sleep.

Ketamine is an NMDA-receptor agonist and is used clinically to produce a state of dissociative anesthesia. The term dissociative arose from the finding that when ketamine is used for surgical procedures, sensory

information reaches the cortex but is not accurately perceived as painful, thus causing a dissociation between objective and subjective experience. When given intravenously or directly into the pontine reticular formation, ketamine suppresses REM sleep and decreases the release of the REM sleep-promoting transmitter ACh.

Adenosine

Adenosine is a purine nucleoside that is derived from the breakdown of ATP, and adenosine has many physiological functions. The function of adenosine most relevant for this volume is as an endogenous promoter of sleep. There are four adenosine receptor subtypes, A1, A2a, A2b, and A3, which are G protein-coupled receptors. A1 and A3 receptors inhibit adenylyl cyclase activity whereas A2a and A2b receptors activate adenylyl cyclase. One of the most widely used legal drugs in the world is caffeine, which promotes wakefulness and increases alertness by blocking adenosine receptors. Adenosine levels in the brain increase during wakefulness and decrease during sleep (**Table 9**).

Adenosine levels in different brain regions have been quantified during sleep deprivation and subsequent recovery sleep. These studies show that changes in adenosine levels during sleep deprivation and recovery sleep were different depending on the brain region analyzed. For example, adenosine levels in the cortex and basal forebrain accumulate during prolonged wakefulness and fall during recovery sleep. In contrast, adenosine levels do

not increase in the dorsal raphe or pedunculopontine tegmental nucleus during sleep deprivation. Furthermore, adenosine acting on A1 receptors inhibits wakefulness-promoting neurons in the basal forebrain. Adenosine also inhibits wakefulness-promoting histaminergic and hypocretinergic neurons in the posterior and lateral hypothalamus, and increases the activity of anterior hypothalamic GABAergic neurons that promote sleep.

Pharmacological approaches have provided novel evidence that adenosine is sleep promoting. Adenosine A1-receptor antagonists, delivered directly into the pontine reticular formation or the prefrontal cortex, shorten recovery time from general anesthesia, whereas A1 receptor agonists increase anesthesia-recovery time. Administering adenosine into the lateral dorsal tegmental nucleus decreases wakefulness and increases sleep. Adenosine A1-receptor activation in the pontine reticular formation increases REM sleep and decreases wakefulness. Microinjection of A2a agonist into the pontine reticular formation increases ACh release and increases REM sleep. Taken together, current data demonstrate that although adenosine levels are highest during wakefulness (**Table 9**), adenosine is a sleep-promoting agent.

Concluding Remarks

Sleep is important for many physiological functions, including the immune system, cognition, learning and

memory, and mental health. As of 2006, over 70 million Americans suffer from sleep-related disorders, costing an estimated 15.9 billion dollars. The elderly population is increasing, and the incidence of sleep disorders increases with aging. Understanding how sleep is regulated by neurotransmitters and neuromodulators, and discerning how these transmitter and modulator system interact will improve the medications prescribed for sleep disorders. In 2008, a study demonstrated that the inverse histamine-3 receptor agonist tiptolosant reduces excessive daytime sleepiness in narcoleptic patients and in hypocretin-deficient mice. Modafinil is another drug used to reduce excessive daytime sleepiness, and although the mechanism of action is not well understood, modafinil acts through multiple neurotransmitter systems. Olanzapine is an atypical antipsychotic that improves sleep in schizophrenics and acts at several neurotransmitter receptors. Future studies will need to focus more on elucidating interactions between multiple neurotransmitter systems and on interacting sleep-related brain regions.

Plasticity in the Primary Auditory Cortex: Substrate of Specific Long-Term Memory Traces

N M Weinberger, University of California, Irvine, CA, USA

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Best frequency (BF) – The frequency that produces the best cellular response to a frequency at a given sound-level intensity.

Conditioned response (CR) – A behavioral response that is elicited by a conditioned stimulus as a result of classical or instrumental conditioning.

Conditioned stimulus (CS) – An initially neutral stimulus that elicits a behavioral response after it has been associated with an unconditioned stimulus.

Frequency receptive field (frequency RF) – The portion of the acoustic spectrum to which a cell in the auditory system is sensitive. Frequency RFs are often called ‘tuning curves.’

Local field potentials (LFPs) – Responses of sensory (auditory) cortex to sensory (acoustic) stimuli, which are comprised of evoked voltage changes in the low-frequency range (1–300 Hz). They generally index excitatory postsynaptic potentials recorded in extracellular space with a large electrode on the surface or in the depths of the cortex.

Tonotopic map – The progressive distribution of best frequencies across primary auditory cortex. The posterior-to-anterior axis has a systematic range of BFs, from lower to higher, respectively.

Unconditioned response (UR) – An innate behavioral response that is elicited by a stimulus in the absence of conditioning.

Unconditioned stimulus (US) – A stimulus that elicits a UR.

represented and stored has languished. The two domains of neglect are related, because sensory systems, particularly sensory cortex, appear to be sites of the specific storage of experiences. They are not the only sites of storage, but they provide a particularly advantageous means of locating storage sites and they have now been successfully exploited. The primary auditory cortex (A1) is perhaps that sensory region for which research has yielded the greatest dividends.

This article concerning learning-based plasticity in A1. It will summarize the evidence for specific long-term memory traces. But in so doing, it will more broadly examine the usually implicit assumptions about brain-behavior organization, concluding that the schema, which has served behavioral neuroscience since its inception, is no longer valid.

The Dominant Model of Brain-Behavior Relationships

Scientific study of brain-behavior relationships may be traced back to a sensory-motor conception of the nervous system in the early nineteenth century. Bell and Magendie separately discovered (*c.* 1812–30) that the dorsal roots of the spinal cord are sensory, while the ventral roots are motor. These seminal findings provided the first brain-behavior, structural-functional organizational principle. Much of the research program for the rest of the century concerned the extent to which the entire neuraxis was organized on sensory-motor principles. The last 30 years of the nineteenth century witnessed the discovery of the motor cortex, and the approximate delineation of sensory cortices based on modality-specific sensory deficits following cortical ablations.

Still, sensory and motor areas did not comprise the entire neocortex. Could an overarching principle of cortical organization be discovered? In 1901, Fleischsig reported that sensory and motor cortices exhibited myelination at birth, while other areas could require as long as one postnatal month to myelinate. Further, his observations of fibers in the internal capsule led him to the erroneous conclusion that only the sensory and motor cortices received subcortical projections; the association areas were thought to receive inputs only from other cortical regions. Thus, Fleischsig provided an anatomical

Introduction

The search for the neural substrates of learning and memory has been extremely biased in at least two dimensions: brain structures under investigation and aspects of memory under consideration. With regard to functional anatomy, most attention has been focused on structures such as the hippocampus, amygdala, striatum, cerebellum, frontal, and the so-called association fields of the cerebral cortex. In contrast, the sensory systems have been relatively ignored. Concerning memory itself, interest has been focused on the processes that enable memory storage while inquiry into how the contents of memory are

basis for the distinction between lower (i.e., sensory-motor) and higher psychological functions.

It remained only to specify in greater detail the nature of these lower and higher functions. This was supplied in the anatomical studies of AW Campbell. Purely on the basis of cytoarchitectonics (i.e., study of the fine structure of the cortex), Campbell divided sensory cortical fields into two types, such as primary visual cortex (V1) ‘visual sensory’, and nearby regions (e.g., areas 17 and 18) ‘visual psychic’. Similarly, the region now known as A1 was termed ‘auditory sensory’ while adjacent areas, in modern parlance, auditory belt areas, were ‘auditory psychic.’ In so doing, Campbell executed an almost metaphysical leap that has plagued brain-behavior research to the present day, because he cleaved sensory processes from cognition. Subsequent neurophysiological studies of sensory cortices operated within this conceptual constraint, so that the analysis of sounds, sights, and touches was assumed to occur in the primary sensory fields, while interpretation of the behavioral meaning or comprehension of the external world was assigned to nonprimary sensory areas, that is, to the psychic regions. A major implication of this schema was removing learning and memory from primary sensory cortices.

Once learning, memory, and other cognitive processes were removed from the primary sensory regions, without any experimental support, the dominant brain-behavior paradigm was essentially in place. So imbued into neuroscience as to have gone largely unquestioned, it holds a three-stage processing chain: sensory–association–motor. In short, primary sensory cortex analyzes stimuli, association and related cortex comprehend the stimuli, in large part based on past experiences, and send the results to the motor cortex which is responsible for actual behavior.

Note that this S–A–R theory comprises a reflex model of brain-behavior substrates. In reality, this is an extended model of the functional operation of the spinal cord. As this model still dominates neuroscientific thinking, it would seem that we have not achieved fundamental conceptual advances. This would not be a problem if the S–A–R model was adequate. That it cannot account for the role of A1 in learning and memory will soon become apparent.

In closing this section, we would do well to not look at Pavlovian conditioning as a willing accomplice of this reflex-based model. Pavlov himself emphasized the association between two stimuli, for example, the conditioned and unconditioned stimuli (CS and US, respectively). Such CS–US learning (i.e., stimulus–stimulus, S–S) contrasts with stimulus–response learning (S–R) that has come to dominate much thinking. S–R conditioning is, of course S–A–R in reality, for no one holds that Pavlovian conditioning consists of a monosynaptic connection between the CS and the conditioned response (CR). While both S–S and S–R learning certainly occur,

the former appears to develop within a few trials, before the appearance of specific motor CRs. Indeed, conditioning seems to be at least a two-stage process, in which CS–US (S–S) associations first enable animals to predict the future, followed by the formation of CS–CR (S–R) links that enable an animal to take overt behavioral action based on this knowledge. Certainly, S–R conditioning is of great importance and its circuitry has been well delineated, to an extent unmatched for other forms of learning. However, S–S conditioning remains of central importance. Contemporary understanding of Pavlovian conditioning views it as a general process for determining the ‘causal fabric’ of the environment, a general-purpose mechanism for making the best possible predictions in the service of adaptive behavior. Only when Pavlovian conditioning is narrowly construed as S–R, and labeled ‘procedural learning’ in contradistinction to ‘declarative learning’, can one conclude that it supports the S–A–R model. Unfortunately, such a construal is all too popular and grows more so as workers minimally versed in these matters attack the neurobiology of learning and memory.

Learning, Memory, Plasticity, and the Auditory Cortex: The Foundational Period

Introduction

Vast majority of investigations into the neurophysiology of learning and memory and A1 have studied associative learning, in the form of either Pavlovian (classical conditioning) or instrumental conditioning. This is not a constraint because the formation of associations is so fundamental. Associative processes can account for a surprisingly wide range of learning, memory, and other cognitive processes, far transcending traditional narrow construes of conditioning. Studies during the foundational period, roughly 1956–85, focused on the question of whether associative learning involved (e.g., was accompanied by) associative plasticity in A1.

Conditioning

Galambos and colleagues published the first Western study on Pavlovian conditioning and plasticity in A1. Cats received an auditory (click) CS paired with an immediately following puff of air to the face (US), resulting in significantly larger local field potentials (LFPs) to the CS click. The authors validated learning by noting the development of behavioral CRs. Furthermore, they also controlled for CS constancy at the ear by obtaining the same findings with subjects under neuromuscular blockade, thus preventing head and pinna movements and possible contractions of the middle ear muscles that can alter effective sound levels at the tympanic membrane. Interestingly, the authors failed to include a

nonassociative control, such as a group that received the CS and US unpaired. However, subsequent investigations did include proper controls, confirming the associative nature of increased response magnitude of LFPs in A1. LFP research was extended to different conditioning tasks and Pavlovian processes, with essentially the same findings of enhanced responses to sounds that became behaviorally important. Similar results were obtained for instrumental avoidance learning.

In addition to the use of LFPs, workers began recording cellular discharges in A1. Most studies recorded from clusters of cells (multiple-unit activity). The results generally were the same, that is, increased discharges to an acoustic CS as animals formed CRs. This increase in response was fairly consistent, both in simple (one-tone) conditioning and in two-tone discrimination training. Reversal was also obtained when the CS⁺ and CS⁻ acoustic stimuli were interchanged after initial learning. Moreover, acoustic CS⁺ stimuli acquired the ability to elicit responses in the sensory cortex of the shock US, that is, primary somatosensory cortex.

Such cluster recordings have the advantage over single-unit recordings of yielding good data over many hours or days. They have the disadvantage of being unable to determine if single cells develop different directions of plasticity, that is, either increased or decreased responses. In other words, if associative processes produce both increased and decreased responses to the CS, but increased responses dominate, then the decreased responses would not be detected.

Study of single units in auditory cortex during learning also found plasticity. However, as suspected, despite the detection of many cells that developed increased responses to the CS, a substantial number developed decreased responses, and yet others exhibited no change. Similar heterogeneity of unit discharge plasticity was also found in secondary auditory cortex (A2). Such divergent results were not attributable to inadvertent changes in effective acoustic stimulus level in the auditory periphery, undetected movements, muscle contractions, or feedback from muscle spindles, because the same results were obtained when animals were trained while under neuromuscular blockade.

Although single-unit plasticity was shown to be associative, the findings of opposite sign made little functional sense. Thus, while recording in A1 during training trials had provided fundamental information, this approach appeared to be yielding diminishing returns after almost 30 years of research. Nonetheless, research during the foundational period had sufficiently answered the original question in the affirmative: "Yes, associative learning does involve associative plasticity in the primary auditory cortex." Thus, a major crack in the foundation of the S-A-R model was found. Primary sensory (auditory) cortex does not only analyze stimuli but also changes its response to

the same physical stimuli when they acquire behavioral importance. That is, the responses of the same cells in A1 are governed by at least two factors: physical acoustic parameters of sounds and their acquired meaning. Campbell would not have approved.

Contemporary Approaches: A Synthesis of Two Disciplines

Introduction: Toward Specificity of Plasticity, Memory Content and Memory Codes

The contemporary era may be considered to have been initiated in the 1980s when a new question was posed. Instead of asking whether A1 is involved in learning and memory, focus shifted to the functional significance of associative plasticity. For example, do associative processes change the large-scale functional organization of the auditory cortex? If so, then sensory analysis and learning-induced plasticity do not merely coexist, but rather sensory analysis is shaped by learning processes. Moreover, if learning shapes sensory representations of experience in primary sensory cortex, then it may also store them in primary sensory cortex.

In addressing this previously ignored issue, inquiry transcended associativity to reach the domain of specificity of neuronal plasticity, which is necessary to understand how the brain represents and stores the details of experience, that is, the actual contents of memories. While much research has been devoted to the processes that enable memory and to demonstrations of plasticity in learning, there had been virtually no focus on the information itself that is stored or on the memory codes that transform neural activity into an accurate neural representation of a memory.

For example, learning and memory could have caused increased responses to CS frequencies in either of two ways: first, they could have increased responses not only to the CS but also to most other frequencies; or second, they could have specifically increased responses to CS frequencies but had no effect or even decreased responses to other frequencies. In the latter case, learning could have shifted the tuning of cells to the CS frequency, hence revealing that associative processes actually shape sensory analysis within primary sensory cortex. These alternatives cannot be resolved during training trials because the other test tones either would have to be followed, or not followed, by the US. Both situations would constitute new learning tasks so that one could never find out what happens in simple associative learning. The solution was to determine frequency tuning before and after conditioning. To accomplish this goal, it was necessary to combine two fields that had developed along parallel, seldom-intersecting trajectories, auditory neurophysiology and the neurobiology of learning and memory ([Figure 1](#)).

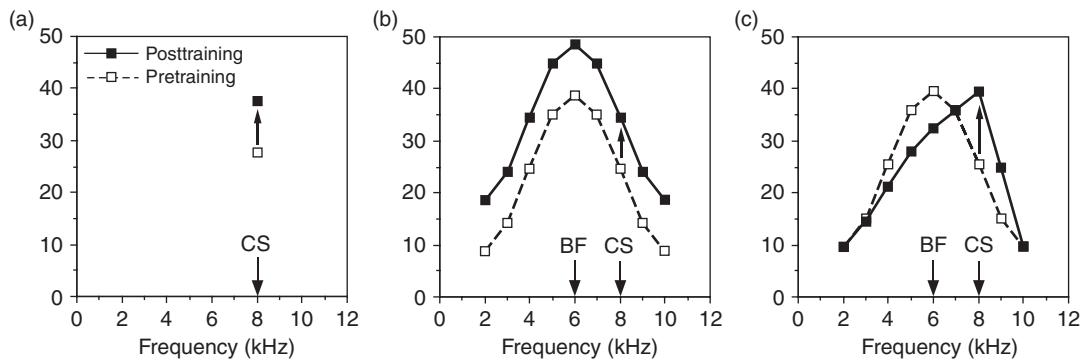

Figure 1 Receptive field analysis reveals whether learning-induced plasticity is general to the dimension of a CS or specific to the value of the CS. (a) During training trials, one can determine whether or not responses to the CS changed; in this case, they increased. However, both general and specific plasticity could produce this result. (b) A general change revealed by receptive field analysis before and after conditioning. (c) A CS-specific instance of associative representational plasticity, in which responses to many non-CS frequencies are reduced, producing a shift in tuning to the frequency of the CS.

Conditioning

Gonzalez-Lima and Scheich used a variant of the new approach. They trained gerbils (tone and aversive stimulation of the mesencephalic reticular formation) and later determined the metabolic response (uptake of 2-deoxyglucose, 2-DG) of the auditory cortex to the CS frequency. Paired animals developed both the behavioral index of learning, that is, conditioned bradycardia, and an increase in the area of A1 with metabolic response to the CS frequency. The absence of similar effects in control groups (CS-US unpaired, CS alone, and US alone) showed that the CS-specific plasticity was associative. These findings indicate that associative processes can enlarge CS-response areas and strongly imply that the underlying neurons have shifted their tuning toward or to the CS frequency within the tonotopic map.

At about the same time, direct evidence of receptive field plasticity was found by obtaining RFs before and after learning. Cats received a single session of tone-shock pairing and behavioral learning was validated by the formation of the pupillary dilation CR. The tuning of single units in two nonprimary auditory fields, A2, and ventral ectosylvian (VE) cortices developed CS-specific plasticity in the paired group but not a control group. Extinction (tone alone) produced a reversal of the RF plasticity, indicating that A1 plasticity reflects the current state of behavioral salience of sound.

Studies then focused on A1 of the guinea pig, with behavioral validation of associative learning, for example, conditioned bradycardia. Following determination of frequency receptive fields, the frequency to be used as the CS was then selected to not be the best frequency (peak of the tuning curve), in order to determine if conditioning caused tuning shifts within the tonotopic map. Animals then received a single session of tone paired with shock. A comparison of posttraining with pretraining RFs revealed increased responses to the CS frequency accompanied by

decreased responses to the pretraining best frequency and many other frequencies. These opposing changes were often sufficiently large to produce frank shifts of tuning toward, and even to, the frequency of the CS, which could become the new best frequency (**Figure 2(a)**). RF plasticity was found to be associative, as it required stimulus pairing; sensitization training produces only a general increase in response to all frequencies across the RF.

CS-specific shaping of frequency tuning also can develop when receptive fields are complex and even nonexistent (i.e., below threshold). **Figure 2(b)** shows an example of a pretraining double-peaked frequency RF. The CS frequency was selected to be in the valley between the peaks. For posttraining, the maximum change was an increase in response at the CS frequency. **Figure 2(c)** illustrates a case in which there was no response to any frequency before conditioning. Nonetheless, postconditioning observations revealed a clear excitatory response to the previously ineffective CS frequency, alone.

Several other attributes of RF plasticity make it an attractive candidate for a process that operates in normal concert with sensory coding processes to subserve the storage of behaviorally relevant auditory information. First, RF plasticity is highly specific to the CS frequency; responses to frequencies a small fraction of an octave away are attenuated. Second, it exhibits generality across different types of training, for example, instrumental avoidance conditioning, two-tone classical discrimination training (i.e., increased responses to the CS⁺ frequency but decreased responses to the CS⁻, BF, and other frequencies), and discriminative instrumental avoidance conditioning. Third, RF plasticity develops very rapidly, after only five training trials, as rapidly as the first behavioral (e.g., cardiac) signs of association. Fourth, RF plasticity exhibits consolidation, that is, continues to develop increased responses to the frequency of the CS

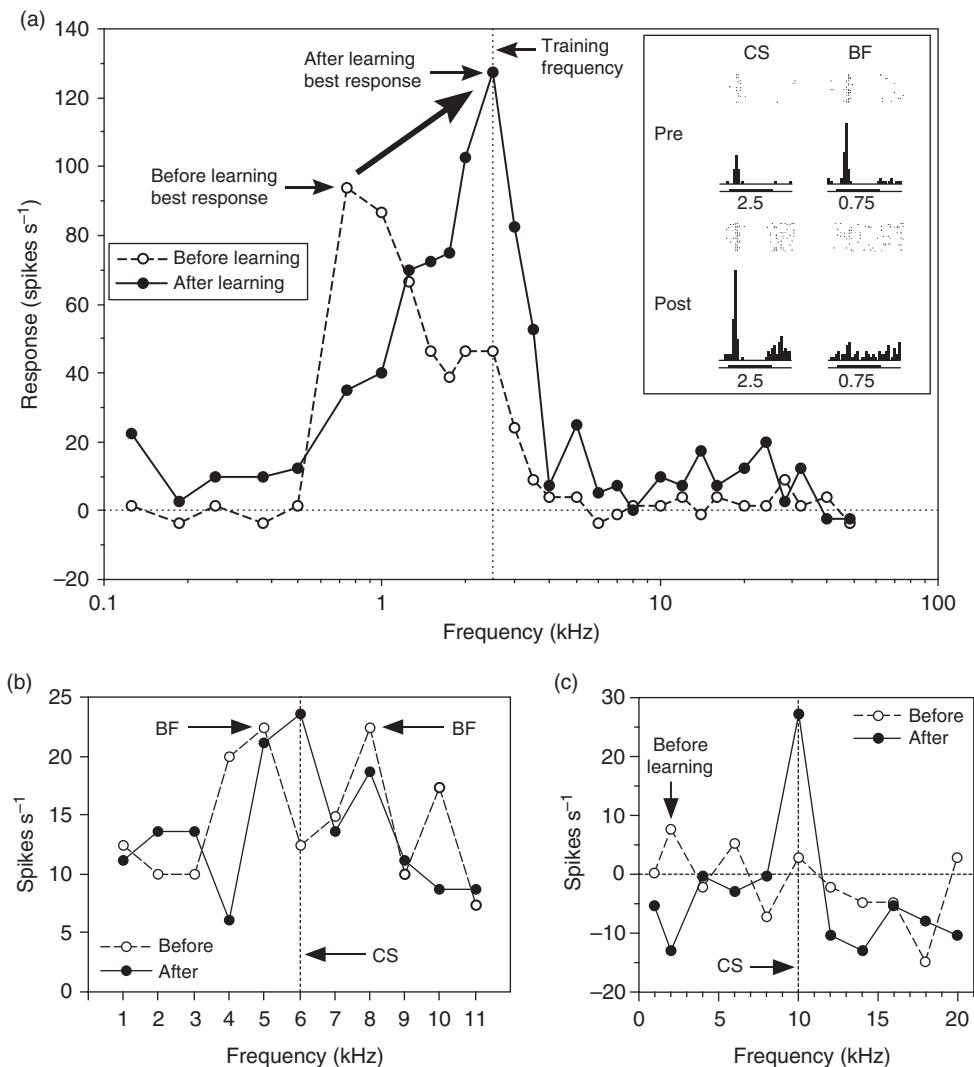

Figure 2 Classical conditioning produces CS-specific facilitation and tuning shifts. (a) An example of a complete shift of frequency tuning of a single cell in A1 of the guinea pig, from a pretraining best frequency (BF) of 0.75 kHz to the CS frequency of 2.5 kHz after 30 trials of conditioning. Inset shows pre- and posttraining poststimulus time histograms (PSTHs) for the pretraining BF and the CS frequencies. (b) Double-peaked tuning, with pretraining BFs at 5.0 and 8.0 kHz. The CS was selected to be 6.0 kHz, a low point. After conditioning (30 trials), responses to the CS frequency increased to become the peak of tuning. (c) A cell that exhibited minimal or no response to tones before tuning developed tuning specifically to the CS frequency after conditioning (30 trials).

versus decreased responses to other frequencies in the absence of further training over hours and days. Fifth, RF plasticity exhibits long-term retention, enduring for the longest periods tested, up to 8 weeks after a single 30-trial conditioning session.

Specific associative RF plasticity is not an artifact of spontaneous changes in tuning because tuning is stable prior to conditioning and shifts are CS directed. Neither is it an artifact of state. Whereas animals exhibit arousal and related responses to sustained (e.g., 2–5 s) CS frequencies during training trials, they do not exhibit any behavioral (e.g., cardiac) responses to the frequency of the CS when it is presented as one of a number of rapidly presented, brief (e.g., 200 ms) sequential tone pips during

RF determination. Moreover, animals trained in the waking state exhibit RF plasticity when tested under deep general anesthesia.

CS-specific associative tuning shifts develop in the A1 of all species studied to date: guinea pig (*Cavia porcellus*), echolocating big brown bat (*Eptesicus fuscus*), cat (*Felis catus*), and rat (*Rattus rattus*). Additionally, CS-directed tuning shifts should increase the representational area of CS frequencies in the tonotopic map of A1. This has been found in instrumental learning in both the owl monkey (*Aotus trivirgatus boliviensis*) and the rat.

Learning-induced tuning plasticity is not limited to animals. The same paradigm of classical conditioning (tone paired with a mildly noxious stimulus) produces

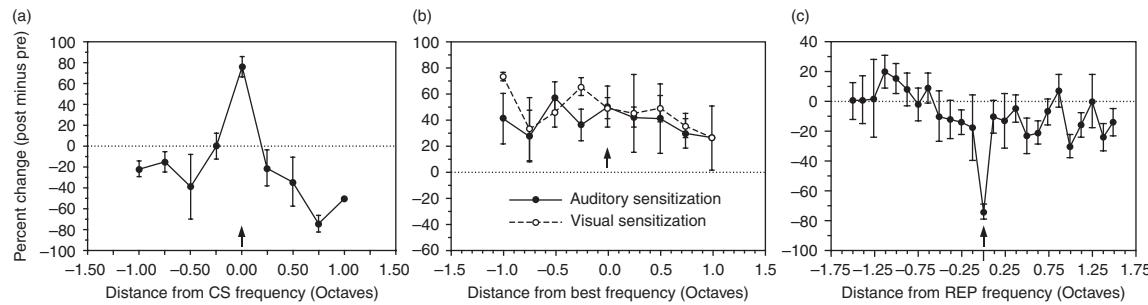

Figure 3 Summary of the effects of (a) conditioning, (b) sensitization, and (c) habituation on frequency receptive fields in the primary auditory cortex (A1) of the guinea pig. Data are normalized to octave distance from (a) the CS frequency, (b) the presensitization best frequency, or (c) the repeated frequency. Note that conditioning produces a CS-specific increased response whereas sensitization (tone-shock or light-shock unpaired) produces general increases across the spectrum. Habituation produces a frequency-specific decreased response.

concordant CS-specific associative changes in A1 of humans (*Homo sapiens*).

In summary, CS-specific RF plasticity has major characteristics of associative memory. It is not only associative, but is also highly specific, discriminative, rapidly acquired, develops consolidation over hours and days, is retained at least for many weeks, and exhibits generality across training tasks, types of motivation, and species. Additionally, when the same tone is repeatedly presented without reinforcement, subjects habituate, that is, learn that the tone does not signal reward or punishment. Habituation produces the opposite effect of associative learning, that is, a frequency-specific decrease in the response of A1 to the repeated sound. **Figure 3** summarizes changes in tuning for conditioning, sensitization, and habituation.

Beyond Specific Plasticity of Acoustic Frequency

Although the plasticity of acoustic frequency has been most extensively studied, specific associative changes in the processing of sound are not confined to this feature of sound. For example, rats were trained in a sound maze in which food reward was contingent upon successful navigation using only auditory cues. In this task, the repetition rate of noise pulses increased as the distance between the rat and target location decreased. After subjects had learned this maze, A1 cells exhibited enhanced responses to high-rate noise pulses and stronger phase locking of responses to the stimuli. In other words, learning produced a shift in tuning to high-repetition rates, that is, the stimulus features that were most closely associated with procurement of food. Similarly, owl monkeys trained to detect an increase in the envelope frequency of a sinusoidally-modulated 1 kHz tone developed increased sensitivity to small changes in envelope frequency. Even the processing of sound intensity (level) is specifically

shifted by associative processes. Rats were trained in a sound maze to move to a place in a small arena guided only by changes in the changing loudness of ongoing sound bursts. A1 responses became selective to relevant sound levels. Moreover, attentional demands can switch plasticity between stimulus parameters, such as frequency and intensity.

These findings are illustrative and we can expect further demonstrations that sensory processing in A1 is shaped by learning. It is likely that most, if not all, acoustic parameters are subject to specific associative plasticity. Moreover, other sensory systems are undoubtedly operating on the same principle: “Behaviorally relevant stimuli receive preferential processing and gain both processing capacity via tuning shifts and representational area, within primary sensory cortices.”

Additional Cognitive-Based Plasticity

The A1 is involved in many other cognitive processes. Space limitations permit only a listing. They include specific neurophysiological correlates of working memory, reference memory, attention, concept formation, and expectancy.

Moreover, cross-modality interactions are prevalent in A1. For example, in monkeys trained in a complex auditory discrimination task, the cue light that signaled trial availability developed the ability to elicit responses in A1. In humans, the sight of speech without sound elicits neural activity in A1. A recent anatomical study in the gerbil may provide an anatomical basis for some cross-modality effects. The authors found a surprisingly large number of inputs to A1 from nonauditory regions of both the cortex and the thalamus.

Perhaps one of the most surprising findings is that learning strategy, rather than the type or amount of learning determines auditory cortical plasticity. Thus, different groups of rats learned to bar press for water reward

contingent on the presence of a tone. Although both groups achieved high levels of correct performance, specific plasticity in A1 (CS-specific decrease in threshold and bandwidth) developed only for subjects that used a strategy based on attention to tone onset rather than tone duration.

Does the Auditory Cortex Form and Hold Specific Long-Term Memory Traces?

A specific long-term memory trace (SMT) is an enduring neural record of a particular aspect of experience. How might one determine if specific RF plasticity does index actual long-term memory traces? One might expect that destruction of A1 should remove its long-term memory traces, which would in turn be revealed by behavioral tests showing a specific loss of auditory memories. This apparently simple and decisive test proves to be neither because A1 is both sensory and mnemonic. Lesions will therefore interfere with both processes, so that any deficits cannot be attributed to either.

If not lesions, then what might be done? One approach is to attempt to defeat the proposal that long-term memory traces form in A1. As A1 does form associative plasticity (above), what line of attack might be taken? It could be argued that in addition to such plasticity, SMTs should possess the major characteristics of behavioral associative memory itself. This would impose a second level of criteria that have not previously been demanded of any neurophysiological studies of learning and memory. Nonetheless, this is not an unreasonable demand.

What are these characteristics? In addition to being associative, SMTs should also exhibit specificity, fairly rapid formation, long-term retention, and even consolidation, that is, continued strengthening over time after training in the absence of additional reinforcement. Another feature of memory is that it can be formed in a wide variety of learning tasks, rather than being confined to, for example, classical conditioning. A further key feature of memory is that it transcends a particular type of motivation, but develops in both appetitive and aversive situations. Additionally, one would expect SMTs to be manifest for whatever the type of CS or signal stimuli used in training, as is the case for genuine associative memory. That is, SMTs should not be limited to plasticity of frequency representation but should develop for any acoustic parameter that can serve as a signal for reward or punishment. Finally, as in the case of memory, SMTs should be biologically conserved, that is, develop across diverse taxa.

Convergent findings reviewed above show that specific plasticity in A1 meets all of these criteria. Moreover, as this is an active area of inquiry, new acoustic parameters are continually being studied. Although this article can

never be up-to-date, at least one prediction can be made: If an acoustic parameter can serve as a signal or gain behavioral relevance through learning, then its processing in A1 will develop specific representational plasticity.

Conclusions

A1 can no longer be considered to function merely as an acoustic analyzer. Nor is it likely that either the primary visual or primary somatosensory cortices differ fundamentally from A1. The auditory cortex is simply that sensory structure which has been most extensively investigated in learning and memory. In fact, both primary visual and somatosensory fields do exhibit some specific learning-based associative plasticity.

The findings reviewed above should be understood to transcend most approaches to neurophysiological correlates of learning and memory. Of course, demonstrations of such correlates are a necessary starting point but it is not in, and of, itself an ending point. In the absence of another level of inquiry, which seeks to understand the functional significance of learning-related plasticity, we are left largely with a list of plastic places and justified, but not fully satisfying conclusions, that these regions are involved in learning and memory. The evidence to date strongly suggests that at least one of the functions of specific associative tuning shifts and related plasticity in A1 is to store information, that is, serve as locus of specific long-term memory traces. To be sure, most memory substrates probably involve widespread networks of neurons. However, that in no way lessens the need to identify a component of such a network. By both determining the degree of specificity of A1 plasticity and delineating its attributes and characteristics in detail, it is possible to meet the criteria for identifying specific long-term memory traces.

The larger-scale implication of a modern concept of A1 is that the S-A-R model is no longer tenable. Despite understandable attempts to separate the analysis of stimuli from the comprehension and assignment of behavioral importance to stimuli at the level of the cerebral cortex, this approach simply cannot account for the data. It is time to seek a new brain-behavior organizational principle.

Glossary

Cortex – The outside layer of an organ, in this case the brain.

Dendritic spine – A tiny protrusion that extends from the dendrite of a neuron which is used to receive synaptic input from another neuron.

Estrogens – Steroid compounds which function as the primary female sex hormone.

Golgi stain – A histological technique first developed over 100 years ago by Golgi and Ramon y Cajal that uses metallic impregnation to randomly label a small number of cells in their entirety so that detailed information regarding dendritic branching, length, and spine density can be measured.

Hippocampus – A brain structure located deep in the medial temporal lobe which plays a critical role in some processes of learning and memory, especially those related to trace conditioning, declarative memory, and spatial navigation learning.

NMDA receptor – Binds the excitatory neurotransmitter glutamate.

Postsynaptic density – Otherwise known as PSD, these cytoskeleton specializations are located at the membrane of a postsynaptic neuron and consist of receptors, ion channels, and signaling systems involved in synaptic transmission.

Sex differences – Systematic difference between individuals of a different sex but within the same species.

The capacity to learn and remember is undeniably critical for the survival of virtually all organisms. However, the neurobiological mechanisms that underlie the formation of memories, their encoding, and storage remain largely unknown. While changes in the efficacy of synaptic transmission are now widely accepted to play a major role in learning, such changes are transient and thus insufficient to explain the stable nature of memory. Because memories persist long after the molecular events involved in their induction have degraded, changes in structural plasticity and, in particular, changes in synaptic architecture are also likely to be necessary. Cajal and others first proposed, more than a

century ago, that memory processes might involve anatomical modifications:

... one can admit as very likely that mental activity provokes a greater development of the dendritic appendages and axonal collaterals in the part of the brain most utilized. In this way, preexisting connections between groups of cells could be notably reinforced by multiplication of the terminal branches of the dendritic appendages and nerve collaterals; and, in addition, novel intercellular connections could be established thanks to the new formation of collaterals and dendrites. (Santiago Ramon y Cajal, 1894)

Despite a long history of speculation, only recently has evidence accumulated to support this idea. The lag in empirical investigation was likely due to the belief that unlike development, which is characterized by massive synaptogenesis and other growth, the adult brain was structurally stable. Moreover, the search for structural change following learning and memory was thought to constitute a needle-in-the-haystack problem, given both the complexity of behavior and the underlying neural circuitry. However, these assumptions have proven to be incorrect. Not only does the brain retain the capacity for structural change throughout life, there is also a growing body of data showing a relationship between synapse formation and cognitive function. These topics are the focus of this article.

Dendritic Spines

Dendritic spines – small protrusions found on the shaft of dendrites in the mammalian brain – are one of the most studied aspects of cellular anatomy that may be associated with memory formation (Figure 1). Because a typical mature spine has a single glutamatergic synapse on its head, measurements of spine number or density provide an estimate of synapse density. Moreover, since dendritic spines represent the main locus of postsynaptic excitatory input, they can regulate the amount of excitatory neurotransmission in a particular brain region and presumably the processing of information by that region.

Although various methods have been used to examine dendritic spines, most studies until recently have used light-microscopic imaging of Golgi-stained material.

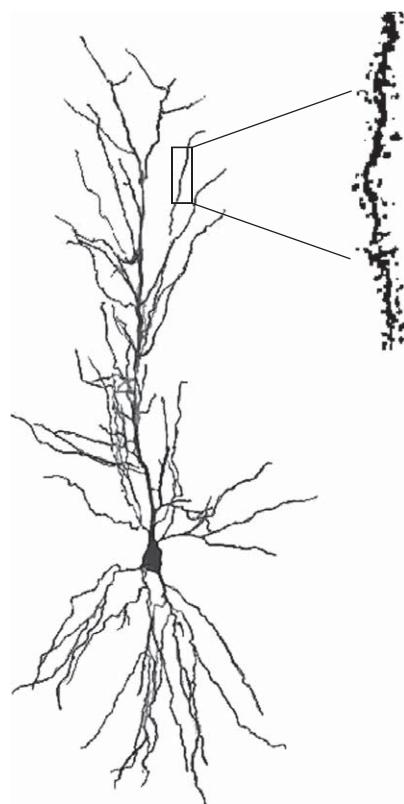

Figure 1 A pyramidal neuron from the hippocampus with a dendritic segment shown at higher magnification. Dendritic spines stud the surface of the dendrite.

Such studies have provided valuable information with regard to alterations in spine density, but due to limits in resolution are generally unable to reveal subtle changes in spine morphology. More recent work has employed fluorescent labeling of neurons followed by confocal microscopy, which can produce spine images of a better resolution. Quantitative immunohistochemical analysis of synapse-associated proteins is another way to identify changes in synaptogenesis. However, electron microscopy is ultimately necessary for the analysis of three-dimensional ultrastructure. Even so, it is limited in that it gives a static view of dendritic spines. The use of two-photon laser scanning microscopy in combination with fluorescent molecular tools has allowed for high-resolution, time-lapse imaging of spines in living slices. At present, it is even possible to study dendritic spines *in vivo* using transgenic mouse lines that sparsely express genetically encoded fluorescent proteins in specific neuronal types. By creating a ‘window’ in the skulls of these mice and positioning them under a two-photon laser scanning microscope, the same dendritic segments can be imaged over extended periods of time, as well as before and after exposure to stimuli. This form of imaging has been used primarily to visualize neurons in the most superficial layers of the cortex, although preparations for *in vivo* imaging of dendrites and spines in the hippocampus

have been reported. One limitation of this technique is that, because anesthesia is required, examination of structural plasticity in an animal as it actively engages in specific behaviors cannot be done. Moreover, although dynamic changes in the individual shapes of spines can be detected, resolution is not sufficient to count numbers or identify exactly where synapses occur. Recent studies have suggested that the cranial window itself can cause substantial glial activation and influence spine dynamics. An alternative approach involves viewing neurons through a thinned skull preparation. Results from this method have shown naturally occurring changes in dendritic spine number and shape but of a less extensive nature than that observed with a cranial window. However, examining deep structures such as the hippocampus with this method is difficult.

Using these techniques, it has been shown in cultured neurons, fixed and live brain slices, as well as in the intact brain that dendritic spines are remarkably dynamic structures. In the adult brain, their numbers are subject to change as a result of spine formation and elimination. Dendritic spines are also highly motile undergoing changes in size and shape over a timescale of seconds to minutes. Because small, thin dendritic spines are most likely to undergo these structural changes, whereas large, so-called ‘mushroom’ spines tend to maintain their form, it has been suggested that mushroom spines are more stable memory spines whereas the more plastic thin spines are learning spines.

Spines contain a postsynaptic density (PSD), the electron-dense thickening on the spine head that consists of receptors, ion channels, and signaling systems involved in synaptic transmission. The size of the spine head is proportional to the area of the PSD, to the number of postsynaptic glutamate receptors, and to the number of presynaptic docked vesicles. Thus, large spines are sites of strong synapses and, accordingly, the growth of the spine head likely correlates with a strengthening of synaptic transmission. In addition to changes in dendritic spine number and morphology, structural plasticity might also reflect modifications in a number of other measures including, but not limited to, changes in the size and configuration of the PSD.

Hormones

Estrogen

Numerous lines of evidence implicate the ovarian hormone estrogen as one of the most potent modulators of dendritic spines. Rapid fluctuations in spine density of CA1 pyramidal neurons of the hippocampus occur over the 5-day estrous cycle of the rat; during proestrus, when estrogen levels are at their highest, spine density is maximal. Between proestrus and estrus, when estrogen levels

decline, a 30% reduction in spine density occurs. Similarly, elimination of estrogen in young adult rats by ovariectomy is accompanied by decreased hippocampal dendritic spine density – an effect that can be reversed by estrogen treatment. The regulation of dendritic spines by estrogen also occurs in nonhuman primates as well as in cultured hippocampal neurons *in vitro*.

Serial reconstruction electron microscopic studies have shown that spine density changes associated with exposure to estrogen, either exogenously or endogenously across the estrous cycle, reflect a change in the density of synapses. Moreover, the increase in spine synapses with estrogen treatment results from the addition of new dendritic spines to preexisting boutons, which in turn make connections to multiple different postsynaptic cells. Thus, not only does estrogen increase the density of excitatory synaptic input to individual CA1 pyramidal cells, it also alters the pattern of synaptic connections. Additionally, it has been reported that estrogen modifies spine morphology by increasing the number of spines with mushroom shapes.

How do these estrogen-induced alterations in synaptic structure influence behaviors associated with the hippocampus? Although there are some exceptions, several studies have reported a beneficial effect of estrogen on cognitive ability. For example, classical eyeblink conditioning is enhanced during proestrus, when spine density is at its peak, relative to other stages of estrus. A correlation between spatial working memory and the estrogen-induced increase in spine density has also been demonstrated – working memory is improved when female rats are tested at a time after estrogen treatment when spine density is elevated but not before spines are increased or after spine density has returned to low levels. The influence of ovarian hormones on dendritic spine/synapse density and cognitive function extend beyond the hippocampus. For example, in rodents and monkeys, estrogen improves performance on tasks that depend on the medial prefrontal cortex and produces a parallel increase in dendritic spine/synapse density. Overall, these studies indicate that hormonally regulated changes in synaptic structure may have an important impact on certain forms of learning and memory.

Testosterone

Much of what is known about gonadal steroid-induced neuroplasticity has focused on the effects of estrogen. However, Recent work has shown that androgens also exert important effects on hippocampal structure. Specifically, castration leads to a loss of dendritic spines indicating that androgens maintain spine number in males. Although the loss of dendritic spines following castration can be reversed by treatment with testosterone, estrogen is without effect. Thus, the hormonal regulation

of hippocampal spine density differs in males versus females. As with estrogen, there are data to suggest that testosterone-mediated changes in spine density may be associated with cognitive ability. Testosterone depletion reduces cognitive performance – an effect that can be prevented by testosterone replacement.

Experience

Stress

The effects of aversive stressful experience on dendritic spines are influenced by the type, intensity, and duration of the stressor, the brain region examined, as well as numerous other factors. For example, acute stress alters the number of dendritic spines on hippocampal CA1 pyramidal cells of adult rats, but this is dependent on the sex of the animal and in the case of females on the stage of estrus. Exposure to brief, intermittent tailshocks increases the number of dendritic spines on pyramidal cells of males. In contrast, females show a decrease in the number of dendritic spines on pyramidal cells when exposed to the stressor during diestrus but not estrus. These sex differences in the effects of stress on dendritic spines are paralleled by stress-induced alterations in classical eyeblink conditioning – stress enhances learning in males but decreases learning in females. Thus, exposure to an acute stressful experience has a similar effect on spine density as it does on new learning, at least of this particular learned response.

In the CA3 region of the hippocampus as well as in the medial prefrontal cortex, acute and chronic stressors induce spine loss and dendritic remodeling of pyramidal neurons. These structural changes have been suggested to underlie stress-induced deficits in spatial navigation learning and attention – cognitive abilities that depend on these respective brain regions. By contrast, aversive experience increases spine density in the amygdala – a locus of storage for fear memories.

Enrichment

Beginning with the seminal studies of Rosenzweig and colleagues, it has been repeatedly shown that exposure to complex or enriched settings either during development or adulthood enhance multiple measures of neuronal morphology in the hippocampus and cortex of rodents and primates. Compared to laboratory control animals, animals living an enriched environment have more dendritic spines and synapses as well as increased dendritic branching. Other studies have shown that environmental enrichment has a beneficial impact on the ability to perform a variety of spatial, nonspatial, hippocampal dependent, and independent tasks. Two points are worth mentioning when considering the effects of

enrichment on brain structure and function. First, enriched environments typically include enhanced opportunities for social interactions, exercise, and learning. The extent to which one or more of these factors contribute to the consequences of environmental enrichment remains unknown. However, some studies have suggested that physical activity may play an important role. For instance, exercise and living in enriched environments similarly enhance dendritic spine density on granule cells of the dentate gyrus and improve performance on some learning tasks. Another point to consider is that under standard laboratory housing conditions, dendritic architecture, spines, and synapses may atrophy from disuse. Enrichment may restore these measures to a baseline closer to that of wild animals. Thus, it's possible that experimental enrichment represents a reversal of the impoverishment generally found in the laboratory setting rather than enrichment over a natural setting.

Long-Term Potentiation

Numerous studies have attempted to link morphological changes with long-term potentiation (LTP) – an enduring enhancement of synaptic transmission widely assumed to be a cellular model of learning and memory. Although early studies failed to find evidence for alterations in overall spine number, more recent work indicates that the induction of LTP is associated with the growth of new spines, some of which become mature synaptic contacts. For example, live-imaging with two-photon microscopy has shown that LTP in hippocampal slice cultures leads to the formation of new spines, and that inhibition of LTP with an N-methyl-D-aspartic acid (NMDA) receptor antagonist prevents this structural change. One possible reason for the contradictory findings may relate to the stimulation methods used in older studies which were not localized and could have reduced the chances of detecting a change.

Modifications in spine morphology, including an enlargement of the spine head as well as a widening and shortening of the spine neck, have also been reported to follow LTP. These effects can occur rapidly – within minutes after stimulation – and can be persistent, lasting up to 24 h. The growth-inducing effects of LTP at one spine can even lead to spine enlargement at neighboring spines. Other structural changes have been associated with LTP, including alterations in the size of the PSD, spine splitting, the formation of perforated synapses, changes in spine curvature, and the formation of multiple spine synapses. Taken together, these data demonstrate that the formation of new spines and modulations in synaptic structure correlate with LTP. Whether these alterations contribute to enduring changes in synaptic strength remains to be determined.

Long-term depression (LTD) is also thought to play an integral role in learning and memory processes but, in contrast to LTP, is a long-lasting reduction in synaptic transmission. Although the morphological correlates of this form of synaptic plasticity have received less attention than those accompanying LTP induction, evidence indicates that LTD produces morphological changes that are seemingly the converse of those associated with LTP. Specifically, induction of LTD results in a shrinkage and retraction of dendritic spines. The functional significance of these observations is presently unknown, but they, nonetheless, provide further evidence that alterations in dendritic spines are dynamically regulated by activity.

Learning and Memory

Invertebrates

There are several examples in the invertebrate world of synaptic reorganization following learning. For instance, spines are altered during learning in honeybees such that their first orientation flight leads to spine-stem shortening. In the marine snail *Aplysia*, nonassociative modification of the gill-siphon withdrawal reflex is accompanied by structural transformations in the network mediating the behavior. Following long-term habituation, in which the snail learns to ignore a neural stimulus, the number of synapses between sensory and motor neurons decreases. Following sensitization, in which the snail reacts more strongly to a noxious stimulus with repeated presentations, synapses between these neurons exhibit changes in size, shape, and number.

Birds

There is also evidence that learning can induce spine changes in vertebrate species such as birds. For example, one-trial passive-avoidance conditioning in chicks is associated with an increase in spine density on neurons of two forebrain regions important for memory storage. These changes appear specific to memory formation since chicks rendered amnesic for the experience by subconvulsive shock shortly after training do not exhibit an increase in spine density. Morphological correlates of learning have also been shown to occur in songbirds. Those songbirds that learn large song repertoires have a greater number of dendritic spines in a specific forebrain nucleus of the song system than birds that learn small repertoires. These studies suggest that neurons of the bird brain are also sensitive to learning-related changes in dendritic spines.

Mammals

In mammals, increases in hippocampal spine number have been reported following training on a variety of tasks, including passive-avoidance conditioning, olfactory

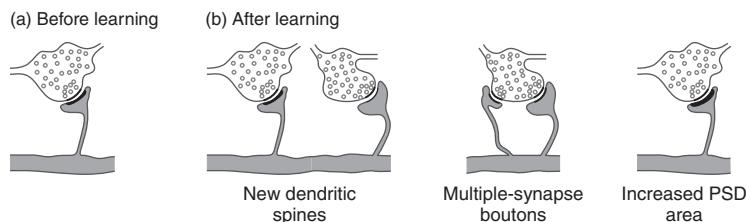

Figure 2 Pyramidal neurons in area CA1 of the hippocampus undergo alterations in synaptic structure following classical eyeblink conditioning. (a) An axospinous synapse prior to learning. (b) Following learning, new dendritic spines appear, multiple-synapse boutons are formed, and the area of the PSD (depicted as the darker area in the dendritic spine) is increased.

discrimination, spatial navigation, and classical eyeblink conditioning, although there are some differences in the magnitude, time course, and location of the effects across studies. For example, eyeblink conditioning increases hippocampal dendritic spine density 24 h later (Figure 2), an effect that is prevented by blocking learning with an NMDA-receptor antagonist. However, the learning-induced changes in spine density are localized to CA1 pyramidal neurons and do not occur on granule cells of the dentate gyrus. Moreover, changes in spine number are found on basal dendrites of stratum oriens but not on apical dendrites of stratum radiatum. It is possible that changes in spine density could occur in other cell regions at earlier or later time points and at different stages in the learning process. However, the observation that classical conditioning does not affect spine density on apical dendrites is consistent with other work reporting that synapse density in CA1 stratum radiatum is unaltered by learning the trace version of the eyeblink conditioning task. These data suggest that structural modifications following learning may occur without an overall change in synapse number. Indeed, trace eyeblink conditioning has been shown to increase the number of boutons that synapse with multiple dendritic spines and to enlarge the area of the PSD (Figure 2). That learning may be accompanied by a remodeling of existing synapses rather than a lasting increase in their number may also explain other results demonstrating transient changes in spine density/synapse number after training in the water maze or on a passive-avoidance task. In addition, finding no overall change in synapse density does not exclude the possibility for increased density of certain spines at the expense of others. Since it appears that changes in spine formation are activity driven, it is likely that strengthened synapses may be preserved, whereas spines that are activated but not strengthened are reduced. Indeed, some type of homeostatic process is probably necessary to maintain a balance between structure and stability and so learning could involve changes in spine morphology in addition to, or instead of, alterations in spine number.

Learning also influences structural plasticity in brain regions other than the hippocampus. For example, a large

body of work by Greenough and colleagues has shown that synaptogenesis occurs in the cerebellar and motor cortices after motor skill learning. Increased synaptic number in the cerebellum has also been associated with eyeblink conditioning and in the piriform cortex following olfactory learning. In the lateral amygdala, fear learning leads to increased numbers of dendritic spines as well as an enlargement of the PSD.

Human Brain Disorders

Accumulating evidence indicates that structural synaptic plasticity plays a vital role not only in normal brain functions, but also in the development of neurological and mental disorders. In humans, abnormalities in dendritic spine number and structure have been associated with deficient cognitive capabilities. There are reports indicating an abnormality of dendritic spines in numerous mental retardation disorders such as Down's and Fragile X syndromes. In persons with Down's syndrome, the density of dendritic spines is decreased in the neocortex and hippocampus while the incidence of abnormally long and short spines is increased. Fragile X syndrome is characterized by abnormal spine morphology and an increased density of dendritic spines – possibly as a result of deficits in spine maturation and pruning. Similar findings have been observed in a mouse model of Fragile X syndrome, although the developmental regulation of the spine changes differs from that in the human. Schizophrenia is another disorder characterized by poor performance on cognitive tasks, particularly those in which the dorsolateral prefrontal cortex is important. Spine density in this region, as well as the temporal cortex, is decreased in schizophrenic subjects. Finally, dendritic spine abnormalities have been observed on cortical pyramidal neurons of patients with Alzheimer's disease and senile dementia as well as in animal models of Alzheimer's. Taken together, these data implicate dendritic spines as an anatomical substrate important for normal cognitive processes and suggest that dendritic spine alterations may contribute to the cognitive dysfunction characteristic of these disorders. However, other

interpretations are feasible and the possibility remains that structural changes are a consequence and not a cause of the disorder.

Functional Implications

Some fundamental questions with regard to the relationship between synapse formation and cognitive function have yet to be elucidated. For example, is learning-induced spine/synapse formation an anatomical substrate for information storage or does it represent a more general property of the engaged parts of the brain circuitry underlying these behaviors? In the case of eyeblink conditioning, the latter possibility may be more likely. Notably, the hippocampus is necessary for acquiring the learned response but it is not the site of memory storage. In addition, the increase in dendritic spine number occurs following hippocampal-dependent and -independent types of eyeblink conditioning, both of which are known to enhance excitability in the CA1 pyramidal cell region during, and for some time after, training. Thus, excitability and spine density tend to correlate. Whether the increase in excitability results in the formation of new spines or vice versa is debatable but, in either case, this increased network excitability could thereby enhance its processing capability. This idea proposes a rather broad and nonspecific effect of training on spine formation and is thus inconsistent with the effects of LTP on synapse formation and, more generally, with traditional ideas of how spines may be involved in cognitive processes. It is assumed that the changes occurring at the synaptic level are relatively specific to just a few synapses necessary to encode an association; learning would not influence most or even a substantial number of cells in the network. However, hormones and experience, including learning, lead to 20–30% increases in spine density – substantial changes which are not likely relegated to just a few neurons in a network.

Along similar lines, it is unknown whether the structural changes are temporary or long lasting and representative of memory storage. If temporary, it remains to be determined how changes in spine number would alter processes involved in learning. One might propose that the presence of spines enhances synaptic efficacy and thereby enhances the excitability of the network involved in the learning process. In this particular scenario, learning is not necessarily dependent on spine density changes; rather changes in spine density indirectly enhance the support for information processing; that is, they provide anatomical structure for processes that are either occurring or will occur in the future. In the case of estrogen, for example, an increase in spine density would alter the presence of spines during proestrus – a time in the female cycle when she is most exploratory and when

mate selection would generate offspring. In the case of stress, the increase in spine density in males precedes the enhancement in learning ability; that is, within 24 h of the stressful event, increased spine density is evident and persists for several days thereafter. This is a time period when the chance of stressful encounters (e.g., with predators) remains relatively high. The presence of spines may thereby provide anatomical support for forming associations at a more rapid rate during that time period.

Concluding Remarks

Although the work reviewed here supports the long-held belief that synapse formation and remodeling may be important substrates underlying memory formation, other mechanisms are also likely to play a role. For example, neurogenesis occurs in the adult hippocampus and has been linked to some types of learning and memory. Understanding how these mechanisms interact or whether they have a unique contribution to cognitive function is a challenge for future work. It is also important to keep in mind that despite a number of advances in the field, much of the current data is correlative and no causal relationship between cognitive processes and synapse formation has been established. Advances in imaging technologies, allowing for the observation of structural changes in behaving animals, combined with molecular approaches enabling the manipulation of dendritic spines *in vivo* should help to resolve this issue and bring us closer to elucidating the role of this form of structural plasticity in brain function.

Hormones and Female Sexual Behavior

J D Blaustein, University of Massachusetts, Amherst, MA, USA

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Conditioned place preference – A behavioral technique in which the rewarding aspects of a particular situation can be assessed. In the study of sexual behavior, the rewarding aspects of particular mating situations can be studied.

Copulatory behaviors – Those behaviors which result in successful transfer of sperm from the male to the female; used instead of receptivity, because it connotes an active participation by the female, and because the same term is applied to the active behaviors shown by males. Lordosis is a sexually receptive behavior.

Estradiol – The predominant steroid hormones (usually 17β -estradiol, but the 17α -estradiol isomer is also active in some systems) belonging to the class of hormones – estrogens – circulating in vertebrates. Although estradiol is sometimes incorrectly called estrogen, the two terms should not be confused. Estradiol is a specific hormone; estrogens are a class of hormone.

Estrogen receptor – A protein that binds estradiol and other estrogenic compounds. Although there are two genes synthesizing distinct estrogen receptors – estrogen receptor (ER) α and ER β – the indispensable function of ER α has been best characterized. There are other forms of ERs; however, the classic ER acts as a transcription factor.

Estrogens – A class of steroid hormones defined either by structure, by binding properties, or by their influence on particular responses.

Genitosensory stimulation – The mating stimulation received by a female from a male or, in some cases, from manual palpation by the experimenter or a mechanical probe.

Lordosis – The prototypical, reflexive element of sexual behavior in many species, characterized by immobility and dorsiflexion of the spine to accommodate intromissions by a male.

Paracopulatory behaviors – Species-typical behaviors displayed by females which arouse males and stimulate them to mount. These behaviors have sometimes been termed proceptive, precopulatory, or solicitational behaviors.

Progestative behaviors – Those behaviors that occur throughout mating, which maximize the likelihood that pregnancy will occur.

Progesterone – The predominant steroid hormone of the class progestins or gestagens, circulating in vertebrates.

Progestin receptor – A protein that binds progesterone and other progestin-like compounds. Although there are other types of progestin receptors, the classic progestin receptor exists in two forms, A and B, and acts as a transcription factor.

Progestins – A class of steroid hormones defined either by structure, by binding properties, or by their influence on particular responses (also called gestagens or progestagens).

Pseudopregnancy (also called the progestational state) – A physiological condition that resembles pregnancy, which is initiated by twice-daily surges of prolactin, resulting in rescue of the corpus luteum. It can result from primarily intromissive stimulation received during copulation or by experimenter-applied vaginal cervical stimulation.

Vaginocervical stimulation – A reproductively relevant genitosensory stimulus that is an important component of mating stimulation received by females. It can be provided by males during intromissions or ejaculations, or it can be provided by an experimenter with a glass or plastic rod. It should be noted that the experimenter-applied stimulation is primarily stimulation to the uterine cervix.

Introduction

The study of female sexual behavior has been an active, perhaps the most active, area of investigation within the field of Behavioral Endocrinology for over 75 years for a variety of reasons. Female sexual behavior is robust, reliable, and, at some levels, relatively easy to study. Furthermore, it lends itself to both behavioral analysis and mechanistic analysis. Sexual behavior is undoubtedly biologically important, and no inference is necessary to understand its relevance to the animal. Sexual behavior is also the prototypical model for sexual differentiation of the brain, since in most species the behavior is sexually dichotomous. Finally, although this was not clear in earlier years, female sexual behavior in some rodent species

provides a useful model for understanding the role of hormones in certain aspects of human sexuality.

Female sexual behavior has also been used extensively as a model behavior for understanding the mechanisms by which hormonal and afferent neural signals from the social environment interact at the cellular level to modulate behavior. Some of the most interesting aspects of this model are the many ways in which behavioral response is shaped by environmental stimuli, as well as the ways in which behavioral output changes physiology. Although various components of these complex interactions can be studied in a reductionistic manner, they also lend themselves to analysis at all levels from organismic to cellular and molecular.

Model Species

Because of its obvious biological importance, the sexual behaviors of many species have been studied, and much is known about the female sexual behaviors of all species from primates to the most primitive sexual organisms. Although there are many interesting differences among species in the behaviors and their regulation, a great deal of research on hormones and female sexual behavior has used rats, guinea pigs, hamsters, and mice as model species. These species have much in common with each other, and considerable similarities to regulation of sexual desire in humans. This article focuses primarily on rats with some discussion of commonalities with work involving other species. Although the behaviors themselves differ widely among species, the hormones involved are quite consistent, and the mechanisms and brain areas involved are quite conserved.

Classifications of Sexual Behaviors

Sexual behaviors in female rodents include postural stances and adjustments required for vaginal intromission by males and other behaviors that attract the male and modulate the timing of sexual interactions. Some of these

behaviors facilitate the transfer of sperm from the male to the female reproductive tract and increase the probability of successful pregnancy. Some other behaviors are relatively stereotyped and reflexive; other, more complex patterning of behavioral events during copulation are necessary for successful pregnancy.

Numerous metrics have been used to study sexual behavior, and each has its appropriate place in the armamentarium available to the researcher. The appropriate measure chosen for a particular experiment depends upon the specific questions being asked. If the question focuses on whether a particular treatment induces the expression of estrous behavior, a simple measure of lordosis is sufficient. Alternatively, if the question is one of sexual readiness and the female's motivation to mate, then other behaviors might be more relevant, as well as tests for sexual motivation. When examining the effects of the female's sexual behavior on neuroendocrine function and reproductive success, behaviors involved in the induction of pregnancy and facilitation of sperm transport are studied.

Historically, most studies of rodent female sexual behavior relied on the lordosis reflex as the sole measure of sexual behavior, and this continues to be quite useful to answer questions relating to the neuroendocrine bases of a relatively simple behavior. The study of the lordosis response allows for reliable assessment of the female's responsiveness to the mating stimuli provided by the male. Likewise, it allows the study of the cellular and molecular underpinnings of a relatively simple behavior and how these factors are integrated in the moment-to-moment changes in behavioral expression.

Generally, female sexual behavior is considered to comprise three basic elements as proposed by Frank Beach (**Table 1**): receptivity, proceptivity, and attractivity. Beach acknowledged the multiple components of female sexual behavior, and his terms provide a framework for studying female sexual behavior. More recently, however, recognition of the additional behaviors involved, and the recognition that females are active rather than passive participants, in sexual interactions called for a more appropriate set of terms. Blaustein and

Table 1 Classifications for female sexual behavior

Category	Example in rats
<i>Beach's characteristics of female mammals in estrus (1976)</i>	
Attractivity	stimulus value in evoking sexual responses by male
Receptivity	lordosis
Proceptivity	ear-wiggling, darting and hopping
<i>Blaustein and Erskine's classification of female sexual behaviors (2002)</i>	
Copulatory	lordosis
Paracopulatory	ear-wiggling, darting and hopping
Progestative	Pacing

Erskine described three functional components of female sexual behavior, which are useful in studying the neural and endocrine regulation of female sexual responsiveness: copulatory, paracopulatory, and progestative behaviors, and this article will be organized along these components.

Copulatory Behaviors

Copulatory behaviors refer to behaviors that result in transfer of sperm from the male to the female. It is used instead of Beach's term, 'receptivity,' because it emphasizes the female's active role. Females of many species, including rats, display the lordosis posture, which positions the vagina to allow penile intromission in response to flank and perineal somatosensory stimulation typically received from males during mounts. The reflexive dorsiflexion of her spine, lordosis, involves her becoming immobile, extending her rear legs, elevating her head, and deflecting her tail (**Figure 1**).

Lordosis has been used as the dependent measure in the majority of mechanistic and neuroanatomical studies of female sexual behavior. The percent lordosis responses observed in response to mounts from the male (lordosis quotient) is used as an index of the basic level of sexual receptivity. The lordosis rating of the intensity of each spinal dorsiflexion is used as an index of the magnitude of the lordosis response. Unlike rats, in which the display of lordosis occurs briefly ($\approx 0.5\text{--}1.5$ s), in some species the duration that the posture is held is used as an index of strength of response, since it can last for minutes in hamsters and 10–20 s in guinea pigs.

Hormones

Hormones are generally thought of as increasing the probability of a particular behavior occurring in a specific

Figure 1 Drawing illustrating the immobile lordosis posture adopted by a sexually receptive female rat in response to copulatory stimulation by a male rat. Note the deflection of the tail and dorsiflexion of the spine.

condition. That is to say, appropriate hormonal priming increases the probability that a female will express particular sexual behaviors when confronted with a sexually vigorous male of the same species. The frequency and rate with which these behaviors are expressed are influenced by ovarian steroids, by the rate at which a male copulates with a female, and by the specific experimental conditions under which mating is observed.

A prominent characteristic of the estrous cycle of rats, guinea pigs, hamsters, and mice is that the secretion of estradiol followed by progesterone induces a period of sexual behavior (heat or behavioral estrus) that is linked to the time of ovulation (**Figure 2**). After heat terminates, sexual receptivity is not expressed until the same stage of the next estrous cycle (**Table 2**). Most experiments on the neuroendocrinology of female sexual behavior have assessed influences only on receptivity. Removal of the ovaries causes the cessation of the expression of female copulatory behaviors due to the loss of ovarian hormones. While there is a good deal of commonality with other sexual behaviors, caution in generalization is warranted.

Although female copulatory behavior is generally considered to be hormone dependent, like most behaviors, it is regulated by, but is not entirely dependent on, hormones. First, consider the copulatory behavior – lordosis – which is the most reflexive of the sexual behaviors. During the estrous cycle, estradiol and progesterone are secreted sequentially, and both are essential for the expression of lordosis. Although estradiol alone, particularly when administered for prolonged periods or at high dosages, can induce lordosis, under typical physiological conditions, both estradiol and progesterone are required. However, in the apparent absence of both hormones, the reflex can be induced by an extraordinary stimulus (e.g., experimenter-applied, vaginocervical stimulation (VCS) with flank stimulation).

Often, after exposure to progesterone, rats, hamsters, guinea pigs, and mice become refractory to further facilitation of copulatory behavior by either progesterone alone or, in some cases, estradiol and progesterone. Progesterone desensitizes the response to itself, which has been suggested as a mechanism by which progesterone-facilitated sexual behavior terminates (i.e., heat termination).

The time course of action of estradiol on copulatory behavior differs markedly from that of progesterone. While estradiol priming typically takes about a day, progesterone when administered intravenously can facilitate the expression of lordosis much more quickly, even within less than an hour of injection. This is seen in ovariectomized rats, as well as during the estrous cycle, in which estradiol secretion precedes progesterone by about a day, and sexual behavior commences soon after the start of the rise in progesterone levels.

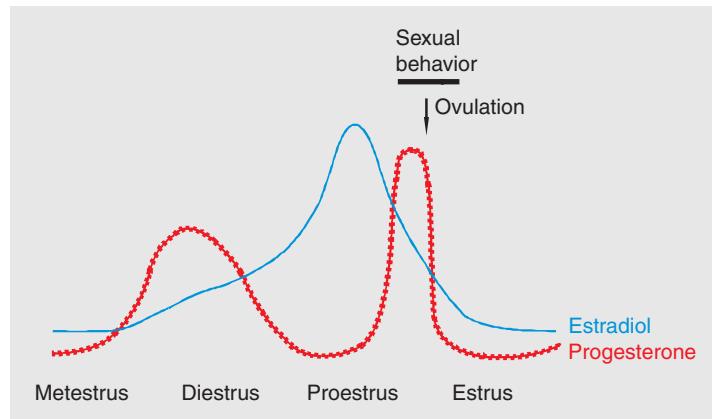

Figure 2 Schematic illustrating the relative changes in estradiol and progesterone levels during the estrous cycle of female rats. It is the peak of progesterone following the rise in estradiol levels that results in the expression of sexual behaviors overlapping the time that ovulation occurs. The second increase in progesterone levels during metestrus/diestrus is a result of secretion from the short-lived corpus luteum in species with short estrous cycles.

Table 2 Facilitation and subsequent desensitization of female sexual behavior by progesterone in estradiol-treated rats and some other rodent species

Day 1 injection	Day 3 injection	Day 3 test	Day 4 injection	Day 4 test
Estradiol	Oil	No		
Estradiol	Prog	Yes		
Estradiol	Oil	No	Prog	Yes
Estradiol	Prog	Yes	Prog	No

Prog = progesterone.

No = absence or low levels of sexual behavior.

Estradiol and progesterone are not the only steroid hormones involved in the regulation of female copulatory behaviors. In fact, dihydrotestosterone is inhibitory to the induction of sexual receptivity, and it has been suggested as one of the factors that determines the duration of the period of sexual receptivity during the estrous cycle. Furthermore, corticosterone, secreted from the adrenal gland, typically inhibits the expression of female sexual behavior.

Paracopulatory Behaviors

Paracopulatory behaviors, which have also been called proceptive, precopulatory, or solicitational behaviors, are species-typical behaviors displayed by females which arouse the male and stimulate him to mount. These behaviors differ markedly among species. Paracopulatory behaviors exhibited by estrous female rats during mating include hopping, darting, and ear wiggling, a presenting posture, a rapid sequence of approach to, and withdrawal from a sexually active male, and production of ultrasonic vocalizations. These behaviors are expressed repeatedly before and between mounts.

Hormones

Paracopulatory behaviors are generally considered to be dependent on progesterone as well as estradiol. While lordosis can be seen within an hour of progesterone treatment, maximum levels of paracopulatory behaviors are generally seen with a slightly longer latency. Although estradiol alone can induce copulatory behaviors in ovariectomized rats, in most cases the expression of paracopulatory behaviors requires progesterone either administered exogenously or secreted by the adrenal gland. It should be noted that paracopulatory behaviors have sometimes been observed even in ovariectomized–adrenalectomized rats administered only estradiol, suggesting that paracopulatory behaviors are not absolutely dependent on progesterone.

Progestative Behaviors

Female rats receive multiple, spaced mounts and mounts with intromissions prior to an ejaculation. Progestative behaviors include pacing of the rate of stimulation through intermittent approaches to and withdrawal from the male, the selection by the females of males that are ready to ejaculate, and the females' postejaculatory

interval, which enhances sperm transport by preventing rapid displacement of the copulatory plug deposited by the male. These short-term behavioral adjustments in the patterning of copulatory stimulation increase the likelihood of optimal reproductive success.

Given an opportunity, by using a two-chamber testing apparatus in which the male is restricted to one chamber, but the female can move freely, or a bi-level testing apparatus, female rats actively regulate the types and amounts of VCS received during mating by pacing their interactions with the male. The females return to the male with shortest latency after a mount. The latency to return to the male is longer after an intromission and even longer after an ejaculation. Therefore, the rate of receipt of mounts is greatest, followed by intromissions and then ejaculations. Females mated in undivided test arenas are unable to avoid contact with the male and thus receive nonpaced coital stimulation. Typically, paced mating, in which the female determines the rate of stimulation, occurs at a slower rate than nonpaced mating, in which the male determines the rate. Mating stimulation by a male is reinforcing when the female is allowed to pace the sexual interaction, which is consistent with the idea that paced mating, besides being a progestative behavior, is a rewarding aspect of sexual behavior.

The temporal patterning of VCS that females receive during mating is critical in determining whether the neuroendocrine responses required for pregnancy occur, including secretion of sufficient progesterone from the corpus luteum to promote successful implantation (i.e., induction of a progestational state necessary for pregnancy). Intromissions and ejaculations are effective, whereas mounts-without-intromission typically are not. The postejaculatory interval imposed by the female is also progestative, because this interval may ensure that maximum sperm transport has occurred.

Hormones

Pacing behavior is dependent on estradiol and progesterone, as seen both in estrous-cycling rats and ovariectomized rats injected with estradiol and progesterone. Although pacing appears to be dose-dependent on progesterone, the influence of estradiol seems to be all-or-none. Much of the work on hormones and sexual behavior has focused on the action of hormones in the brain. However, the effects of hormones on peripheral tissue must also be considered. For example, systemic injection of ICI-182,780 – an anti-estrogen, which does not cross the blood–brain barrier – is without effect on the expression of lordosis in ovariectomized rats. However, in a paced mating situation, the anti-estrogen caused a lengthening of the return latencies after intromission and ejaculations. It has been suggested that estradiol decreases the aversive component of genitosensory stimulation via a

peripheral site of action. This is consistent with earlier findings that estradiol induces robust changes in the sensory field of the pudendal nerve, which innervates the perineal region, and the report that transection of this nerve disrupts pacing behavior in estradiol-treated rats.

Motivation

The rate of display of paracopulatory behaviors, such as darting, hopping, and ear-wiggling (actually rapid head oscillations giving the ears the appearance of wiggling or quivering) is often used as an index of a female rat's motivation. However, other tests that are more direct tests of motivation to mate have been developed. These include tests of partner preference in which a female is given an opportunity to seek proximity to a sexually active male over another stimulus animal, the use of a runway to assess the female's motivation to approach a male, and conditioned place preference in which rewarding aspects of a particular mating situation can be assessed. Unfortunately, the extensive studies to understand the role of particular hormones that have been undertaken for copulatory behavior have not been performed for tests of motivation.

Partner Preference

In general, rats in the proestrous/estrous stage of the estrous cycle – when estradiol and progesterone levels are elevated – or ovariectomized rats injected with estradiol, an androgen, or estradiol and progesterone are more likely to approach sexually active males, suggesting, not surprisingly, that ovarian hormones increase the female's sexual motivation. The female's motivation to mate is also influenced by the ability of the male to copulate with her, with them typically showing a stronger preference for males that are not allowed to copulate with them than with males that are. However, if sexual interaction or genitosensory stimulation by the males is restricted (for instance, by keeping the males in a wire cage or by preventing intromissions), females prefer a sexually active male. These results suggest that females initially seek out contact with sexually active males, but that the mating stimulation results in subsequent avoidance of this stimulation. This is consistent with the idea that there is an aversive component to genitosensory stimulation.

Runway Method

Similar influences are seen when a runway is used to assess the female's motivation for a male. Ovariectomized rats treated with estradiol or estradiol and progesterone increase speed and time spent in proximity to a male – as

is seen during the proestrous–estrous stages of the estrous cycle when ovarian hormone levels are highest.

Conditioned Place Preference

The use of conditioned place preference to assess the sexual motivation of female rats has demonstrated that ovariectomized female rats primed with estradiol and progesterone prefer a compartment which has previously been associated with sexual interaction. Interestingly, similar to partner-preference experiments, females prefer places associated with males which are not allowed to copulate.

Generally, females develop a conditioned place preference for compartments in which they have been allowed to pace the mating, but not places where rate of copulation has been determined by the male. Progesterone is essential for the development of a conditioned place preference in female rats that pace their rate of sexual interaction. Interestingly, recent work suggests that nonpaced mating also induces a conditioned place preference if a single male provides all of the intromissions, but not if multiple males are used. So while the conditioned place preference technique is a powerful one for assessing female's preference, it is also very sensitive to relatively small differences in the stimulus animal.

Summary of Hormonal Influences on Female Sexual Behaviors

It is clear that the prototypical copulatory behavior – lordosis – requires the sequential action of estradiol and progesterone during the estrous cycle. However, under some conditions, in ovariectomized rats, it can be induced with estradiol alone. The situation with paracopulatory behaviors is a bit different. Although most reports suggest estradiol injection must be followed by progesterone, there are some cases of high levels of paracopulatory behavior with estradiol alone. The progestative behavior – pacing – requires both estradiol and progesterone, perhaps because pacing is dependent upon motivation for sexual behavior. To the extent that it has been studied, female sexual motivation seems to be dependent on both progesterone and estradiol.

Mechanisms of Action of Steroid Hormones

Many studies on the cellular mechanisms by which estradiol and progesterone act in the brain have relied on the female sexual behavior model. Although steroid hormones act through a wide array of mechanisms from membranes to genes, the most well-characterized mechanism for feminine sexual behavior involves

intracellular steroid receptors acting as transcriptional regulators. Although an understanding of the cellular mechanisms involved in the effects of estradiol and progesterone on the motivational aspects of sexual behavior and pacing is of tremendous importance, most work has focused on lordosis.

Estradiol's Mechanisms of Action

The discovery of estrogen receptors (ERs) in the brain 40 years ago led to studies to determine if binding of estradiol to those receptors was causally related to the induction of female sexual behavior by estradiol and other estrogenic compounds. The necessity of ERs for the actions of estradiol on sexual receptivity has been assessed by use of a variety of techniques: estrogen antagonists – which block the binding of estradiol to ERs; ER gene-disrupted mice (ER knockouts (ERKOs)) – in which the gene for ERs has been disrupted; and by techniques to block the synthesis of ERs either globally or in specific brain regions. Although other mechanisms are undoubtedly involved, the results of each approach are consistent with the conclusion that ERs are essential for the effects of estradiol on the expression of copulatory behavior.

There are two different genes for transcription-factor ERs that are independent but have a great deal of homology. Although it is clear that ER α is indispensable for female sexual behavior, the role of ER β is less defined, perhaps acting to modulate response to ER α .

Progesterone's Mechanisms of Action

Progesterin receptors (PRs) were first characterized in the brain close to 30 years ago. The discovery of neural PRs led to the hypothesis that the facilitation of sexual behavior by progesterone requires interaction of progesterone with those receptors in critical neurons. As was the case with ERs, a variety of techniques have been used to demonstrate that PRs are necessary for the facilitation of sexual behavior by progesterone: injection of progestin antagonists, antisense oligonucleotides to PR mRNA, and PR-knockout strains of mice. It follows that sensitivity to progesterone is determined by the concentration of PRs available in those neurons, and behavioral response requires an adequate concentration of PRs activated by progesterone in those neurons. Estradiol induces response to progesterone, presumably by increasing the concentration of PRs in relevant cells. The decrease in behavioral response seen following heat termination subsequent to progesterone treatment, and indeed, heat termination itself, is referable to the downregulation of PRs by progesterone in some neurons.

Role of the Social Environment and Nonhormonal Influences on Sexual Behavior

One of the most interesting aspects of female sexual behavior is that it is an interactive behavior. As a social behavior, response is dependent not only on the presence of proper hormones in the proper sequence, but on the appropriate stimulation as well, typically by a sexually active male.

Tactile stimulation provided by a male of the same species or by the experimenter influences both the moment-to-moment response of the female as well as the longer-term response. For example, female rats during the appropriate stage of the estrous cycle or ovariectomized rats primed with estradiol and progesterone respond to tactile stimulation of the perineal and/or back or flank region with the lordosis response.

In addition to its regulation by ovarian hormones, the microregulation of copulatory behavior is influenced by afferent input from the social environment, that is, from stimulation received from mating. For example, the postural changes which accompany lordosis – developed in response to stimulation of the receptive field of the pudendal nerve by stimulation of the flanks and perineum – facilitate intromission. Ovarian hormones influence the receptive field of the pudendal nerve, and changes in the response of that nerve in turn influence the female's response to mounting stimulation by the male.

Genitosensory stimulation from social interactions can also have dramatic effects on longer-term changes in behavioral response. Stimulation of the vagina and/or cervix (VCS) either by a male rat or artificially by a mechanical probe may cause abbreviation of the period of sexual receptivity (i.e., early heat termination). On the other hand, nonintromissive, genitosensory stimulation can both prolong heat duration in rats and even induce sexual behavior in the absence of progesterone in estradiol-primed, ovariectomized rats.

As discussed earlier, the expression of sexual behaviors requires interaction of estradiol and progesterone with their respective intracellular receptors. However, as has been shown in many other tissues, a variety of messengers – including neurotransmitters – can act on neurons to substitute for progesterone in its effects on sexual behaviors. While some of these may activate downstream consequences of PR activation (e.g., modulation of neurotransmitter synthesis or release), others facilitate the expression of sexual behavior by acting in neurons containing PRs to activate those receptors. This ligand-independent activation does not occur by binding of the neurochemical to the receptor in the way that progesterone acts; rather, some neurotransmitters, acting through their own membrane receptors, activate second-messenger

systems that, in turn, activate PRs. Likewise, stimulation received from mating can substitute for progesterone, presumably by tapping into this mechanism; that is, mating stimulation induces the release of some of these neurotransmitters onto PR-containing neurons. This, in turn, induces intracellular changes that activate those receptors in the absence of progesterone, resulting in the expression of copulatory and paracopulatory behaviors.

Effects of Mating Stimulation on Reproductive Physiology

In discussing female sexual behavior, it is important to keep in mind the outcomes of the expression of sexual behavior. On one level, it is obvious that the appropriate expression of sexual responses ultimately leads to the opportunity for successful fertilization. On another level, this stimulation results in a variety of physiological responses, some which promote pregnancy, and others which influence the expression of the luteinizing hormone (LH) surge, which in turn results in ovulation.

Prolactin Release and Pseudopregnancy

Vaginocervical stimulation in rats, typically derived from mating stimulation by a male rat, results in pseudopregnancy (also called the progestational state) – a pregnancy-like physiological state characterized by twice-daily surges of prolactin and resultant high levels of progesterone secreted from the corpus luteum. In rats and other species with short (4–5 day) estrous cycles, the corpus luteum is short-lived. VCS, through its actions on the brain, induces surges of prolactin from the pituitary gland twice per day, and these in turn rescue the corpus luteum, causing it to be a functional, secretory tissue for 10–12 days. In the case of a fertile mating, pregnancy continues beyond this period.

Although pseudopregnancy can be induced by cervical probing or mating stimulation during the estrous stage of the estrous cycle, the optimal stimulation is that of paced mating. A particular number of intromissions is more effective if they are spaced in a pattern characteristic of the species.

Prolactin levels also rise in unmated females in conjunction with the preovulatory LH surge stimulated during each estrous cycle by rising estradiol levels. However, intromissive stimuli received during copulation in estrous females also induce an acute prolactin response within 5 min of mating that quickly terminates. This early, VCS-induced prolactin response is not influenced by the female having the opportunity to pace the rate of VCS or by the number of intromissions. Therefore, there are multiple mechanisms by which genitosensory stimulation can influence reproductive physiology.

Oxytocin

Genitosensory stimuli, including VCS, induce the synthesis and release of neural oxytocin in some mammalian species. Mating can induce an increase in oxytocin that may act on the lactotrophs of the pituitary gland to induce the prolactin response to intromissive stimulation; that is, oxytocin is integral to the initiation of the prolactin surges that are a prerequisite for pseudopregnancy.

LH Release and Induced Ovulators

The best examples of species in which mating influences the secretion of LH and ovulation are reflex (or induced) ovulators – that is, species that do not ovulate without appropriate genitosensory stimulation (e.g., cats, rabbits, ferrets, and camels). Although rats, like humans, are spontaneous ovulators, ovulating spontaneously without external stimulation, rats can become induced ovulators (expressing an LH surge in response to VCS) during aging or by maintaining them in an environment of constant light. There is some evidence that humans, like many other spontaneously ovulating species, can become induced ovulators under certain conditions, but this is quite controversial.

In addition to the induction of the LH surge by VCS in reflex ovulators, LH release can be increased in response to mating or VCS in rats undergoing normal estrous cycles. This is consistent with the idea that, even in spontaneous ovulators, genitosensory stimulation influences reproductive physiology.

Relevance of Animal Models to Understanding Human Sexual Desire

For many years, the study of hormones and female sexual behavior in rodents was considered a strong model for studying hormone–brain–behavior relationships within a biological context, but it was generally not thought of as an animal model for understanding hormones and human sexual behavior. For a variety of experimental design reasons, early studies failed to demonstrate a relationship between hormones and sexual desire in humans that might parallel the relationship between hormones and sexual motivation or sexual behavior in rodents. However, more recently, it has become clear that if studies are designed to consider the sexual desire of the females, rather than merely incidence of sexual

intercourse, the study of hormones and rodent sexual behavior can inform an understanding of hormones and sexual desire in humans.

Glossary

Dual-solution task – A maze that can be solved equally well using either place or response learning strategies.

Estrogen receptors (ERs) – A set of receptors that bind the hormone estradiol. The receptors have several forms including: (1) intracellular receptors which, when activated by estrogen, translocate to the nucleus to influence gene transcription and (2) G-protein-coupled membrane receptors which, when activated, initiate intracellular signaling cascades. Both types of receptors include both α - and β -receptor forms, encoded by separate genes.

Memory consolidation – Processes initiated at the time of an experience that provide the mechanisms underlying long-lasting memory.

Memory modulation – Processes initiated at the time of an experience that regulate the mechanisms of memory formation.

Memory retrieval – Recall of previously learned information on later test trials.

Place learning – Acquisition of correct performance on a maze with an optimal solution based on integration of extramaze cues.

Response learning – Acquisition of correct performance on a maze with an optimal solution based on egocentric selection of turns.

of coherent information without a need for long-lasting change. Included in this category are events that are perceived but are not committed to memory. We discuss evidence that specific hormonal responses to some experiences will set the neural stage for memory formation, up-regulating those substrate mechanisms that form memories. To illustrate this feature of hormones and memory, this article discusses stress-related hormones that modulate memory formation. Second, it is also clear that the same information impinging on an animal may be processed, learned, and remembered differently depending on the internal state of the animal. The internal state, in this case, might be considered a background state instead of one that is initiated by the experience. Hormones important to stress, reproductive status, and motivational status appear to create conditions that favor learning certain aspects of a situation more than others. In particular, hormones differentially regulate the balance among memory systems, resulting in an animal using one or another strategy to learn a task and resulting in the animal remembering better one dimension or another of that task. In this article, we use estrogens to provide the principal example of hormones that regulate strategy selection.

While this article deals with memory, hormonal effects on memory should be placed into the broader context of the behavioral actions of the hormones – preparing animals for fight-or-flight, for mating behaviors, or for feeding and drinking behaviors. Regulation of these behaviors, including memory, as well as the effects on physiological processes, represents the functions of the hormones. This article extracts only a small portion of the functions of those hormones we describe.

Introduction

The general field of neurobiology of learning and memory focuses on the mechanisms by which neurons and neural systems change their input–output functions. At a cellular and molecular level, the issue is how particular forms of cell–cell communication can initiate plasticity like long-lasting changes in dendritic spines, in receptor number or binding properties, or in the dynamics of neurotransmitter release. Classes of neural plasticity such as these are believed to characterize the major substrate mechanisms of memory formation.

However, there are layers of additional richness that overlie and interact with these processes. First, it is clear that not all neural activity results in long-lasting changes that might represent memory. Most communication between neurons is likely to be responsible for passage

Arousal and Memory

Imagine that you are waiting at a red light before crossing a busy street from east to west on the way to work. Cars are passing in front of you and pedestrians crossing in the direction on your right walk toward and away from you. The light changes to green, your turn to cross arrives, and you walk across the intersection and continue on to work. A few hours later, your co-worker walks to your desk and asks about your morning. “Did you have trouble with the traffic this morning? It took me 30 min longer than usual to get here.” “It sure was cold this morning but the sun shining made it feel warmer than it was.” But now, the

co-worker gets specific. "What color jacket was the woman wearing who crossed the street when you did?" "What make of car passed in front of you just before you crossed the street?" The blank look on your face says that you have no idea how to answer those last questions.

Now imagine a different scenario. You are again waiting at a light before crossing a busy street as before. As you are waiting for your light to change, there is an automobile accident. A woman runs across the street to see if she can help. A car swerves into oncoming traffic to avoid a pile-up. A police officer is at the same corner and you see her call for help as she approaches the accident. The light changes and, since everything is now under control, you walk across the intersection and continue on to work. A few hours later, your co-worker arrives with the same questions. This time questions like "what color jacket" and "what make of car" elicit long and intricate answers.

The amount of information impinging on your nervous system in the two episodes is about the same. Why would you remember the details of one episode and not the other? One answer is that the accident resulted in a set of physiological responses that included up-regulation of memory formation processes. In extreme form, these responses may make memories more indelible, resulting in flashbulb memories or, in more extreme form, recurring and intrusive memories of posttraumatic stress disorder. As an aside, flashbulb memories while subjectively quite strong can be inaccurate. That is an interesting area of study but not one that is considered here. The important point for this article is that the memories are intense and are maintained with great (even if sometimes erroneous) detail for a very long time. In part, it appears that hormonal components of arousal and stress are important in engaging the mechanisms of memory formation.

Epinephrine Enhancement of Memory

One of the best-studied examples of hormonal enhancement of memory formation comes from experiments that examine the effects of epinephrine on memory. Epinephrine is released into blood from the adrenal medulla in response to arousal and stress and is a classic flight-or-fight hormone. The hormone is released in graded manner across levels of arousal and stress. In rats, epinephrine levels in the blood can increase by 10–15 times across increasing levels of arousal.

Initial studies to show that epinephrine enhances memory involved training rats in a one-trial inhibitory (passive) avoidance task and administering epinephrine near the time of training. Memory is tested at 24 h or later. A standard version of this task is a straight alley divided by a door into a well-lit start (safe) compartment and a

dark shock compartment. Because rats prefer the dark, they will quickly cross from the start compartment to the dark compartment. Upon entering that compartment, the rats receive an electric shock to the feet delivered through metal flooring. If the shock level is sufficiently high, the rat will remain in the start compartment on the memory test trial. If the shock level is lower, the rat might hesitate but still cross into the dark compartment. Thus, the latency to cross into the dark compartment is the operational definition of memory; high latencies indicate strong memory while low latencies indicate weak memory. Because the higher and lower shock levels differ in how aversive they are, it is unremarkable that the rats' performance on memory tests reveals better memory after strong versus weak shock.

The question here, however, is: What is the contribution of epinephrine release to making memories strong? To address this question, rats were trained with a low shock intensity and received epinephrine injections immediately after training, that is, a posttraining design (**Figure 1**). The results show that epinephrine injections after low shock intensity resulted in strong memory – as might come from a higher shock intensity – on later test trials. The effects of epinephrine on memory follow an inverted-U dose-response curve; high doses can cause amnesia instead of hypermnesia. The optimal dose of epinephrine resulted in blood epinephrine levels comparable to those obtained by increasing the shock intensity. Therefore, the findings suggest that epinephrine is released in response to an experience in a manner that modulates the formation of memory for that experience.

The posttraining design is of interest in two main respects. First, because the hormone is administered after training is complete, epinephrine effects on memory cannot readily be attributed to nonmnemonic actions such as sensory, motor, or motivational differences. Second, injections of epinephrine delayed by an hour or more after training have no effect on later memory scores, indicating that epinephrine has retrograde and not anterograde effects on later memory and is therefore exerting its effects on the processes responsible for the formation of memory. The retrograde actions fit the endogenous pattern of epinephrine release. In many experiences, the information to be remembered may well precede the release of the hormone by a short time duration.

Since these early experiments, additional research has shown that epinephrine enhances memory for a wide range of tasks, including both aversive and appetitive tasks, and also enhances memory in a wide range of species including the humans. In addition, epinephrine enhances long-term potentiation (LTP) in both acute and chronic preparations, in the latter case especially delaying the rate of decay of LTP. Therefore, epinephrine appears to modulate a form of neural plasticity that may participate in memory formation.

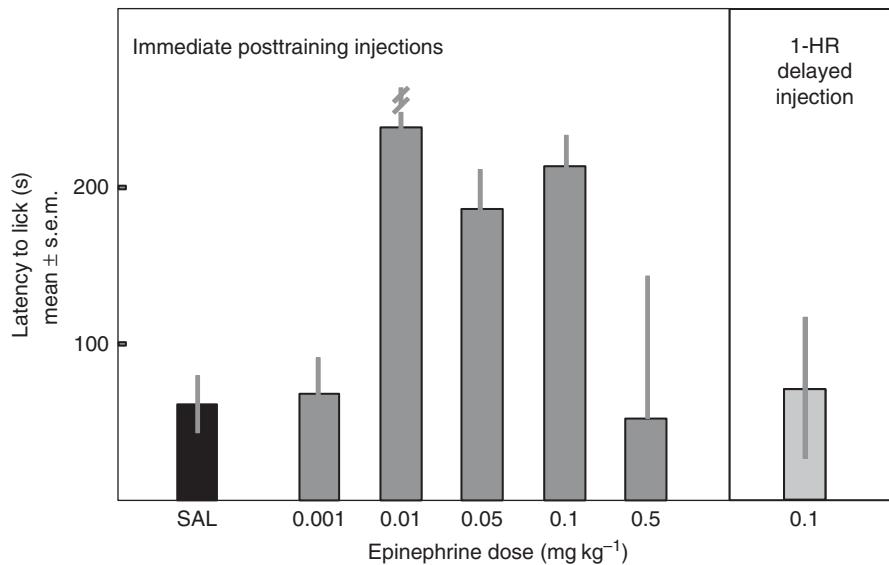

Figure 1 Epinephrine enhancement of memory. Rats received a single injection of epinephrine immediately or 1 h after training on a one-trial inhibitory avoidance task. Memory was assessed 24 h later. Rats that received epinephrine immediately after training exhibited enhanced 24-h memory in an inverted-U dose-dependent manner. The retrograde effects of epinephrine on memory had dissipated by 1 h following training. From Gold PE and van Buskirk RB (1975) Facilitation of time dependent memory processes with posttrial epinephrine injections. *Behavioral Biology* 13: 145–153.

The generality of epinephrine effects extends beyond task and species. Epinephrine may also contribute to both enhancement and impairment of memory by many treatments. The main evidence for this statement is that peripherally administered adrenergic receptor antagonists, blocking the peripheral effects of epinephrine, attenuate the effects on memory not only of epinephrine but also of treatments such as subseizure and supraseizure electrical stimulation of the brain, analeptic drugs, neurotransmitter synthesis inhibitors, and protein synthesis inhibitors. Thus, epinephrine may be part of a common pathway for the effects of multiple treatments on memory. Results suggest that impairments of memory by many treatments – for example, those that produce seizures or inhibit protein synthesis – may reflect extreme physiological stress responses to those treatments, releasing epinephrine and other modulators of memory at levels that reach the high end of inverted-U functions to cause amnesia.

Mechanisms of Epinephrine Enhancement of Memory

Although there is a relatively small epinephrine neurotransmitter system within the brain, epinephrine does not enter the brain from the blood under normal physiological conditions. Therefore, there must be intermediate peripheral mechanisms that are sensitive to epinephrine and then act on the brain to modulate memory. A major contributor to the effects of epinephrine on memory

appears to be glucose. One of the classic effects of epinephrine is to liberate glucose from hepatic stores upon activation of β -adrenergic receptors. There is considerable evidence showing that the increase in blood glucose levels contributes importantly to epinephrine effects on memory. One example is that glucose itself, injected or ingested by laboratory rodents and by humans, enhances memory. In rats, memory enhancement by glucose follows an inverted-U dose-response, as seen earlier for epinephrine. The doses of epinephrine and glucose that are optimal for enhancing memory result in comparable blood glucose levels. However, there are three circumstances in which epinephrine modulation of memory is attenuated while glucose modulation of memory is retained. These nonparallel results each provide good evidence that epinephrine modulation of memory is mediated by increases in blood glucose levels. First, as noted above, adrenergic receptor antagonists block the effects on memory of epinephrine and many other treatments. For epinephrine, there is direct evidence that the receptor antagonist also blocks release of glucose after epinephrine administration, consistent with the idea that epinephrine acts through glucose. In addition, even in the presence of adrenergic receptor blockade, glucose retains the ability to enhance memory, apparently acting downstream from the function of epinephrine. Second, food-deprived rats lose the glucose stores in the liver, making epinephrine ineffective at releasing glucose into blood. Food deprivation results in decreased efficacy of epinephrine enhancement of memory but robust enhancement of memory with glucose. Third, senescent

Fischer-344 rats exhibit poor memory, evident as rapid forgetfulness of new information. During aging, the ability of epinephrine to release glucose and to enhance memory is diminished. However, glucose remains as potent an enhancer of memory formation in aged as in young rats. Thus, these several dissociations of epinephrine and glucose effects on memory each suggest that increases in glucose represent a mechanism downstream from epinephrine in modulating memory.

In contrast to the exclusion of circulating epinephrine from the brain, glucose itself enters the brain via a facilitated uptake mechanism. Still, it remains possible that glucose also acts on peripheral physiology to enhance memory by an additional mechanism outside the brain. Evidence that glucose acts directly on the brain to enhance memory takes two forms. First, direct microinjections of glucose into specific brain targets such as the hippocampus and amygdala enhance memory. Second, measurements of extracellular glucose levels in the hippocampus before and during memory tests indicate that glucose is depleted by these tests and is repleted by peripheral injections of glucose. Interestingly, the depletion of glucose in the hippocampus is far greater in aged rats, which do not exhibit increases in blood glucose levels during training, and memory is restored to the values seen in young rats by either central or peripheral injections of glucose that block the depletion of brain glucose during memory testing.

Understanding the mechanisms by which glucose acts to modulate memory within the brain is an active area of investigation but the story is not complete. One mechanism with some support is that glucose closes potassium-adenosine triphosphate (K-ATP) channels on neurons, thereby increasing excitability and neurotransmitter release. This mechanism is based on the manner in which glucose regulates release of insulin in the β -cells of the pancreas, modulating stimulus-secretion coupling by availability of ATP derived from glucose. Drugs that close and open K-ATP channels enhance and impair memory, respectively, when microinjected directly into the brain. In addition, glucose enhancement of memory is accompanied by increases both in acetylcholine and norepinephrine release at the time of behavioral testing. Both of these are neurochemical modulators of memory processing in the brain. Whether these or other neurotransmitters mediate enhancement of memory by glucose is unclear.

Corticosterone Enhancement of Memory

In addition to the adrenomedullary hormone epinephrine, the adrenal cortical hormone corticosterone also has potent effects on memory. Like epinephrine, corticosterone enhances memory for many tasks, also generally

following an inverted-U dose-response curve and also exhibiting time-dependent enhancement of memory. Unlike epinephrine, corticosterone can enter the brain directly and act on brain steroid receptors. Corticosterone is effective at enhancing memory if direct brain injections are administered into the hippocampus or amygdala. The amygdala is especially important to the effects of corticosterone on memory formation. Lesions of the basolateral nucleus of the amygdala block the effects of corticosteroids on memory. In addition, lesions of the stria terminalis – an output path from the amygdala – also block enhancement of memory by corticosterone. Furthermore, corticosterone does not enhance memory in rats pretreated with injections of β -noradrenergic antagonists into the amygdala. The results obtained with intra-amygdala infusions of β -noradrenergic receptor antagonists are consistent with ideas that noradrenergic mechanisms in the amygdala integrate modulators of memory and regulate memory formation in many brain areas.

Although corticosterone treatments generally enhance memory formation when administered near the time of training, the same corticosterone treatments impair retrieval of memory when administered shortly before test trials. In contrast to modulation of memory formation, impairments of memory retrieval by corticosterone injections do not appear to involve the amygdala as a primary target of the hormone but, instead, the amygdala seems to be permissive for these impairments. Infusions of corticosterone into the amygdala near the time of test trials do not impair retrieval of memory for a swim task. However, lesions of the basolateral nucleus of the amygdala or pretreatment of the basolateral nucleus of the amygdala with β -adrenergic receptor antagonists block impairment of memory at retrieval resulting from intrahippocampal injections of glucocorticoids.

Estrogenic Enhancement of Memory

Estrogens, including estradiol (the predominant form of estrogen produced by the ovary in humans and other mammals), modulate memory formation. In this regard, the basic information is similar to that for epinephrine and corticosterone. Both pre- and posttraining injections of estradiol near the time of training result in enhancement of learning and memory for several tasks. For example, injections of cyclodextrin-encapsulated estradiol, a rapidly metabolized estrogen, given to ovariectomized rats immediately after training in a swim task enhanced memory when tested 24 h later. Similar results have been obtained with other estrogenic compounds administered after inhibitory avoidance, object recognition and place recognition training. In each case, injections delayed by 1–2 h after training had no effect on the later memory

tests. Direct injections of estrogens into the hippocampus also enhance memory. Thus, estrogens are effective retrograde enhancers of memory formation after training in several tasks, providing results similar to those obtained with epinephrine and corticosterone. However, the available information about the dose-response properties, the mechanisms of action on memory, and the brain loci, beyond the hippocampus, for time-dependent modulation of memory is scant at the present time.

Estrogens and Learning Strategies

While estrogens are better known for their enhancing effects on memory, there is growing evidence that performance on some cognitive tasks is impaired by estrogen treatment. The direction of estrogenic effects depends upon several factors including the stress or age status of the animal and the learning strategy required for optimal task performance. Most notably, acute treatments of

estradiol to young adult rats deprived of ovarian hormones through ovariectomy produce impairments in sensorimotor learning that requires rats to make a body turn – that is, right or left – to find food in a maze or to use a cued target to escape water. In these instances, rats with negligible-to-low levels of estrogens perform quite well. In analogous tasks that require rats to use place- or spatial-based strategies in which rats use extramaze cues to guide navigation, the same treatments of estradiol produce enhancements in learning (**Figure 2**). Moreover, when given an option between response and place strategies in dual solution tasks, rats with high estrogen profiles tend to use place strategies while rats with low levels use response strategies. Therefore, both high and low levels of estrogens regulate learning strategy. Learning speed in these dual-solution tasks is similar across rats with different hormonal profiles, further supporting the idea that ovarian hormones regulate not only how much, but also *what* information is acquired. Stress also biases the

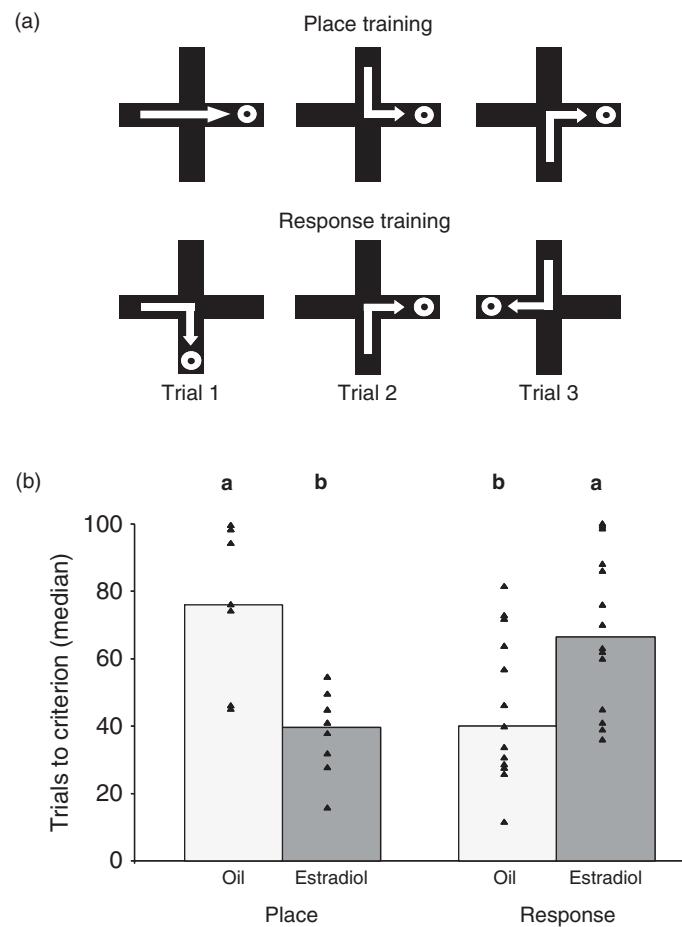

Figure 2 Effects of systemic estradiol on place and response learning in ovariectomized rats. (a) Rats were trained to find food in a plus-shaped maze using either a place strategy, which the goal was always in the same place in the room, or by using a response strategy in which the goal was reached by turning right (or left). (b) Estradiol-treated rats exhibited enhanced learning in the place task relative to oil-treated rats, while the converse was true for response learning. Triangles indicate number of trials for individual rats. Groups marked with different letters are significantly different from each other. From Korol DL and Kolo LL (2002) Estrogen-induced changes in place and response learning in young adult female rats. *Behavioral Neuroscience* 116: 411–420.

relative use of different cognitive strategies, providing possible evidence of convergence between reproductive and stress hormones and highlighting the possibility that a broad array of hormones may regulate learning strategy.

Mechanisms of Estrogenic Effects on Memory

Anatomical substrates and loci of action for estrogens

From findings in male rats, it is well established that response and cued learning is impaired by structural or chemical lesions to the dorsolateral striatum, while place learning is impaired by lesions to the hippocampus. Thus, the opposing effects of estrogens are likely due to differential modulation of these, and perhaps other, memory systems, that is, the specific neural structures and related networks upon which optimal task performance relies. In fact, estradiol infused directly into the hippocampus enhances place learning with no apparent effect on response learning, whereas infusions into the striatum produce response-learning impairments without having an effect on place learning. Estradiol administered to the hippocampus and prefrontal cortex enhances working memory, but with different effective time courses for the two neural loci. From results such as these, it is becoming clear that estrogens potently regulate learning, memory processing, memory formation, and long-term retention through actions across many diverse brain regions.

Some of the earliest reports examining ‘nonreproductive’ regions of the brain pointed to the hippocampus as a particularly estrogen-sensitive tissue. It has been known for decades that high estrogen levels render the hippocampus more seizure prone due to increased neuronal excitability. Increased activity may result from or even lead to other forms of plasticity such as changes in neuronal structure and chemistry. A landmark set of studies in the 1990s demonstrated that the density of dendritic spines and excitatory synapses in the hippocampus fluctuated in synchrony with circulating levels of ovarian steroids either naturally across the rat 4–5-day estrous cycle or following treatments of estradiol in ovariectomized rats. Perhaps the most remarkable characteristics of these synaptic changes are their magnitude and timing. As large as a 40% increase in synapse density can be observed within 2–3 days of estradiol treatment. Equally impressive is that synapse loss with declining levels of hormone occurs over the course of about 1–2 days. Thus, the synaptic content of the brain is in constant flux, with the dynamic regulated by ovarian hormones. Glucocorticoids have also been shown to restructure dendrites in the hippocampus. In this way, estrogens and other neuroactive hormones may orchestrate information processing and subsequent cognitive function.

The focus on the hippocampus as a primary site for estrogenic modulation is warranted given the robust

responsiveness of the hippocampus to estrogen treatment. However, several other brain regions that are implicated in learning and memory, such as the prefrontal cortex, basal forebrain nuclei, striatum, and amygdala, also demonstrate structural, chemical, and functional plasticity following estrogen exposure and most likely play important roles in estrogen modulation of specific aspects of learning and memory. For example, estradiol treatments facilitate acetylcholine synthesis in the striatum and augment amphetamine- or behavior-induced nigrostriatal dopamine release. It is thought that these neurochemical systems are important for reward and stimulus-response based learning. Interestingly, estradiol reduces glutamate signaling through N-methyl-D-aspartate (NMDA) and α -amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) receptors in the striatum and thus may impair cortical-striatal plasticity and related behaviors such as response learning.

Neurochemical actions of estrogens

One striking feature of estradiol is its robust effects on neuromodulator systems. Estrogens may act through the modulation of other neuromodulators to produce effects on cognition and underlying neural mechanisms. Several reports show alterations in the synthesis, release, and metabolism of acetylcholine derived from the basal forebrain. Moreover, acute treatments of estradiol facilitate potassium-stimulated and training-induced increases in acetylcholine. In addition, estrogen-induced synaptic change in the hippocampus depends upon the presence of acetylcholine. When selective lesions are made to the cholinergic afferents to the hippocampus, estradiol treatment no longer increases spine density or facilitates place learning, indicating that estrogens may act through acetylcholine modulation of structure and function. Other neurotransmitters such as dopamine, norepinephrine, and serotonin have also been implicated in estrogen-induced changes in brain and cognition. Thus, estrogens may act as ‘metamodulators’ to regulate cognition indirectly by modulating cognitive modulators.

Estrogen receptors

Like other steroid hormones, estrogens up- and down-regulate gene transcription by binding to cognate receptors, translocation to the nucleus of receptor–hormone complexes, and binding to specific response elements on a variety of genes. Estradiol effects on learning may be mediated through the activation of two classical subtypes of estrogen receptors (ERs), ER α and ER β , differentially distributed throughout the central nervous system (CNS). Intrahippocampal ER blockade with an estrogen-receptor blocker can reverse the enhancing effects of systemic estradiol on place and object-recognition learning while intrastratial ER blockade attenuates the impairing effects

of systemic estradiol on response learning, suggesting that estradiol likely acts through ERs in specific brain regions to modulate cognition.

Not all brain regions express classical ERs, not all neurons within a brain region are ER-positive, and not all ER-positive neurons express both subtypes of ERs. The complexity of ER expression may lay the foundation for the complexity of estrogen effects on cognition, in that estradiol activation of ER α produces a different profile of gene activation than does ER β activation. Through a variety of cell biological methods, ERs have been localized to the hippocampus, amygdala, and prefrontal cortex. While the prefrontal cortex is enriched in ER β , both ER α and ER β can be found in the hippocampus and the amygdala; in some cases, both receptor subtypes are expressed in the same neurons. Interestingly, assessments of the mRNA and protein for both ER subtypes suggest little-to-no nuclear distribution of ERs in the striatum. It may thus be surprising that estradiol dramatically alters striatal dopamine release and calcium signaling in dissociated striatal neurons, functions that may also play a role

in estrogen regulation of striatum-sensitive learning. However, recent evidence demonstrates that estrogens can initiate cell-signaling pathways leading to rapid activation of transcription factors, precluding the need for classical, nuclear ERs to produce emergent effects on brain. Importantly, extranuclear ERs have recently been found in dopaminergic neurons in the substantia nigra that project to the striatum and also in cholinergic interneurons in the striatum. It is very likely then that estrogens modulate striatal function and striatum-mediated learning through nonclassical receptor-mediated events. Similar rapid effects of estrogens on hippocampal and cortical neurons have been described, suggesting that parallel rapid and slower pathways are active in neurons in these brain regions (Figure 3).

Estrogens may also produce very different effects on brain function and cognition when acting through ER α , ER β , or both subtypes, irrespective of the mode of ER activation, that is, by rapid or slow actions. Based primarily on early behavioral reports and on ER distribution patterns in different brain regions, for example,

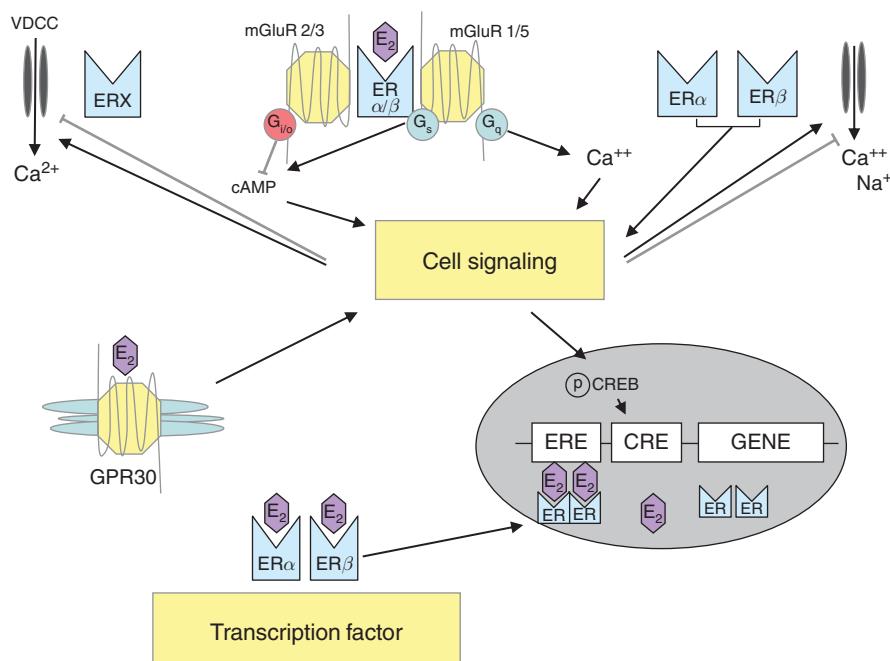

Figure 3 Schematic depicting cellular mechanisms of estradiol (E₂) signaling. Shown in this graphic is a subset of possible pathways through which estrogens can influence neuronal cell function and thus learning and memory through several different mechanisms. The classic mode of estrogen signaling is through estrogen receptors (ERs) that act as transcription factors. Both ER α and ER β subtypes of ERs translocate to the nucleus upon ligand binding, dimerize, and bind to estrogen-response elements (EREs) on genes either to activate or to repress transcription. Estrogens can also act through nonnuclear means to activate or inhibit signaling cascades, some of which may act on L-type or voltage-dependent calcium channels (VDCC) or neurotransmitter channels (NMDA/AMPA) while other cascades activate, by phosphorylation, the transcription factor, cAMP response-element-binding protein (CREB). In both hippocampal and striatal neurons it has been suggested that membrane-associated ER α and ER β interact with metabotropic glutamate G-protein-coupled receptors (GPCR) to increase and decrease phospho-CREB (pCREB) depending upon the glutamate receptor subtype and the activation status of the cells. A new GPCR, GPR30, that binds estradiol has been found in endoplasmic reticulum of neurons. These nonclassical forms of signaling can be quite rapid in onset, despite the possibility for longer more durable effects through pCREB-related gene transcription. Grey lines indicate inhibition, black arrows activation.

hypothalamic versus other, it has been suggested that estrogenic regulation of sexual behavior relies on ER α activation but regulation of cognition relies on ER β activation. Direct tests of the involvement of different ER subtypes in estrogenic modulation of cognition have been made by using compounds that bind preferentially to one ER subtype, including phytoestrogens, such as genistein derived from soy, that selectively bind ER β and selective ER agonists or modulators (SERMs) targeted toward ER α or ER β . ER β -selective agonists enhance memory in a variety of contexts, for example, in the spatial version of an escape swim task and in a passive avoidance task. Interestingly, ER α agonists are also effective memory enhancers for passive avoidance, suggesting a role both for ER α and ER β activation in learning and memory. The evidence pointing to the cognitive role of one ER subtype over another is clearly mixed. However, while it is tempting to sort estrogenic effects solely by ER subtype, it is perhaps more parsimonious to sort effects by neural systems that are engaged during behavior, and thus, by association, the pattern of ER subtypes across these different neural regions.

Temporal aspects of estrogen-induced modulation

As alluded to above, estrogens may act on cognition through mechanisms that are slower in onset, through rapid-signaling events, or both. The induction of dendritic spines in the hippocampus, shown to occur across the estrous cycle and to peak after 48 h of estrogen exposure, can occur rapidly within 30 min of estradiol exposure, most likely through nongenomic signaling processes involving mitogen-activated protein kinases. Many of the cognitive effects of estradiol can be also seen within 1–2 h of treatment. For example, estradiol infused into the striatum 2 h prior to training impairs response learning to the same degree as 2 days of exposure. Immediate treatments of estradiol, but not those delayed by 2 h, either into the hippocampus or systemically, enhance spatial learning and memory. Together, these data suggest that estrogen actions are rapid in onset and may modulate both learning processes and memory-formation mechanisms. The activating effects of steroids may promote or facilitate the genomic response. Equally likely, and not mutually exclusive, the slower, more trophic actions of steroids may provide an activated neural state or platform upon which the faster, activating effects may take place. In this way, hormones may put the brain into a state ready for plasticity.

Glossary

Corpora cavernosa – A pair of sponge-like tubes along the length of the penis that contain most of the blood during erection; they merge at the head of the penis.

Corpus spongiosum – A sponge-like tube along the bottom of the penis that contains the urethra and enlarges at the distal end to form the glans penis.

Postejaculatory interval – The time after an ejaculation until the next vaginal intromission.

Spinal nucleus of the bulbocavernosus (SNB) – A nucleus in the lumbosacral spinal cord that exerts somatomotor control of genital reflexes through the pudendal nerve, which splits into motor and sensory branches, both of which also carry sympathetic efferents.

Urethrogenital reflex – A model of ejaculation and orgasm elicited in anesthetized, spinally transected male rats by distending the urethra with saline and then releasing the pressure; it is characterized by clonic contractions of the perineal muscles, rhythmic firing of the cavernous nerve, erection, and ejaculation.

Vomeronasal organ – A pair of tunnels along the sides of the nasal cavity that contain receptors for species-specific chemosensory stimuli; it is the first processing stage of the accessory olfactory system.

Most, but not all, male mammals ejaculate after multiple intromissions. Ejaculation in rodents includes a deeper, longer thrust during which semen is ejected. The male dismounts and begins genital grooming. Male canids begin to ejaculate soon after penile insertion; a swelling at the base of the penis results in a lock of the male to the female. Male ungulates ejaculate immediately upon intromitting. In humans, rhythmic contractions of skeletal and striated perineal muscles accompany ejaculation and are associated with orgasm.

Ejaculation is followed by sexual quiescence, the post-ejaculatory interval (PEI). In rats, this lasts 5–10 min and is accompanied by 22 kHz ultrasonic vocalizations during the first 75%, called the absolute refractory period, because the male will not copulate in response to any stimulus. During the remaining PEI, the relative refractory period, the male may resume mating in response to nonspecific arousal or a novel female partner. After the PEI, male rats copulate until they reach satiety, often after seven to nine ejaculations. Copulation to satiety increases dopamine (DA) metabolites in the medial preoptic area (MPOA) and nucleus accumbens (NAcc) and enkephalins in the hypothalamus. Androgen receptor density decreases in the MPOA, NAcc, and ventromedial hypothalamic nucleus (VMH).

Sexual Experience

Sexual experience decreases latencies to copulate and to ejaculate. It also may decrease the disruptive effects of a novel environment, various lesions, and castration. Experienced rats have higher levels of nitric oxide synthase (NOS) in the MPOA, greater androgen secretion, and more cells in the MPOA and NAcc activated by ejaculation.

Puberty and Aging

Male rats begin mounting between 40 and 50 days of age, intromitting between 44 and 75 days, and may show the behavioral pattern of ejaculation between 48 and 75 days.

Patterns of Male Sexual Behavior

Description of Behavioral Elements

Most male mammals mount females dorsally from the rear. The female may assume a reflexive dorsiflexion of the spine, called lordosis. The male then begins pelvic thrusts, which may or may not result in vaginal insertion. During a nonintromissive mount, the male dismounts slowly. Intromission is characterized by a deeper thrust, followed by a springing dismount and genital grooming.

Prepubertal castration prevents copulation, while exogenous testosterone (T) or estrogen (E) can hasten its onset. However, exogenous hormones cannot hasten copulation in male Syrian hamsters. In male rats, T levels start to rise about day 40, with a surge occurring around day 50. However, the T surge occurs after the onset of copulatory behaviors and *ex copula* reflexes. Copulation in male hamsters begins after the increase in T begins, but before the T surge; the lack of pubertal T impairs T-induced mating in adulthood.

Aging in humans, monkeys, and rodents decreases the probability of mating and increases latencies to mount, intromit, and ejaculate. In male rats and humans T levels decline, but exogenous T may only partially restore sexual ability. A decline in estrogen receptors (ER), but not androgen receptors (AR), may mediate the ejaculatory deficit of old male rats. Behavioral deficits in middle-aged rats (18–19 months) may be associated with decreased DA and norepinephrine (NE), and increased serotonin (5-HT), in the NAcc and MPOA.

Sexual Reflexes

Observations during Copulation

In many species, the penis is visible during copulation; however, erections in rodents are very brief and hidden from view. Erection, intromission, and ejaculation are usually inferred from characteristic behaviors, and the female's vagina can be examined for the presence of sperm. Penile pressure and electrical activity in the striated perineal muscles can be measured during copulation; however, these techniques are technically difficult. Therefore, *ex copula* measures of sexual reflexes are often used. However, *in copula* and *ex copula* erections may differ in their hormonal, physiological, and neurochemical regulation.

Ex-Copula Sexual Reflexes

Male rodents occasionally have erections without any obvious sexual stimulus; such erections may be increased by certain drugs or the presence of an inaccessible receptive female. They consist of extension of the engorged glans from the penile sheath and are often accompanied by genital grooming. Reflexive erections can be elicited by manual stimulation in many species. However, such stimulation in rats inhibits erection. Genital reflexes can be elicited in rats or mice by restraining them on their backs and retracting the penile sheath. Pressure around the base of the penis elicits erections and anteroflexions (flips); seminal emission may also occur. The urethrogenital reflex in anesthetized, spinally transected male rats is a model for both erection and ejaculation. The urethra is distended with saline; when the pressure is released,

clonic contractions of the perineal muscles occur, with rhythmic firing of the cavernous nerve, erection, and ejaculation. A similar pattern is observed in human climax and rats' ejaculation.

Mechanisms of Erection

Erection of the vascular penes of humans, monkeys, dogs, cats, and rodents results primarily from vascular relaxation, coordinated with striated muscle contraction, whereas the fibroelastic penes of ungulates, such as sheep and goats, are extruded by the penile muscles. Most of the penile shaft comprises the paired corpora cavernosa; the corpus spongiosum surrounds the urethra and enlarges into the glans at the end of the penis. The corpora cavernosa are enclosed by a tough capsule, so when they fill with blood, pressure against the venous outflow traps blood in the penis. Contraction of perineal striated muscles enhances the erection.

Three major pathways control penile erection: the pelvic nerves (mostly parasympathetic, proerectile), the hypogastric nerves (sympathetic, antierectile), and the pudendal nerves (somatosensory and motor). The pelvic nerve exits the lumbosacral spinal cord and travels to the penile corpora and vasculature through the pelvic plexus and cavernous nerve. It also carries some sympathetic axons. The spinal nucleus of the bulbocavernosus (SNB) exerts somatomotor control through the pudendal nerve, which splits into motor and sensory branches, both of which also carry sympathetic efferents. Stimulation of the striated perineal muscles increases rigidity of an erection, but does not result in erection if the penis is flaccid. Sympathetic, primarily antierectile influence arises from two sources. The lumbar splanchnic nerves synapse in the hypogastric plexus, from which hypogastric nerves travel via the cavernous nerve to the penis. Axons from the paravertebral sympathetic chain travel via the pelvic nerve to the pelvic plexus, then through the cavernous nerve to the penis. Tonic sympathetic input keeps the penis flaccid. However, the sympathetic system contributes to erection, perhaps by constricting nonpenile vessels, thereby diverting blood to the penis.

Cellular Mediators of Erection

The main mediator of erection is nitric oxide (NO), a soluble gas produced by nitric oxide synthase (NOS), that acts as both a second messenger and a neurotransmitter. Parasympathetic nerves contain neuronal NOS (nNOS), and the endothelium contains endothelial NOS (eNOS). NO from parasympathetic nerves diffuses into smooth muscle cells and activates guanylyl cyclase, which produces cGMP, which then activates protein kinase G, and to some extent protein kinase A. These enzymes phosphorylate proteins that sequester Ca^{2+} , leaving less in

the cytoplasm and relaxing the smooth muscle. Phosphodiesterase 5 (PDE₅) terminates cGMP activity. Sildenafil citrate (Viagra), tadalafil (Cialis), and vardenafil (Levitra) treat erectile dysfunction by inhibiting PDE₅. The initial increase in blood flow induces shear stress in endothelial tissue, which activates eNOS and prolongs the erection. Erection can also be elicited by vasoactive intestinal peptide, calcitonin gene-related peptide, and prostaglandin E₁.

Ejaculation

Ejaculation depends on coordinated autonomic and somatic responses. Seminal emission includes autonomic activation of the prostate, and ejection involves rhythmic contraction of perineal and pelvic floor striated muscles. Friction on penile skin and intravaginal pressure stimulate seminal drain into the posterior urethra, and chemical and mechanical stimulation of the urethra by the semen triggers expulsion. A central pattern generator in the lumbosacral cord includes a group of galanin-containing neurons that integrate and relay genital sensory and motor signals related to ejaculation. Serotonin (5-HT) from the nucleus paragigantocellularis (nPGi) in the medulla tonically inhibits ejaculation, though intraspinal 5-HT may act through 5-HT_{1A} and 5-HT_{2C} receptors to elicit ejaculation. Dopamine (DA), norepinephrine (NE), acetylcholine (ACh), and oxytocin may also stimulate ejaculation.

Role of Gonadal Steroids

Testosterone (T) and its Metabolites

Male sexual behavior is heavily dependent on T and its metabolites estradiol (E₂) and dihydrotestosterone (DHT). Although steroids are essential for mating in most rodents, they play a more modulatory role in humans. T exerts organizational effects during sex differentiation and activational effects in adulthood. T has primarily slow, genetically mediated effects, although it can also have faster effects through membrane receptors. T levels are higher than necessary to activate sexual behavior; higher levels are needed for sperm production in the testes.

Castration and T Restoration

Plasma levels of T become immeasurable by 24 h after castration, though male rats may continue to copulate for days or weeks. However, intromission latency increases within days, and the number of intromissions before ejaculation actually decreases; thus, T may increase intromissions preceding ejaculation, thereby increasing sperm in the ejaculate and triggering a progestational state in the female. Half to two-thirds of men who were

castrated as treatment for sexual offenses lost sexual interest rapidly, while others reported gradual decreases. Long-term castrated rats require 5–10 days of T to restore mating; 5–7 weeks are required for hamsters. However, in rats, T affected MPOA firing within minutes, and rats and mice started mounting in 35 and 60 min, respectively. Thus, steroids activate brain areas within minutes but require slower genomic effects to restore copulation fully. Compared to copulation, *ex copula* reflexes are lost more quickly after castration and restored more rapidly after T replacement. In spinal transected rats, reflexive erections were decreased 24 h after castration and restored by 24 h of T replacement. Spinally intact males required an additional day of T, probably to reduce supraspinal inhibition.

Role of T Metabolites

T is primarily a prohormone, being converted in target organs to either E₂ or DHT. There are at least two E receptors, ER α and ER β . Both T and DHT bind to the AR, but DHT binds with greater affinity. Some target cells produce both E₂ and DHT and have both ERs and ARs. The relative importance of estrogenic and androgenic stimulation is species specific. In castrated rats and mice, E₂ can reinstate most aspects of copulation. DHT, which cannot be aromatized to E₂, cannot. However, E is usually insufficient to fully maintain or restore copulation. Thus, stimulation of both ER and AR is necessary to fully restore mating. In addition, DHT is both necessary and sufficient to maintain and restore *ex copula* reflexes in rats. Gonadally intact males that lack ER α (ER α knockout mice, ER α KO) or aromatase (ArKO) have almost no ejaculations. However, treatment with T and a dopamine agonist in ER α KO mice restored copulation. Aromatization is not required in other species, including rabbits, guinea pigs, hamsters, deer mice, and monkeys. However, males normally produce both classes of hormone, which together promote all aspects of mating. Men with erectile dysfunction have relatively normal T levels. However, T or DHT treatment of hypogonadal men or aging men with moderate decreases in T can improve erectile function.

Systemically and Intraventricularly Injected Drugs

Dopamine (DA)

In the late 1960s, the DA precursor L-Dopa was found to increase libido and sexual potency in Parkinsonian patients. In rats, mice, and men, systemically administered DA agonists facilitate, and DA antagonists impair, copulation and sexual motivation. There are two families of DA receptors: the D₁-like family activate adenylyl cyclase

and comprise the D₁ and D₅ subtypes; the D₂-like family consists of D₂, D₃, and D₄ subtypes that inhibit adenylyl cyclase. D₁-like agonists increase sexual motivation in rats and mice and facilitate sexual behavior across taxa, including whiptail lizards, geckos, quail, and starlings. The effects of DA agonists are dose dependent; low doses facilitate, and high doses inhibit copulation, perhaps by inducing stereotypic behavior. There are contradictory effects of D₁- and D₂-like agonists on *ex copula* reflexes, due perhaps to lack of selectivity of the agonists.

Norepinephrine (NE)

NE can either facilitate or inhibit male sexual behavior, depending on the dose and receptor subtype activated. Sympathetic axons to the penis promote detumescence. However, increased NE activity, either by blockade of α₂ autoreceptors or stimulation of α₁ adrenoceptors, can increase sexual arousal. The influence of β adrenoceptors is not clear.

Serotonin (5-HT)

5-HT generally inhibits male sexual behavior. Selective serotonin reuptake inhibitors (SSRIs) increase 5-HT in the synapse and impair sexual function in humans and rats. However, 5-HT_{1A} receptor stimulation markedly facilitates male rat ejaculation. 5-HT's inhibitory actions may be mediated by 5-HT_{1B} and 5-HT₂ receptors in rats. In mice, in contrast to rats, both the 5-HT_{1B} and the 5-HT_{1A} subtypes inhibit mating. Stimulation of 5-HT_{2C} receptors can increase erections and inhibit ejaculation in monkeys and facilitate erection in rats.

The fact that the facilitative effects of 5-HT_{1A} agonists on ejaculation are opposite to those of 5-HT itself and that somatodendritic autoreceptors are the 5-HT_{1A} subtype, suggest that 5-HT_{1A} agonists act at those auto-receptors to reduce 5-HT release. However, facilitative effects of 5-HT_{1A} agonists are obtained after infusion into the sites where only postsynaptic receptors are found. Therefore, postsynaptic receptors may mediate the facilitative effects.

Glutamate

Glutamate is the major excitatory neurotransmitter in the central nervous system (CNS). Low doses of kainic acid, an agonist at α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)/kainate glutamate receptors, enhance copulatory behavior in sexually sluggish male rats, but not in good copulators. Systemic injection of an N-methyl-D-aspartate (NMDA) antagonist impairs mating in experienced and naïve male rats and blocks the improvement due to noncopulatory exposures to estrous females.

Nitric Oxide (NO)

NO facilitates erection (parasympathetic) but inhibits ejaculation (sympathetic). Neuronal nitric oxide synthase knock-out (nNOS KO) mice have normal penile function due to a compensatory increase in endothelial NOS (eNOS) and ejaculate with fewer mounts and intromissions. Intraperitoneal injection of NO's precursor, L-arginine, enhances copulation in naïve and experienced rats, whereas intracerebroventricular (icv) injection of a NOS inhibitor impairs mating in naïve rats.

Endocannabinoids

Endocannabinoids are retrograde neuromodulators. The cannabinoid CB1 receptor is located almost exclusively at axon terminals, where it inhibits neurotransmitter release. Delta-9-tetrahydrocannabinol (THC) and other endogenous and exogenous CB1 agonists impair copulation in mice and rats, while a CB1 antagonist accelerates ejaculation.

Endogenous Opioids

There are three major classes of endogenous opioid peptides: endorphins, enkephalins, and dynorphins. Exogenous opiates, such as morphine and heroin, impair sexuality in male addicts and in various other species. Furthermore, sexually inactive male rats have increased basal concentrations of several endogenous opioids in the hypothalamus. Endogenous opioids act on μ, δ, and κ receptors, with μ and δ receptors mediating most of the inhibitory effects. Opioid antagonists facilitate sexual behavior in sexually inactive or naïve rats, reverse sexual satiation, decrease ejaculatory threshold, and increase the percentage of ejaculating animals.

However, opioids may also have facilitative effects, depending on dose, brain site, time of the day, and sexual-activity level of the animals. Opioid peptides are apparently released during mating, since physiological mechanisms of analgesia and reward are activated during sexual behavior, and naloxone blocks both. Systemic morphine inhibits reflexive erections and seminal emission; naloxone antagonizes those effects, but a low dose, administered alone, also inhibits erection, suggesting that some opioid activity can facilitate reflexes.

Oxytocin (OT)

OT is released from the posterior pituitary and in numerous brain and spinal sites. Systemic or icv injections of OT facilitate copulation in male rats, and icv injections of an OT antagonist impair or abolish copulation. Systemic OT can reverse the inhibitory effects of chronic fluoxetine, an SSRI. Furthermore, OT in cerebrospinal fluid markedly increases after copulation.

Gonadotropin-Releasing Hormone (GnRH)

GnRH stimulates the anterior pituitary to release gonadotropins. GnRH is released naturally when male rodents encounter female vaginal fluid. It facilitates motivation or copulation in several rodent species and exogenous GnRH restores fertility and sexual activity in hypogonadal men. However, adverse effects of GnRH can result from continuous high doses, which inhibit LH release and gonadal function; endogenous GnRH is released in a pulsatile fashion.

Orexin/Hypocretin

Orexin/hypocretin (orx/hcrt) is produced in neurons of the perifornical lateral hypothalamus that project to monoaminergic nuclei in the midbrain and brainstem and to basal forebrain areas, including the medial preoptic area (MPOA). Orx/hcrt regulates feeding and wakefulness and also enhances male sexual behavior. Orx/hcrt expression is decreased after castration and restored by E₂, and systemic administration of an orx/hcrt antagonist impairs copulation.

Other Neurotransmitters

GABA is the main inhibitory neurotransmitter in the mammalian brain. Systemic administration of GABAergic drugs inhibits male rat sexual behavior, and cerebrospinal fluid levels of GABA increase dramatically during the postejaculatory interval (PEI). Prolactin (PRL), secreted by the anterior pituitary, promotes

lactation but has numerous other functions. Hyperprolactinemic patients often have erectile problems and low sexual desire. Plasma PRL levels increase markedly after ejaculation in men and may contribute to postejaculatory refractoriness. Chronically elevated PRL impairs male rat sexual behavior, but short-term PRL has no effect or facilitates copulation. Early studies using high doses of acetylcholine agonists and antagonists produced contradictory results. However, lower doses of nicotine and muscarinic agonists have produced facilitative effects.

Brain Areas and Circuitry

See **Table 1** for a summary of neurotransmitter effects in specific brain areas.

Sensory Inputs

Olfactory bulbs

Volatile odors are transduced by receptors in the nasal mucosa, whose axons project through the cribriform plate to the main olfactory bulb (MOB). Both nonvolatile and volatile species-specific cues are detected in the vomeronasal organ (VNO), located at the base of the nasal cavity and projecting to the accessory olfactory bulb (AOB). Vomeronasal cues are important in rodents, but the VNO and AOB are regressed in humans. Olfactory bulbectomy abolishes mating by male Syrian hamsters, though the relative importance of the main and accessory systems is not clear. Male rats are less dependent on chemosensory

Table 1 Brain areas and neurotransmitter effects on male sexual behavior

stimuli, though bilateral bulbectomy severely compromises mating in some males. In rats and mice, the main olfactory system is more critical than the vomeronasal system. Odor cues result in neurons immunoreactive for the immediate early gene product c-Fos (Fos-ir) in the MOB and AOB of male hamsters, rats, and mice, whether they can mate or not; however, only experienced copulators show Fos-ir in all downstream structures of the VNO.

Amygdala

The amygdala is a collection of nuclei that contribute to learning, motivation, and fear (central nucleus and basolateral division) and chemosensory processing and social behaviors (corticomedial division). The medial amygdala is larger in males than in females, and the corticomedial region is critical for integration of chemosensory, genito-sensory, and hormonal stimuli. Corticomedial lesions impair copulation, with the severity dependent on the specific location and species. The posterodorsal medial amygdala (MeApd) is one site at which serotonin 5-HT_{1A} agonists facilitate copulation. A subregion of the MeApd is linked to sexual satiety. Fos-ir in the MeA, but not the MPOA, of male rats correlates with the length of the PEI, suggesting that some neurons there contribute to postejaculatory quiescence. T or E, but not DHT, implants in the MeA of castrated rats and hamsters delay the loss of, or partially restore, sexual behavior. However, DHT implants in male rats treated with subthreshold systemic E can restore mating. Thus, both ARs and ERs in MeA contribute to mating.

A major output of the MeA is to the MPOA. Unilateral lesions of the MPOA impair, but do not abolish copulation in male rats or gerbils; however, contralateral lesions of the MeA and MPOA severely disrupt mating. Chemical stimulation of the MeA increases MPOA DA release similar to that during copulation, and microinjection of a DA agonist into the MPOA restores copulation abolished by large lesions of the MeA. Small radiofrequency MeA lesions do not affect basal MPOA DA but do eliminate the DA response to a female and also impair copulation. Thus, MeA activity increases MPOA DA in anticipation of and during mating. The MeA of rats contains no dopaminergic neurons, but MeA efferents may directly or indirectly activate MPOA DA cell bodies or terminals.

Bed nucleus of the stria terminalis (BST)

Axons from the MeA either travel directly to the MPOA or synapse in the BST, which then relays information to the MPOA and other sites. However, the BST does more than simply relay input. The posteromedial BST has abundant steroid receptors and is important for male sexual behavior. Males also have more BST neurons that contain arginine vasopressin, galanin, and the aromatase enzyme, which converts testosterone to estradiol. In

male rats, hamsters, and gerbils, copulation, or to a lesser extent, exposure to female odors, elicits Fos-ir in the BST. However, mating decreases Fos-ir in male macaques.

Central tegmental field and subparafascicular nucleus of the thalamus (CTF/SPF)

The midbrain tegmentum, MPOA, MeA, and anterior hypothalamus are reciprocally connected. Subregions of the tegmentum have been called the central tegmental field (CTF) or dorsolateral tegmentum (DLT). The CTF/DLT is dorsal to the lateral half of the substantia nigra and may include the adjacent subparafascicular nucleus (SPF) and several other nuclei. Bilateral lesions of the CTF in rats impair mating but not sexual motivation. The medial parvocellular division of the SPF (SPFp) relays somatosensory input from the genitals to the MPOA and MeA. In male rats, the SPFp receives projections from lumbar spinothalamic neurons that are essential for ejaculation. Fos-ir is increased in the CTF or SPFp only after ejaculation in rats, gerbils, hamsters, and musk shrews. In men, ejaculation stimulates blood flow in the SPFp. In addition, electrical stimulation of the CTF facilitates mating in rats. SPFp neurons contain ARs, and many AR-ir neurons that project to the MPOA express ejaculation-induced Fos-ir. Thus, the SPFp and CTF convey ejaculation-related somatosensory input to higher brain areas.

Major Integrative Sites

Medial preoptic area (MPOA)

The MPOA is a critical integrative site for male sexual behavior. It receives indirect input from all sensory modalities and sends reciprocal connections to modify processing of that input. Steroid receptors in the MPOA and its afferents bias input to favor sexually relevant stimuli. Efferents to hypothalamic, midbrain, and brainstem nuclei regulate somatomotor or autonomic patterns and motivational states. A medial periventricular zone regulates neuroendocrine function, and a medial zone, including the medial preoptic nucleus (MPN) and posterodorsal preoptic nucleus (PdPN), controls male sexual behavior and maternal behavior. Large MPOA lesions abolish copulation in numerous species. More severe deficits occur with more caudal lesions that include part of the anterior hypothalamus. MPOA lesions also diminish, but do not eliminate sexual motivation. Stimulation of the MPOA facilitates sexual behavior in numerous species, but does not reverse sexual satiety. Repeated electrical stimulation of the MPOA in noncopulating male rats can lead to mating on subsequent stimulation-free tests. In anesthetized rats, MPOA stimulation increases intracavernous pressure and can elicit the urethrogenital reflex, even without urethral stimulation. Axons from the MPOA do not project directly to the lumbosacral cord, but

stimulate downstream sites that then control the reflexes. However, the MPOA is not necessary for genital reflexes.

Steroid implants in the MPOA facilitate sexual behavior in castrated rats, ferrets, birds, and lizards, but do not completely restore mating. Aromatization of T in the MPOA is important for T's facilitative effects. T implants in castrated quail facilitated copulation correlated with induction of aromatase immunoreactivity (ARO-ir) in the preoptic area. Sexual preference in rams is also related to aromatization in the MPOA. Rams that prefer to mate with other males have lower levels of serum T and E and decreased MPOA aromatase activity, compared with those that prefer to mate with females. In contrast to E, DHT in the MPOA of castrated male rats is relatively ineffective, unless accompanied by subthreshold systemic E or DHT. However, an antiandrogen in the anterior MPOA impairs copulation, but not partner preference; in the posterior MPOA it impairs motivation, but not performance.

Neurons of the periventricular DA system, along the third ventricle, project laterally into the MPOA and anterior hypothalamus. MPOA microinjections of classic D₁/D₂ agonists and antagonists facilitate and inhibit, respectively, copulation, *ex copula* reflexes, and sexual motivation. A DA agonist in the MPOA can restore copulation in males with large amygdala lesions. D₁-like agonists facilitate parasympathetically mediated erections and the early phase of copulation, and D₂-like drugs produce dose-dependent effects. Low doses disinhibit reflexes (decrease latencies), but high doses of D₂-like agonists, or of D₁ antagonists, shift autonomic balance toward sympathetically mediated ejaculation. It is not clear whether these dose-dependent effects are mediated by different receptor subtypes or populations of neurons with different levels of tonic inhibition.

Large doses of serotonin (5-HT) microinjected into the MPOA inhibit copulation, in part through 5-HT_{1B} receptors. However, reverse-dialysis of a 5-HT_{1A} agonist into the MPOA facilitates mating and increases both DA and 5-HT levels. Some of these facilitative effects are mediated by increased extracellular DA, stimulating D₂-like receptors. There are numerous GABAergic neurons in the MPOA of male rats, and some mating-activated neurons in male gerbils contain GABA. Enhancing MPOA GABAergic transmission impairs copulation in rats and blocking either GABA synthesis or GABA_A receptors enhances mating. However, a GABA_A antagonist did not reverse sexual satiation. Microinjection of low doses of a μ or a κ opioid agonist into the MPOA can facilitate copulation, and a μ antagonist prevents induction of sexual reinforcement. However, high doses of μ agonists impair copulation. Microinjection of NE facilitates sexual behavior, and decreasing NE levels by stimulating autoreceptors impairs copulation.

Reverse-dialysis of the NO precursor L-arginine into the MPOA facilitates copulation, and a NOS inhibitor impairs it, but increases the number of *ex copula* seminal emissions. NO also mediates the facilitative effects of repeated exposures to an inaccessible estrous female. Castration in both rats and hamsters decreases NOS-ir in the MPN; there is also less NOS-ir in ER α KO mice. nNOS is co-localized with both ER α and AR in the MPOA of rats, mice, and hamsters. Reverse-dialysis of an NO donor into the MPOA of castrated rats maintained on systemic DHT (to maintain genital and sensory structures) fully restored copulation in half the animals. NO's effects are at least partially mediated by cGMP.

Glutamate microinjections into the MPOA of anesthetized male rats elicit erectile responses and also the urethrogenital reflex without genital stimulation. Conversely, an NMDA antagonist inhibits mating in male rats. Nearly all neurons in the MPOA that show mating-induced Fos-ir contain NMDA receptors, and an NMDA antagonist decreases mating-induced Fos-ir. Thus, glutamate in the MPOA facilitates mating, at least in part through NMDA receptors.

Orx/hcrt, acetylcholine, and prostaglandin E₂ in the MPOA also exert facilitative effects. Some MPOA neurons increase their firing rates only before male rats or monkeys copulate; others increase only during mating. DA levels in male rats rise in the presence of an inaccessible female and increase further during mating; the DA response shows both anatomical and behavioral specificity. Both basal and female-stimulated DA levels are hormone dependent, with E mediating most, but not all, of the facilitative effects of T on DA levels and behavior. Tissue (stored) DA levels are actually higher in castrates than in intact males, suggesting that castration impairs DA release, but not synthesis. Release is controlled by NO, and T and E positively regulate MPOA NOS-ir. MeA lesions block the DA response to a female but do not affect basal levels; those males show suboptimal mating ability. Similarly, olfactory bulbectomy in hamsters impairs both copulation and MPOA DA release.

Copulation increases Fos-ir in the MPOA of male rats, gerbils, hamsters, and mice. At least some of the Fos-ir is in AR-containing neurons. Previous sexual experience enhances Fos-ir to sexual stimuli in rats and hamsters. Efferents from the MPOA project to other areas of the hypothalamus, midbrain motivation and somatomotor regions, and midbrain and brainstem areas that project to the spinal cord. These connections are mostly reciprocal, allowing downstream sites to influence their own input. Output to the nPGi may disinhibit genital reflexes, while other efferents may activate autonomic areas that regulate erection and ejaculation.

Mesocorticolimbic and Nigrostriatal DA Tracts

DA cell bodies in the VTA send axons to the NAc and mPFC; this mesocorticolimbic tract is critical for motivated behaviors. DA is released in the NAc both before and during copulation. Sexual behavior activates both DA and non-DA neurons in the VTA, apparently mediated by endogenous opioids, which inhibit GABAergic interneurons, thereby releasing DA cells from tonic inhibition. The mPFC sends largely glutamatergic axons back to VTA, providing positive feedback. mPFC axons also contact the NAc, MPOA, BST and subparafascicular nucleus (SPF). Lesions of the mPFC, VTA, and NAc impair sexual arousal. Stimulation of the dorsal VTA facilitates, but ventral stimulation inhibits, copulation. Mating induces Fos-ir in the NAc and VTA, and sexual experience enhances Fos-ir in response to estrous females. Decreasing DA activity, by blocking NAc DA receptors or stimulating VTA autoreceptors, slows motor behavior and may decrease sexual motivation.

The nigrostriatal DA tract originates in the substantia nigra (SN) and projects to the dorsal striatum. DA is released only after copulation begins, suggesting greater importance for motor activation than motivation. Bilateral SN lesions slow copulation and decrease ejaculations.

Paraventricular nucleus of the hypothalamus (PVN)

The PVN integrates endocrine and autonomic functions. Parvocellular neurons project to several brain areas and the spinal cord, and magnocellular neurons release OT and vasopressin from the posterior pituitary. Axons projecting to the spinal cord release several transmitters, including OT, vasopressin, and DA. Input to parvocellular PVN includes DA from periventricular neurons and NE and 5-HT from the brainstem. The PVN is important for noncontact erections and seminal emission, but is less critical for reflexive erections and copulation.

Microinjection of DA (especially D₄) agonists, OT, NO donors, or NMDA elicits drug-induced erections, increases reflexive erections and seminal emissions, and increases intracavernous pressure in anesthetized rats. Both noncontact erections and copulation are accompanied by increases in DA and NO. Intra-PVN morphine inhibits both noncontact erections and the NO increase. Sexually competent male rats have more OT mRNA and less opioid mRNA in the PVN than do impotent males, and NOS and OT are co-localized. The PVN projects to the hippocampus, lumbosacral spinal cord, and other areas, including the nPGi, where terminals form close appositions to serotonergic neurons that inhibit genital reflexes.

Lateral hypothalamus (LH)

The LH contributes to autonomic, endocrine, and emotional responses. Electrical stimulation induces copulation in male rats, and lesions impair mating. 5-HT in the anterior LH (aLH) delays and slows copulation and decreases basal and female-elicited DA release in the NAc. 5-HT levels are increased during the PEI. The aLH contains orx/hcrt neurons, which contribute to arousal and reward and are activated by copulation. 5-HT in the aLH may inhibit copulation by inhibiting orx/hcrt neurons, which would eliminate their facilitation of VTA DA cell firing.

Ventromedial hypothalamus (VMH)

The VMH, known primarily for its role in female lordosis, may also influence males. It has numerous ERs and ARs and receives genital and chemosensory input. Mating induces Fos-ir in the VMH of rats and gerbils, but not in musk shrews, hamsters, mice, ferrets, or macaques.

Major Motor Outputs

Midbrain periaqueductal gray (PAG)

PAG lesions blocked elicitation of the urethrogenital reflex by MPOA electrical stimulation. There are numerous ERs and ARs in the PAG, and afferents from the MPOA end near ER- and AR-ir neurons, some of which project to the nPGi. Thus, hormones can affect control of the nPGi by the MPOA through the PAG.

Nucleus paragigantocellularis of the medulla (nPGi)

Much of the supraspinal inhibition of genital reflexes arises from the nPGi. Lesions facilitate copulation and reflexive erections and allow the urethrogenital reflex to be elicited without spinal transection. They also increase the number of ejaculations preceding satiety. Electrical stimulation activates sympathetic fibers in the pudendal nerve. Most nPGi axons to the lumbosacral cord contain 5-HT, which suppresses the urethrogenital reflex.

Spinal cord

Erection is elicited by inhibiting the thoracolumbar sympathetic antierectile pathway and stimulating the proerectile parasympathetic sacral and pudendal pathways. A central pattern generator for ejaculation in the lumbosacral cord includes neurons that contain galanin, cholecystokinin, and neurokinin receptors. Stimulation of these neurons elicits seminal emission followed by expulsion. Although 5-HT is primarily inhibitory, 5-HT_{1A} and 5-HT_{2C} agonists facilitate the urethrogenital reflex. Cerebrospinal fluid levels of GABA, and to a lesser extent glutamate and aspartate, increase markedly after ejaculation. GABA may inhibit, and glutamate, DA, NE, and ACh facilitate, sexual reflexes at the spinal level.

Sexual Behavior in the Context of Mammalian Social Behavior

Brain areas that control male sexual behavior influence other social behaviors as well, including female sexual behavior, maternal behavior, aggression, and territorial marking. Most of those areas, except the midbrain, contain abundant steroid receptors, and all influence more than one behavior. Perinatal, adolescent, and adult hormones can provide a bias toward sexually dimorphic responses to social stimuli. It is not clear whether the same neurons within a structure contribute to more than one behavior, or whether neurons specific for one behavior lie among those specific for other behaviors. However, there are common themes underlying the various social behaviors and the neural mechanisms that control them.

Glossary

Allostatic load – The physiological costs of chronic exposure to the neural or neuroendocrine stress response. The allostatic load index is conceptualized as a summary measure capturing the cumulative physiological burden exacted on the body to adapt to life's demands. It is thought to reflect the tax on the body and brain resulting either from chronic overactivity or inactivity of physiological systems that are involved in adaptation to environmental challenge.

Cortisol – A corticosteroid hormone that is produced by the adrenal gland (in the zona fasciculata and the zona reticularis of the adrenal cortex) in response to a wide range of stressors. It has a wide range of physiological effects, that is, increases blood pressure and blood sugar, and reduces immune responses; virtually every single nucleated cell in the body is a potential target for cortisol. Only 5–10% of the total plasma cortisol is unbound and biologically active (c. 90% of the fraction is silenced by cortisol binding protein).

Hypothalamic–pituitary–adrenal (HPA) axis – This axis is constituted by a complex set of direct influences and feedback interactions among the hypothalamus, the pituitary gland, and the adrenal glands. It is a major part of the endocrine system that controls responses to stress and regulates many physiological processes, including the immune system, energy storage and expenditure, and a broad range of psychological as well as biological mediators of adaptation to stressful events. The HPA axis mediates stress adaptation. Under stress, the hypothalamus secretes corticotropin-releasing factor and arginine vasopressin that provoke the release of adrenocorticotropic hormone (ACTH) from the pituitary, which targets the adrenals and triggers the secretion of cortisol. The functioning of the axis is controlled by a negative-feedback loop, with cortisol feeding back not only on the pituitary to downregulate ACTH but also on the hypothalamus and the hippocampus, where it acts as a brake of the HPA-axis response to stress.

Introduction

Background

Stressors can take many forms, for example, loud noise, extreme temperature, physical exertion, pathogens, social disturbance, and emotional arousal. Social and psychological stressors are especially prevalent in primates and humans because of their complex social environments and advanced capacity for emotional responding. The perception of social hierarchy and interpersonal exchanges, the capacity for worry and rumination, the pain of self-doubt and low self-esteem, and the preoccupation with possible future events are among the common sources of chronic stress. The organism's repertoire of responses is not well suited to dissipate the impact of these sources of chronic stress. Indeed, the organism's response as it extends over time creates a state of pathology that is characterized by psychological disturbance and physiological states that can progress into illness.

During the mid-twentieth century, Hans Selye, an endocrinologist born in the Austrian–Hungarian Empire and later naturalized Canadian, pioneered the scientific investigation of stress and developed the concept of the 'general adaptation syndrome' to describe the common biological responses to stress. Specifically, he noted the progression from alarm, to adaptation, and then to exhaustion. The initial alarm response is associated with a marked increase of attention to the stimulus and physiological readiness to engage in the fight-or-flight response, which was first described by Walter Cannon at the beginning of the century. The brain triggers an organism-wide response through activation of the sympathetic nervous system and the hypothalamic–pituitary–adrenal (HPA) axis. These systems allow optimal adaptation for the organism to flee a threat or to repel a threat through increased respiratory and cardiac output, release of glucose, blood, and other nutrients to supply fully engaged muscles, constriction of blood to the extremities, and a variety of additional reactions. Selye argued that these neurophysiological responses cannot be indefinitely sustained, and the organism will enter a state of

exhaustion. In fact, subsequent research has demonstrated that the responses do cease, but transform into a sustained and altered state that are damaging.

While Selye believed that these response patterns are nonspecific and account for any type of stressor, Mason, an American endocrinologist, challenged this position in the late 1960s by demonstrating that the HPA response clearly varies with the emotional reaction to the stressor. The exact emotion that is triggered by the stressor and, therefore, the intensity and dynamics of the HPA response depend on factors such as perception of uncertainty, anticipation, novelty, unpredictability, uncontrollability, and ego involvement. These observations have been confirmed in numerous studies in the past 40 years. In addition, it has been found that the HPA response habituates under repeated exposure to stressors in most subjects, once the situation loses the characteristics described above, while the sympathetic response remains largely unchanged under such conditions. This article provides a brief overview of psychological and biological measures of acute and chronic stress.

Definition of Stress

This brief history illustrates the complexities of the definition of stress in showing that there are three distinctive components comprising it. Researchers have focused on different aspects of the definition, often to the exclusion of other parts of the definition, which has created some confusion of the meaning, indeed, even the utility of the term stress. The first approach has been to define stress as an environmental. Records of the number of recent life events or of single, major event, such as death of a loved one, are examples of this approach. The second approach is to measure people's reactions to the environment, regardless of what has actually happened to them. This allows for individual differences such that a given environment could engender little perceived stress in one individual, yet high levels of stress in another (presumably because of differential life histories or constitutional makeup). The third approach is to measure the physiological response of the individual to the environment, which also allows for individual differences in response patterns. We shall discuss measurement strategies for each of these conceptualizations of stress with extra emphasis on physiological measures of stress. A book on stress measurement was published several years ago, and the organization of this article is very similar to the one used by the authors of this book.

Distinction and Importance of Acute versus Chronic Measures

An important distinction in stress research is that between acute stress and chronic stress. While most species are highly adapted to cope with an acute stressor, chronic

stress poses a much more challenging situation. The response to acute stress is designed to provide the organism with the alertness, energy, physiological regulation, and immunological activation that are necessary to counterbalance the effects of the stressor in order to survive. The removal of an acute stressor allows the organism to return to baseline. In contrast, chronic stress presents an unrelenting challenge that can exhaust the organism's response and results in a chronic state of dysregulation.

While the impact of acute and chronic stress may be distinctive, the measurement of the two is less well defined. Measurement of acute and chronic marital discord shows the association between the two measurements. A single marital argument could be considered an acute stressor; in fact, laboratory study of arguments between spouses has shown considerable evidence of brief, but intense, physiological activation. Chronic marital stress can be defined as frequent arguments over some reasonable period of time. In this case, the measurement strategy for acute and chronic stress is distinguished only by duration. However, another strategy for measuring marital stress is to obtain a single rating about marital stressors pertaining to a period of time (e.g., child rearing, finances, etc.). Both measurement strategies are valid, but they probably measure somewhat different aspects of the relationship between spouses. We will note both acute and chronic measures throughout the article.

Environmental Measures of Stress

Self-report questionnaires are the most common method of measuring stress. Several approaches have been developed reflecting different theoretical frameworks for conceptualizing stress. Some of the earliest environmental approaches focused on the occurrence of life events as a means of quantifying the amount of stress the individual had been exposed to. Initially, only major events were measured, while later minor events or hassles and the person's perception of stress caused by the event were incorporated in the measures. Another, more recent approach is real-time assessment of events, mood, and coping responses. In contrast to the traditional retrospective questionnaire approach, real-time assessment involves multiple prospective assessments of the respondent's experience at the moment. (The real-time approach is applicable to the measurement of both environmental and perceived stress.)

The earliest measures of stress focused on the occurrence of life events. The Holmes and Rahe Social Readjustment Scale, published in 1967, includes 43 weighted items of important life changes – both positive and negative, such as marriage or death of family member – that might have happened to the respondent in the last 12 months. The cumulative sum of events was viewed as an

index of the degree of stress experienced by the individual. Ten years later, Sarason and colleagues developed the Life Experiences Survey that asks the respondent to indicate if any 30–57 life events (depending upon instrument version) occurred in the last 12 months and to rate the impact of the event on a 5-point scale that yields life change units. Negative and positive event scores can be summed separately or together for a total score. Bruce Dohrenwend developed the Psychiatric Epidemiology Research Interview (PERI) life events scale in the 1980s, and more recently, Stamm and colleagues developed a 20-item questionnaire, the Stressful Life Experiences Screening, that focuses on traumatic life events and asks the respondent to indicate the extent to which they have experienced each, and the degree of stress at the time of the event and now.

Scales assessing only major life events were criticized by some for failing to include typical sources of chronic stress for most people. Richard Lazarus and colleagues asserted that small daily difficulties or hassles should be the focus of stress measurement to capture the extent to which an individual is psychologically burdened by chronic stressors. They developed the 117-item Hassles Scale including items relating to difficulties with finances, time pressure, employment, health, and family. While earlier research supported the association of major life events and subsequent health, subsequent work documented the independent association of stress induced by daily hassles in predicting health outcomes.

Another approach is a change of measurement method more than item content. Assessment of stress can be done for much shorter time periods, thus avoiding the bias of retrospective reporting. Stone and colleagues were among the first to measure stress on a daily basis prospectively in the early 1980s. This approach has been able to capture the relationship between elevations in stress preceding onset of a respiratory infection and concurrent changes in immunological function. In addition, it has raised doubt about the accuracy of measures of coping that generalize across time and situations.

This was taken to an even finer level of detail with the development of the strategies termed the Experience Sampling Method (ESM) and Ecological Momentary Assessment (EMA). These measurement strategies involve sampling peoples' momentary experiences as they occur using hand-held recording devices, which yield a profile of the experiences throughout the day. These self-reports of both environmental occurrences (small events) and inner feelings (stressfulness) can be associated with ambulatory measurements of physiological indicators, enabling a dynamic view of environmental, perceived, and physiological approaches to stress measurement. A good example of this research is that of Thomas Kamarck, who is studying psychosocial stress exposure during the course of the day. In this work, an individual could be characterized as experiencing work

stress if they felt work experiences were very demanding, yet that they also had little control over them (as opposed to providing the same information based on recall judgments of the same).

Perceptual Measures of Stress

The second type of stress measurement has generated measures that focus on the subjective appraisal of stress in one's life and on associated emotions. With the recognition of posttraumatic stress disorder in the 1980 Diagnostic and Statistical Manual of Mental Disorders, questionnaires and structured interviews began to incorporate the designated psychiatric symptomatology. These measures all involve self-reports from individuals about their feelings and appraisals of their psychosocial environment; thus, they are all questionnaire-based assessments.

Several questionnaires have been designed to assess the degree of chronic stress an individual perceives. The Perceived Stress Scale (PSS) published by Sheldon Cohen and colleagues in 1983 is a typical example. Currently, three versions are available: 4-items, 10-items, and 14-items; all use a reporting period of the last month, and yield a total score. The scale's items are designed to reflect the degree to which the respondent experiences life as unpredictable, uncontrollable, and overloaded, and that the resources necessary to respond to the event are insufficient. Scores from a normative sample of over 2300 adults have been published. Cohen has shown that the PSS not only is associated with psychopathology, but it is also independently associated with health outcomes, such as development of a cold when a rhinovirus is introduced, likelihood of being a cigarette smoker, lower physical activity, and impaired immune function.

The Derogatis Stress Scale, first published in 1980, takes an even more complex approach. It is based on the interactional stress model of Lazarus and Folkman that incorporates measurement of three domains: environmental events (vocational, interpersonal, and health), personality characteristics (time pressure, excessive achievement drive, and relaxation potential), and emotional response (hostility, anxiety, and depression). The scale uses 77 items to assess the three domains and yields scale scores for each, a global score, as well as a score for the respondent's subjective level of stress. Normative data on 1000 working adults is published. Few studies have examined associations with biological or health outcomes.

The Impact of Events Scale, reported by Horowitz and colleagues in 1979, is an example of instruments designed to measure posttraumatic psychiatric symptomatology. This 15–22-item instrument asks respondents to indicate the frequency of intrusive thoughts, avoidance and numbing, and physiological hyperarousal in the last 7 days. It is most frequently used to document traumatic stress in

different populations and as an outcome measure in trials designed to reduce posttraumatic stress.

Physiological Measures of Stress

During the past decades many tests for laboratory research on acute stress in humans have been developed. Probably the most prominent is the Trier Social Stress Test (TSST). In front of an audience and monitored by a camera and tape recorder, subjects are asked to deliver a motivated performance task.

In thousands of TSSTs performed in many different laboratories worldwide, much data have been collected showing a robust rise of stress hormones, autonomic measures, immune parameters, and perceived stress in the majority of the tested subjects. Interestingly, physiological and psychological responses do not or only poorly correlate, indicating that both psychological and biological measures need to be applied for a reasonable assessment of the stress response.

For the TSST, broad intra-and inter-individual differences in the stress response have been observed. Age, gender, dietary and drug consumption, medical conditions and interventions, personality factors, social support and social hierarchy, menstrual cycle, pregnancy and lactation in women, time of testing, habituation, early-life experience, and genetic factors, among others, are known to influence the acute stress reaction. These factors and the complex interaction among them in a given individual finally explain such differences.

The TSST has been shown to exert robust effects on several psychobiological measures:

- Psychological measures: anxiety, negative mood, and perceived stress.
- Autonomic measures: blood pressure, heart rate, heart rate variability, electrodermal activity, perspiration, body temperature, epinephrine, and norepinephrine.
- Endocrine and metabolic measures: adrenocorticotrophic hormone (ACTH), plasma and saliva cortisol, prolactin, growth hormone, and glucose.
- Hematological measures: hematocrit, hemoglobin, and plasma volume.
- Coagulation measures: fibrinogen, von Willebrand factor antigen, D-dimer, and clotting factors.
- Immune measures: neutrophils, eosinophils, basophils, lymphocytes, interleukin-6, and tumor necrosis factor alpha (TNF α).
- Genetic measures: repression/induction profiles of genes in target tissues.
- Psychomotor measures: muscle activity (electromyogram), voice (spectral analyses), limb movements, and dexterity (**Figure 1**).

This broad spectrum of response measures has turned out to be useful in both basic and clinical research. For example, it has been shown that specific pharmacological and psychological interventions change single profiles, predicting comparable effects in clinical practice.

As mentioned above, measures of perceived stress are poorly associated with biological measures of stress. This is also true for the assessment of chronic stress. For example, both elevated and dampened cortisol levels have been reported to be associated with depression, posttraumatic stress disorders, irritable bowel disease, burnout, chronic fatigue, fibromyalgia, etc. Thus, an endocrine status does not necessarily predict a psychological status or specific stress-related disorders. Rather, it seems that the HPA axis can adapt to chronic stress by first becoming up-and later down-regulated. In both cases, however, corticotropin-releasing factor (CRF)/ arginine vasopressin (AVP) neurons of the hypothalamus may be overactivated, first triggering HPA axis hyperactivity, and later becoming disinhibited due to low cortisol levels.

While a hypercortisolemic state may promote the metabolic syndrome and disorders of the immune system, hypocortisolism seems rather to facilitate pain, fatigue, and irritability, probably by disinhibition of proinflammatory cytokines, prostaglandin synthesis, and noradrenergic neurons in the central nervous system. Effects of chronic stress on the sympathetic nervous system seem to be mainly observed in panic disorder and essential hypertension.

Yet another approach to use biomarkers as measures of chronic stress is the concept of ‘allostasis’ and ‘allostatic load.’ The basic assumption is that allostasis allows adaptation to chronic stress by maintaining (homeostatic) stability through change. There are four conditions under which this kind of adaptation occurs: (1) failure to habituate to repeated stressors of the same kind; (2) failure to turn off each stress response in a timely manner due to delayed shut down; (3) repeated frequency of stress responses to multiple novel stressors; and (4) inadequate response that leads to compensatory hyperactivity of other mediators. Allostatic overload refers to dysregulations of multiple physiological systems, which exert cumulative strain on multiple organs and tissues. Measures of allostatic load predict some variance of diverse health outcomes, including cognitive and physical functioning, cardiovascular and inflammatory disease, and even mortality. Allostatic load is assessed as a composite index by the number of biomarkers for which an individual is at risk.

However, the physiological pathways linking chronic stress to health outcomes are affected by the interplay of multiple variables: genetic and epigenetic determinants, brain maturation during pre- and postnatal development, duration, quality, and intensity of life events, and resilience; socioeconomic conditions; coping skills, organ

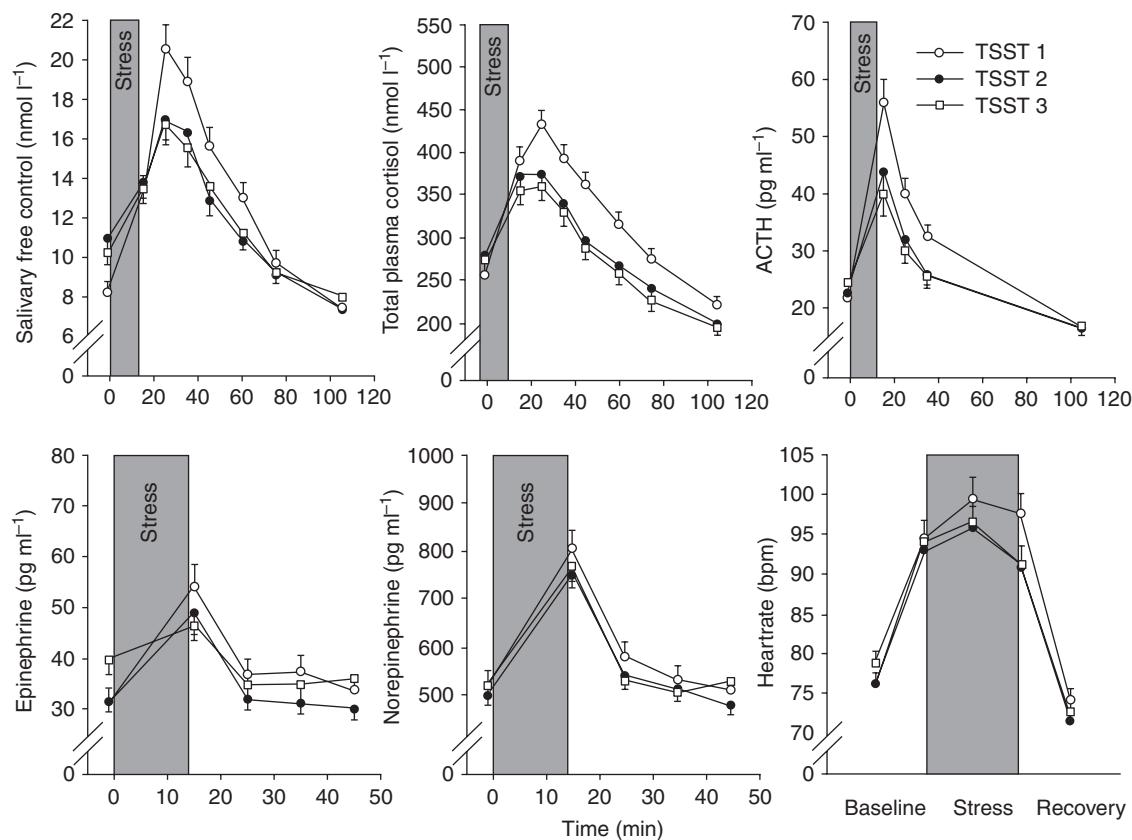

Figure 1 Endocrine and heart rate responses in 88 healthy volunteers under three repeated TSST exposures (\pm SEM; 4-week intervals). function, etc. Thus, chronic stress affects subjects quite differently, and the individual outcomes of stress are very heterogeneous. Clearly, a meaningful interpretation of stress effects on health needs to consider such individual constellations.

From such a viewpoint, measures of chronic stress have to be defined differently, particularly if they should serve a diagnostic purpose. Hypothetically, one could define neuroendophenotypes, which describe discrete brain systems that participate in the stress response. For each of these systems, one could develop psychological, biological, and symptomatic outcome measures, which reflect the activity or reactivity of each system. Furthermore, one could describe how gene–environment interactions affect these systems. A diagnostic assessment of chronic stress effects would then comprehend a number of measures which could probably tell, which of these neuroendophenotypes participate in stress-related disorders of a given patient. If so, individualized pharmacotherapeutic and psychotherapeutic treatments could be assigned.

A first approach of this kind has been termed Neuropattern. To reduce complexity and heterogeneity

as well as to avoid the missing covariance of the psychological and biological stress response, this approach solely focuses on the interfaces, that participate in the cross talk between the brain and the rest of the body. Endophenotypes for the activity and reactivity of these interfaces were defined and are assessed by measures of concomitant psychological, biological, and symptomatic events. Practically, each physician can apply Neuropattern to explore if and how stress affects his/her patient's health. The Neuropattern kit contains questionnaires, a small electrophysiological device, and tubes for the collection of saliva. In his/her office, the physician provides master file data, a brief medical history, and takes several measures, such as blood pressure, waist-to-hip ratio, body mass index, etc. At home, the patient fills questionnaires, collects saliva samples before and after a low-dose dexamethasone test, and uses a portable electrocardiogram. Once all data have been collected, the patient sends the kit to a company, which performs the laboratory analyses of all the data and performs a comprehensive medical report for the physician. This strategy allows to transport expert knowledge to the practitioner across medical disciplines,

and without implying specific education or expertise from the respective physician.

Perspectives

Both our knowledge and methods in the assessment of stress rapidly proceed, and, obviously, new biotechnologies and psychological measure will enable us to assess neuroendophenotypes of stress. In the future, it should be possible to refer such neuroendophenotypes to discrete neurobiological systems and functions, which can be assessed with respect to their genetic, epigenetic, physiological, and psychological features, so as to assess their relevance to the development of stress-related psychological and physical disorders.

Glossary

Angiotensin II – An octapeptide that plays a prominent role in the regulation of cardiovascular and body fluid homeostasis.

Blood-brain barrier – A property of capillaries throughout most of the brain that makes them less permeable to blood-borne substances, thus restricting movement from blood to brain.

Circumventricular organ – A brain structure lacking a blood-brain barrier.

Dipsogen – A substance that produces thirst.

Extracellular fluid – One of the major fluid compartments of the body comprising all fluid residing outside of cells.

Ghrelin – A peptide produced predominantly not only within the stomach and small intestine, but also within the brain. Ghrelin plays a role in the regulation of growth hormone secretion and food intake.

Intracellular fluid – One of the major fluid compartments of the body comprising all fluid within cells.

Neuropeptides – The peptides that are produced by neurons.

Opioid peptides – The peptides that bind to one or more members of the opioid receptor family, including μ , κ , and δ receptors.

Oxytocin – A peptide produced almost exclusively within the hypothalamus that is released from the posterior pituitary and from neural projections to numerous intra- and extrahypothalamic brain sites.

Vasopressin – A peptide produced by magnocellular hypothalamic neurons and by centrally projecting neurons within the hypothalamus and amygdala.

Venticle – A cavity within the brain that is filled with cerebrospinal fluid. The cerebroventricular system comprises four ventricles: two lateral ventricles, the third ventricle, and the fourth ventricle. Cerebrospinal fluid flows from the lateral ventricles, to the third ventricle, and then to the fourth ventricle before leaving the brain and entering the central canal of the spinal cord or into the subarachnoid space.

Introduction

Maintenance of body fluid homeostasis is critical for survival. The deleterious effects of dehydration are well recognized by the scientific and lay communities; however, perturbations in the opposite direction and overconsumption of water are equally problematic and potentially fatal. Drinking large volumes of water has led to fatalities during fraternity hazing rituals, radio station contests, and after strenuous physical activity. Given the importance of maintaining a proper balance of fluid, it is not surprising that numerous physiological factors act in a coordinated effort to maintain body fluid homeostasis. A key component of this regulation involves behavioral changes leading to increased or decreased intake of water and salt. The mechanisms underlying these behavioral changes often hinge on the action of neuropeptides. The information that follows focuses on these actions and extends the discussion beyond neuropeptides to include information about peptides that are neither produced nor secreted by neurons, but that act on the central nervous system (CNS) to regulate water intake.

Vasopressin

From a historical perspective, one of the earliest associations between a peptide and fluid balance is the relationship between dehydration and arginine vasopressin (AVP). These classic studies, mostly the work of E. B. Verney carried out in the 1940s, used dogs that had been preloaded with water such that baseline urination was elevated. Using this preparation, Verney measured urine output after intravenous or intracarotid infusions of various hyperosmotic solutes. Using measures of urine output as a bioassay, he discovered that intracarotid infusions of hyperosmotic solutions that were excluded from cells (e.g., NaCl, sucrose, and mannitol), therefore drawing water from the cells by osmosis and stimulating a form of dehydration referred to as ‘osmotic’ or ‘intracellular’ dehydration, reduced urine output. In contrast, solutes

such as urea that raised extracellular osmolality, but could equilibrate across cell membranes, did not alter urine flow. Moreover, intracarotid infusions of solutes were significantly more effective than intravenous administration, suggesting the brain as a site of action. Although these experiments did not provide direct evidence for the involvement of a peptide in the observed responses, Verney postulated the involvement of a circulating factor that we now know as AVP. Indeed, the subsequent development of a radioimmunoassay for AVP provided confirmation of all of Verney's original findings. The role of AVP in water restriction by the kidney is quite clear, but a role for a peptide as a stimulus for drinking, rather than as a parallel response to dehydration, would not be demonstrated for another 20 years.

Angiotensin

With respect to a direct role of a peptide on fluid intake, the most notable example is that found in the octapeptide angiotensin II (AngII). Angiotensin production starts with the rate-limiting step of renin release from the kidney (**Figure 1**) that occurs under situations of decreased blood volume referred to as 'hypovolemia' or 'extracellular

dehydration.' Renin acts on a plasma α -globulin, angiotensinogen, which is abundantly available in the circulation. The cleavage of angiotensinogen by renin produces a smaller, biologically inert peptide referred to as 'angiotensin I.' Conversion of angiotensin I into the bioactive AngII is performed by angiotensin converting enzyme, which not only is expressed by cells of the lung vasculature, but is also found in other tissues. The bioactive AngII has a diverse array of effects on a variety of tissues, each of which insures the proper behavioral and physiological response to a condition of decreased volume of the extracellular compartment. The discovery of the dipsogenic effect of AngII stemmed from a handful of early experiments demonstrating that renal extracts stimulated drinking in animals that should not otherwise have been thirsty. Initially, the focus of these experiments was on a relatively large AngII precursor, renin, but knowing that the biological effects of renin occur largely, if not exclusively, through AngII, scientists quickly turned their attention to AngII. There had been hints of the dipsogenic potency of AngII in the literature. In the 1960s, studies by David Booth, which focused on hypothalamic injections of norepinephrine, also included experiments using AngII. In this case, however, AngII was included largely as a control for specific aspects of the

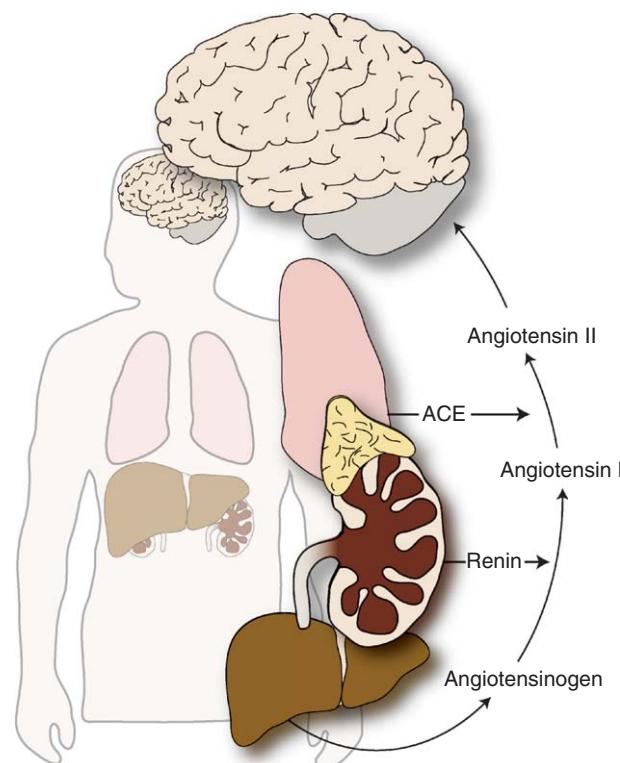

Figure 1 The renin–angiotensin system. The dipsogenic/natriorexigenic peptide angiotensin is produced by a biochemical cascade that begins with the rate-limiting step of renin release from the kidney. Renin cleaves circulating angiotensinogen, which is produced by the liver, to produce angiotensin I. Angiotensin I is biologically inert until it is further cleaved by angiotensin converting enzyme, predominantly in the lungs, to generate angiotensin II, which acts at a variety of tissues including the brain.

study and received very little attention in the report. Shortly thereafter, the studies of Anne Daniels (no relation to the present author), who would later become Daniels-Severs, also demonstrated the efficacy of brain injections of AngII. These studies, first published in abstract form and later as a brief communication, were particularly focused on the pituitary responses to AngII injected into the lateral cerebral ventricle, but included the demonstration that these injections reliably stimulated drinking. The experiments of Booth and of Daniels and coworkers, however, used rather large doses of AngII, making it difficult to draw conclusions about a specific site of action. At the same time these experiments were underway, James Fitzsimons and his colleagues were performing a series of experiments that would clearly demonstrate the dipsogenic actions of AngII. These experiments included intravenous injections and direct injection of small amounts of AngII into several central sites. Interestingly, the efficacy of AngII injected into the lateral ventricle of the brain (intracerebroventricularly, ICV) remained unclear. In fact, Epstein and his coworkers reported that AngII produced drinking only in one of the two rats given ICV injection of AngII, but note that the report of Daniels and his coworkers "leaves the question of ventricular sensitivity unsettled." Of course it is now quite clear that the cerebral ventricles are a very sensitive route of delivery for dipsogenic responses to AngII. Indeed, the responses to AngII are so reliable that numerous laboratories use injections of AngII to verify proper forebrain ventricular cannula placement in laboratory rats and mice, even for experiments unrelated to fluid homeostasis.

The source of the variability in the earlier experiments using AngII remains unclear, but the issue of ventricular sensitivity was decidedly settled by the studies of Johnson and Epstein. These studies, originally designed to investigate parenchymal sites that are sensitive to AngII application, noted that most of the responsive locations in the earlier studies of Epstein and his coworkers were either in close proximity to the cerebral ventricles or were in regions where the cannula shaft traversed a ventricle en route to the intended site. Unsatisfied with the conclusions that could be drawn from the behavioral experiments, the authors used radiolabeled AngII to monitor the diffusion of peptide from the cannula tip and clearly showed that the peptide effluxed up the shaft of the cannulae, thereby gaining access to the ventricles. Indeed, when cannulae targeted a structure shown to be responsive, but were implanted using an angle that avoided the ventricle, the animals failed to drink. These studies also showed that the doses needed to generate a drinking response after ventricular application were actually lower than those needed for the earlier parenchymal injections, clearly implicating the ventricles, and perhaps

the ependymal tissue surrounding them, in the behavioral response.

Although the dipsogenic potency of the exogenous AngII was quite compelling and it was clear that the peptide had a central site of action, the results were initially troublesome. Specifically, it was not clear how a circulating peptide could penetrate the blood-brain barrier to gain access to structures in the CNS involved in the arousal of thirst. Although the answer seems obvious now, the implication of the circumventricular organs was a major breakthrough for the study of the regulation of behavior by hormones, especially peptide hormones. In fact, while Johnson and Epstein's analysis of AngII-sensitive sites progressed, Simpson and Routtenberg were focusing on the subfornical organ (SFO), a relatively small brain structure located just ventral to the hippocampal commissure (also referred to as the 'ventral fornical commissure'). These studies demonstrated that doses of AngII, which were mostly ineffective when given to the ventricle, produced marked increases in drinking when applied directly to the SFO. Moreover, destruction of the SFO blocked the dipsogenic effect of AngII given systemically or into other brain areas. Furthermore, direct SFO application of an AngII receptor antagonist blocked the drinking response to systemic AngII. Importantly, these studies provided an interesting dissociation by showing that lesions of the SFO attenuated drinking after challenges modeling hypovolemic thirst, but had no effect on stimulation of intracellular (osmotic) thirst, helping to establish the role of AngII as a signal of extracellular (hypovolemic), but not intracellular thirst.

In addition to the increases in water intake as discussed above, AngII also stimulates ingestion of saline solutions. The stimulatory effect of AngII on salt ingestion was first suggested by two independent reports that brief infusions of large doses of AngII into the cerebral ventricles or surrounding tissue of the anterior forebrain increased the intake of relatively dilute, yet hypertonic, saline solutions. In subsequent work, Epstein's and Fitzsimons's groups simultaneously demonstrated that more prolonged elevations of AngII in the brain elicited substantial intake of strong salt solutions that were steadfastly avoided by animals not receiving AngII. These studies were useful in pointing to a role of AngII in water and saline intake, but determining the physiological relevance was difficult. The difficulty arose mainly from the doses required to stimulate the salt ingestion and the potential confound of the resultant natriuresis, likely pressor induced, which was directly related to the temporal pattern and magnitude of salt intake. These problems, however, were solved when it became appreciated that the experimental animals used were not in the normal physiological setting under which AngII is normally secreted. Indeed, elevated AngII normally occurs in concert with other responses to hypovolemia, including

increases in circulating levels of the steroid hormone aldosterone. These discussions and debates led to the development of the synergy hypothesis, which suggests that the intake stimulated by the combination of AngII and aldosterone is greater than the addition of the intake stimulated by each in isolation. In support of this hypothesis, exogenous mineralocorticoid and AngII, each at doses that were insufficient to elicit salt intake alone, produced a robust salt appetite when given together. This effect was much greater than additive over a broad range of doses of each hormone, it was specific for saline intake, and it was not secondary to excessive renal sodium excretion. It was further demonstrated that blockade of AngII or aldosterone action alone resulted in a partial reduction in the appetite elicited by dietary deprivation, whereas the simultaneous inhibition of both hormones in the brain, but not in the periphery, abolished it. Collectively, these experiments with agonists and antagonists appeared to confirm the validity of the synergy hypothesis in situations where the appetite was associated with elevated endogenous levels of AngII and aldosterone.

The multiple forms of ingestive behavior stimulated by AngII (water and saline solutions), each coordinated to defend body fluid homeostasis, make this peptide a useful tool for illustrating the diversity of peptide regulation of behavior. Given that AngII is an important factor in the response to hypovolemia, the finding that it stimulates intake of saline, in addition to intake of water, is not surprising. Considering the distribution and composition of body fluids is key to understanding why the stimulation of both forms of ingestive behavior is illustrative. The typical adult human contains approximately 42 l of water, which is nearly 60% of total body mass. The majority of this water, approximately two-thirds of body fluid, is found within cells and is therefore referred to as 'intracellular fluid (ICF).' The ICF contains potassium and bicarbonate ions as well as glucose and several amino acids. The presence of these and other molecules in the ICF results in an osmolality of approximately 300 mOsm. The generation of this osmotic pressure is the key to understanding the dynamic balance between the ICF and the other main compartment of body water, the extracellular fluid (ECF). ECF represents approximately one-third of total body water and comprises several sub-compartments, including circulating fluid (blood plasma) and fluid surrounding cells (but not contained in blood vessels). As is true for the ICF, the ECF also contains several solutes, principally sodium and chloride ions. Thus, when an animal experiences extracellular dehydration, the critical remediating behavioral response must include the consumption of water, but the animal must also restore the lost sodium and chloride ions. On the other hand, depletion of the ICF generally occurs only when the concentration of the extracellular solution increases, thereby drawing water from the cells. Thus,

the increases in both water and saline after AngII injection are consistent with a role of this peptide in the response to hypovolemic, but not osmotic thirst. This hypothesis has been given recent support by studies using mice that are lacking a critical enzyme in the synthesis of AngII. These mice, which are unable to synthesize AngII, respond normally to stimuli inducing osmotic thirst, but they fail to drink in response to hypovolemia.

The example of AngII is also useful for discussing the diversity with which the body can use a single hormone. In this respect, it is unfair to define AngII as a peptide hormone or as a neuropeptide because it actually plays both roles. Indeed, the discussion so far has focused on AngII as a circulating hormone with a central site of action. Even the studies using direct injections of AngII into the brain were performed and discussed as models for peripherally derived AngII and used as evidence that this circulating AngII has a central site of action. It is nevertheless important to recognize that the brain appears to have an endogenous system of synthesizing AngII and may use this AngII as a transmitter within neural circuits. In fact, there is considerable evidence that all of the components illustrated in **Figure 1** can be found within the brain cells. Interestingly, some of the very same circuits that respond to circulating AngII appear to use centrally derived AngII as a peptide transmitter. Accordingly, studies using brain injection of AngII may have more relevance to AngII in its actions as a transmitter than its actions as a circulating hormone. Nevertheless, the circuits engaged by each source of AngII seem to be partially overlapping, if not identical, and the behavioral responses to central or peripheral AngII are markedly similar; most, if not all, differences have been attributed to the confounding actions of AngII on the vasculature directly. Indeed, the strong vasoconstrictive and hypertensive responses to AngII lead to the reduction of thirst through arterial baroreceptors. Thus, after a peripheral injection, AngII acts on the brain to stimulate intake at the very same time its hypertensive effects generate signals from the vasculature that decrease intake. Accordingly, dissociating behaviors solely mediated by AngII synthesized within the periphery or CNS has proven difficult, but it is clear that there is, at the very least, a great deal of overlap between the actions of AngII generated in either compartment.

AngII has also been an interesting illustration of the diversity of intracellular-signaling cascades stimulated by the so-called G protein coupled receptors. Although the traditionally ascribed mechanism of these receptors, including the receptors for AngII, involves the action of G proteins, it is becoming quite clear that members of this superfamily of receptors are capable of acting without their normally associated G proteins. Accordingly, it may be more appropriate to call this family of receptors the seven-transmembrane domain or heptahelical receptors. In the case of AngII receptors, it has become clear

that stimulation of several intracellular cascades, including the activation of p44/42 mitogen-activated protein (MAP) kinase (ERK1/2) occurs in the absence of G protein stimulation. Moreover, the behavioral relevance of each limb of intracellular signaling has also been illustrative. Recent evidence suggests that the G protein mediated limb of AngII receptor signaling is involved in AngII-induced water intake without playing a role in the NaCl intake that also results from AngII receptor stimulation. In addition, evidence is accumulating that MAP kinase family members, which can be activated without G protein stimulation, play a role in the NaCl intake stimulated by AngII, without being involved in the normally concomitant water intake. Although this demonstration of separate behavioral roles of divergent intracellular signals appears unique at the present time, further investigation of other transmitter systems may reveal similar mechanisms. Nevertheless, this recent advance in our understanding of the regulation of water and salt intake is simply an early step. Indeed, additional research is needed to fully understand the roles of the individual intracellular signaling pathways and the mechanism through which the behavioral dissociation may occur.

Oxytocin

In addition to AngII, other peptides are clearly involved in the regulation of water intake, although none has received the same level of attention as AngII (**Figure 2**). Oxytocin, for example, is commonly recognized for its endocrine role, and functions as a neuropeptide as well, being released from sites within the brain where it acts on neurons through a neurocrine (synaptic) mechanism or

through more diffuse paracrine actions. The majority of studies related to oxytocin and fluid balance have focused on its role in the consumption of saline solutions. Oxytocin decreases salt intake, but not water intake, in hypovolemic animals. Moreover, treatments that inhibit oxytocin action such as receptor antagonists or selective destruction of oxytocin-sensitive neurons enhance salt intake by hypovolemic animals, without having any effect on normovolemic animals. Although the relevant findings have been inconsistent, there is some evidence that oxytocin inhibits water intake as well as salt intake. This effect is especially notable in food-deprived rats, but has been observed in freely fed animals as well.

Atrial Natriuretic Peptide

Experiments focused on the role of atrial natriuretic peptide (ANP) in fluid balance reveal interesting commonalities with AngII and oxytocin. Similar to the studies using renal extracts that served as a precursor for the discovery of the renin–angiotensin system in drinking, a role for ANP in sodium balance arose from studies showing that atrial extracts had potent natriuretic effects. Also similar to AngII, which is synthesized in both the periphery and brain, ANP is secreted by brain cells as well as by the atria. Unlike AngII, which seems to have similar effects regardless of the site of production, there may be markedly different effects of centrally and peripherally acting ANP. Given the natriuretic effects of atrial extracts and peripherally administered ANP, one might expect a compensatory behavioral response that includes increased salt intake; however, the empirical findings have not fallen into line with this prediction. In

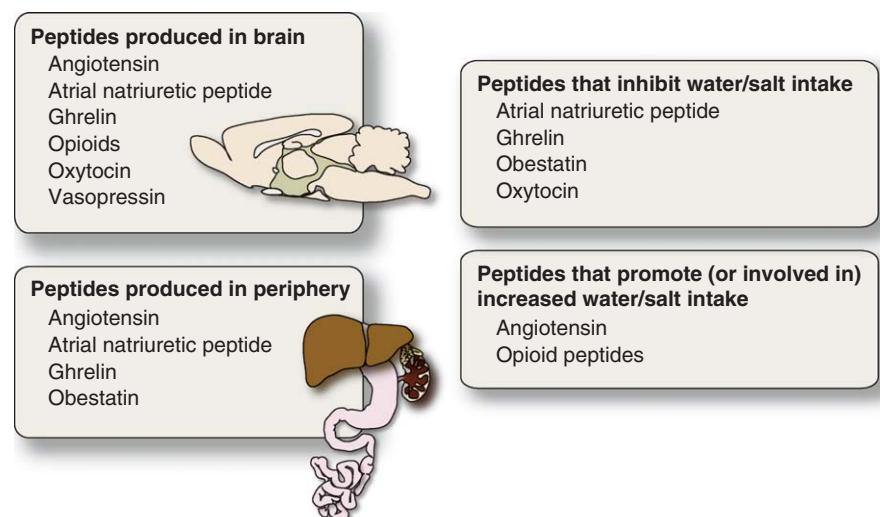

Figure 2 Summary of the peptides discussed in this article. Note that some peptides are produced in the brain and the periphery and that the site of production does not predict the direction of the effect on fluid intake.

fact, central administration of ANP reduces sodium intake in several experimental paradigms. Thus, it appears that the physiological role of ANP is to signal the need to reduce salt and this need is addressed by decreased salt intake and by increased natriuresis.

An inhibitory role of ANP in salt intake has been shown using a variety of techniques. Indeed, the paper described earlier that reported increased saline intake after selective destruction of oxytocin-sensitive cells, demonstrated a similar response after ANP-sensitive cells were destroyed using the same technique. These studies note an important difference between oxytocin and ANP. Specifically, when animals were made hypovolemic, which normally produces saline intake, but also injected with hypertonic saline or hypertonic mannitol, each of which normally counteract the natriorexigenic effects of the hypovolemia, animals without functioning ANP receptors increased salt intake. The comparison of hypertonic saline and hypertonic mannitol provides important mechanistic information because hypertonic saline increases both plasma osmolality and sodium concentration, whereas hypertonic mannitol increases plasma osmolality, without the addition of sodium. In fact, because it contains no sodium, injection of hypertonic mannitol dilutes the existing plasma sodium, effectively decreasing its concentration. Thus, the finding that destruction of ANP-sensitive cells removes the inhibitory effect of either hypertonic saline or hypertonic mannitol supports the hypothesis that ANP pathways are involved in both sodium- and osmolality-induced inhibition of salt intake. In contrast, destruction of oxytocin-sensitive cells had no effect on the inhibition of salt intake when hypovolemic animals were injected with hypertonic saline. Thus, it appears that ANP and oxytocin pathways are differentially involved in osmotically- and sodium-induced inhibition of salt intake under hypovolemic conditions.

Ghrelin and Obestatin

Ghrelin is a peptide produced predominantly in the stomach and small intestine that is best known for its role in food intake. Similar to oxytocin, ghrelin appears to be an example of a peptide that is most often associated with its endocrine actions, but there is increasing evidence that it is also produced within the brain where it functions as a neurotransmitter or neuromodulator. In addition to various anatomical investigations supporting the synthesis of ghrelin in the brain, there are subtle differences in the behavioral responses (specifically related to food intake) to centrally or peripherally administered ghrelin that argue for different roles of circulating and centrally released ghrelin. Although best known for its feeding

effects, a role for ghrelin in fluid balance is just beginning to be appreciated with several independent groups providing evidence for an antidipsogenic role of the peptide. One group found that ghrelin potently inhibited drinking by water-deprived rats. On the other hand, others have failed to observe an effect of ghrelin in water-deprived rats, but instead found that ghrelin reduced water intake stimulated by central AngII or by peripheral injection of hypertonic saline. In spite of these differences and the need for more research to reconcile these apparent discrepancies, it is becoming clear that ghrelin affects water intake and that the direction of the effect appears to be inhibitory.

The gene that encodes ghrelin also encodes another peptide named obestatin, which has been shown to reduce both water and food intakes; however, a careful analysis has suggested that the decreases are unrelated to each other. As is true for ghrelin, the mechanism underlying the behavioral effects of obestatin remains unclear, but the direction of the effects on food and water intake might suggest that ghrelin and obestatin, although encoded by the same gene, have markedly different actions in the CNS. Specifically, obestatin has similar actions on food and water intakes (suppressing each), whereas ghrelin has opposite effects on intakes of food (intake of which is increased by ghrelin) and water (drinking is decreased by ghrelin). The nature of these differences and the underlying mechanisms remain to be explored.

Opioid Peptides

Given the well-studied role of opioid peptides in motivated behavior, it should be no surprise that these peptides also modulate water intake. The involvement of opioids is not simple, however, and different effects have been attributed to different opioid receptor subtypes. Although additional research is needed to clarify some of the subtle issues involved, there is evidence that the involvement of specific receptor subtypes in drinking depends on the dipsogen causing the drinking. More specifically, deprivation-induced drinking appears to involve the μ_2 receptor, drinking after osmotic challenges such as injection of hypertonic saline seems to involve κ receptors, and drinking after AngII or isoproterenol (a β -adrenergic agonist) seems to involve μ_2 , δ , and κ receptor subtypes. These conclusions are based on a very small number of studies, however, and further work is needed to confirm and extend these findings. Nevertheless, given the different distribution of these receptor subtypes in the CNS, additional analysis of their involvement in drinking may reveal interesting information about the pathways involved in the responses to different dipsogens.

Conclusion

Similar to the discussion provided here, our understanding of the role of peptides in drinking behavior is far from complete. Other peptides not described here clearly influence drinking behavior and it is probable that future research will reveal new peptides that play a role in drinking or salt intake. The maintenance of body fluid homeostasis is of such importance, and also subject to so many perturbing factors, that it should come as no surprise that its regulation is complex with many redundancies. Even though a great deal of research has been devoted to understanding the regulation of fluid balance, a comprehensive picture of the neurochemical and neuroanatomical regulation continues to be elusive; however, understanding the peptides involved is an important step.

Glossary

Allostasis – The process of achieving stability through physiological or behavioral change. In allostasis, physiological variables are not kept constant; they vary according to what the organism needs to do.

Homeostasis – The process of achieving variability by counteracting variations in the internal milieu. In homeostasis, physiological variables are kept constant by processes that are activated by deviation from a set point and manage excess or insufficiency.

Stress – There are many definitions of stress. It usually refers to the response of the organism to challenges that tax its adaptive abilities.

Stressors – The internal or external factors that activate the stress response.

Psychoneuroimmunology is dealt with elsewhere in the encyclopedia.

Psychological Influences on Neuroendocrine Systems

The Early Pioneers

The study of psychological influences on bodily functions started in the early 1900s when Walter Cannon described the profound effects of rage and anger on the cardiovascular system and other organs innervated by the sympathetic nervous system. He pointed out the adaptive value of the alarm reaction for an organism exposed to situations that threaten its survival. He emphasized, in particular, the importance of this physiological response in helping the organism to meet the energy requirements of fleeing away from the danger, fighting it or hiding from it.

In the mid-1930s, Hans Selye made use of the same reasoning for his description of the response of the adrenal cortex to every stressor that threatens homeostasis. He proposed that the corticosteroids, which are released by the adrenal cortex in a nonspecific manner to all kinds of stressor, help in maintaining homeostasis and increasing the organism's resistance to the stressor. This formed the basis for his description of the General Adaptation Syndrome. Since Selye emphasized on the features of the response itself rather than on the circumstances in which it occurs, psychology was never an issue for him. This did not prevent Selye from wildly generalizing what he observed in response to catastrophic stressors (e.g., burn, hemorrhage, fractures, etc.) to what he called the stress of life, that is, the response to daily hassles.

From Stress to Psychoneuroendocrinology of Stress

Figure 1 summarizes the main differences between the physiological and the psychobiological models of stress. Cannon and Selye described the hard-wired systems that respond in a rigid manner to all kinds of threats. They both pointed to limits in the capacity of these systems to respond to stressors. These limits were attributed to the genetic makeup of the organism and/or its previous experience, and they accounted for the switch from physiology to pathology, in the form of the stress-related disorders.

Introduction

Psychoneuroendocrinology of stress is a very active field of research. Its success is not only due to curiosity but also due to the hope to understand how exposure to adverse events in life can ultimately culminate in the development of various pathologies gathered together under the label 'stress-related disorders.' These pathologies include both somatic disorders, such as cardiovascular diseases, and psychiatric disorders, such as depression and anxiety. In general, stressors by themselves do not trigger the pathological condition unless they are extreme but they modulate the rate of development of the disorder.

There are two intertwined facets in the psychoneuroendocrine studies of stress. One facet corresponds to the etymology of the word psychoneuroendocrinology. It corresponds to the study of psychological influences on the neuroendocrine systems that mediate the stress response. The second facet could be labeled 'neuroendocrinopsychology' since it actually corresponds to the study of the influences of neuroendocrine systems on behavior and cognition. Psychoneuroimmunology is a variant of psychoneuroendocrinology in which the variable of interest is the immune system instead of only the neuroendocrine systems that are activated by stressors.

This article focuses on the two facets of psychoneuroendocrinology of stress. However, how the stress response can translate into stress-related disorders is not discussed.

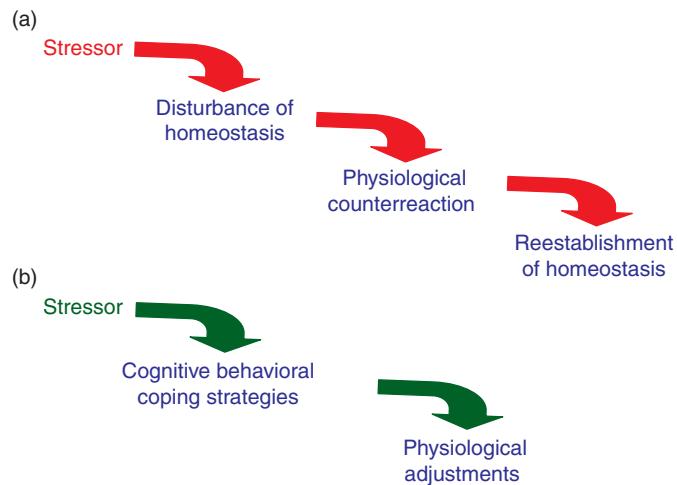

Figure 1 Physiological versus psychobiological perspectives on stress. (a) In the physiological model of stress, the stress response is totally determined by the nonspecific features of the stressor that disturbs homeostasis. (b) In the psychobiological model of stress, coping strategies that involve both cognitive and behavioral aspects determine the nature and intensity of the stress response.

Encouraged by the emphasis laid by Cannon and Selye on the sympathetic adrenomedullary and pituitary–adrenal responses to stressors, research on stress physiology progressed rapidly, thanks to the development of the relatively easily accessible biochemical methods for measurements of stress hormones. Despite these technological advances and the several studies that aimed at characterizing the hormonal stress response to various experimental and real-life situations, in both experimental animals and humans, those investigators who followed up on Selye's path had a difficult time trying to elucidate what exactly was responsible for activating stress hormones. John Mason, a neuroendocrinologist at the Walter Reed Institute, was the first researcher to propose a unified concept relating activation of the pituitary–adrenal system to the emotional arousal caused by the situation. He observed that the degree of change in circulating levels of cortisol in animals exposed to various stressors was more related to the excitation and behavioral agitation of the subjects under study than to the postulated derangement of homeostasis. Based on this observation, he reasoned that the cortisol response should decrease if excitation and behavioral agitation are minimized. Further, he demonstrated that habituating experimental animals to the experimental setup and masking the psychological aspects of the stressor, by making the subject unaware of its occurrence, annulled the cortisol response to various typical stressors such as cold, heat, or food deprivation.

Description of the stress response in terms of emotions was certainly a progress but not necessarily the end of the story since there was no general consensus on what exactly is an emotion and whether emotions could actually be studied in animals. Another important step forward was the demonstration by Seymour Levine

(or 'Gig' as he was affectionately called by his friends) of the importance of novelty, uncertainty, and lack of control in the modulation of the pituitary–adrenal response to stress in rats. An interesting example of the importance of controllability is conditioned taste aversion, which is a form of visceral conditioning in which the new taste of a drinking solution, for example, saccharin, is associated with the experience of sickness caused by nonlethal poisoning. One could think that reexposure to the taste solution previously associated with sickness should function as a stressor and activate the pituitary–adrenal axis. Levine showed that this was indeed the case. Rats that had recovered from poisoning and were inclined to sample the taste solution because they were thirsty displayed increased levels of plasma corticosterone. However, this response was observed only when the sole taste solution they had access to was the litigious taste. When previously poisoned rats were given the choice between the taste solution associated with sickness and water, they did not show any increase in plasma corticosterone levels. This experiment very well illustrates the potent pituitary–adrenal influence of being able to exert a choice, in this case avoiding the taste solution paired with sickness and going for the safe drinking solution.

Holger Ursin, in Bergen, Norway, went one step further and reinterpreted the data available on the importance of novelty, uncertainty, and lack of control in terms of cognition. He argued that the stress response typically occurs in cases of discrepancy of expectations, when the situation that is experienced by the subject differs from the expected one. This can take place in a situation in which the subject has learned to associate two stimuli in terms of the probability level of their association, or in a situation in which the subject has learned to expect certain consequences in response to his/her behavior.

The first situation corresponds to Pavlovian conditioning and the second one to instrumental or Skinnerian conditioning.

Stress and Coping

The shift from emotion to behavioral and/or cognitive elements of the situation is important since it sets up the scene for the convergence of biobehavioral stress research and psychological theories of stress. It also enables reconciling research on stress and psychological research on emotions. Coping theories have been built by psychologists independently of any reference to physiology to account for the factors that modulate the degree of emotional distress experienced during stress. The basic idea originally formulated by Folkman and Lazarus is that we constantly appraise the stream of events to which we are exposed for their threat value. During the first phase, or primary appraisal, we evaluate our possibilities to deal or cope with the situation. Then, during the second phase, or secondary appraisal, we evaluate the way our plan to deal with the situation is likely to succeed. This two-level appraisal process determines not only our level of emotional distress but also our physiological response to the situation. It is relatively easy to predict the direction and intensity of the physiological adjustments to the situation according to coping strategies. Active coping efforts are associated with activation of the sympathetic nervous system, as proposed by Marianne Frankenhausen, whereas the inability to control the situation is associated with activation of the pituitary–adrenal axis.

As pointed out by James P. Henry in his seminal review of the psychobiology of stress, the stress response can be best described over time in terms of a trajectory in the two-dimensional space delimited by the two orthogonal dimensions of coping attempts and coping failures. Another important feature of this representation is that each of these dimensions is truly bidirectional. Full mastery of the situation, together with social support, leads to deactivation of the pituitary–adrenal axis, whereas relaxation is associated with deactivation of the sympathoadrenomedullary response (Figure 2).

Allostasis versus Homeostasis

An important aspect of the stress response that has been left aside in this move from physiology to psychology is the biological meaning of this response. Selye considered the stress response as an attempt of the organism to restore homeostasis. The threats we are exposed to disturb homeostasis and the organism has no other alternative than to restore homeostasis to its original value as soon as possible. As pointed out by Henri Laborit, who promoted hibernation for the treatment of shock and whose seminal work decisively contributed to

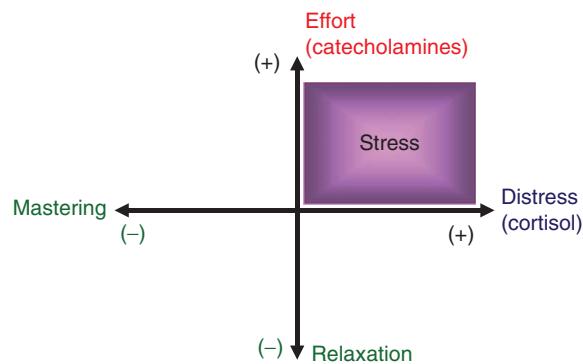

Figure 2 Influence of coping strategies on the stress hormonal response. Activation of the sympathetic nervous system is associated with effort to actively control the situation. Activation of the hypothalamic–pituitary–adrenal axis is associated with distress induced by uncontrollable and unpredictable challenges. Decreased sympathetic nervous system activation is associated with relaxation, whereas decreased hypothalamic–pituitary–adrenal-axis activity is associated with full mastering of the situation and high levels of social support. Note that stress in its classical acceptation corresponds to the upper right quadrant.

the development of neuroleptic drugs, the dictatorship of absolute homeostasis that was enthusiastically embraced by Selye was wrong. Homeostasis is not absolute but relative. The homeostasis of an organism exposed to a threat is different from that of the one at rest since everything – from behavior to physiology – must be attuned to the necessity of coping with the threat. We are constantly changing our homeostasis to adapt to the different situations we are facing throughout our daily life, and we do this in a controlled manner, in accordance with our expectations of what we will have to do.

The same concept was formalized by Peter Sterling and Joseph Eyer in the context of the neural regulation of blood pressure. The term ‘allostasis’ was coined to refer to the process of achieving stability through physiological or behavioral change. In homeostasis, physiological variables are kept constant because deviations from the set point feed back into a correction mechanism as soon as they are sensed. In allostasis, physiological variables are no longer constant but vary according to what the organism needs to do. Bruce McEwen applied the concept of allostasis to the neuroendocrinology of stress by proposing that secretion of glucocorticoids and activity of other mediators of stress, such as the autonomic nervous system and brain neurotransmitters, wax and wane with allostatic load. Adaptation to daily life events is dependent on these allostatic processes rather than on stress mechanisms that intervene only in extreme situations. The inability to turn on or off physiological and behavioral allostatic processes when needed in the face of repeated daily hassles leads to wear and tear or to an allostatic overload that is at the origin of stress disorders. In this acceptation, however, allostasis loses its original reference to the

influence of mental operations such as expectations on physiological variables. This makes allostasis differ from stress only by the inclusion of behavioral changes in addition to the physiological alterations induced by psychosocial stressors.

Social Stress

The study of influences of stress on physiology has benefited, during the last three decades, from an emphasis on psychosocial factors not only at the experimental level but also at the clinical level. Most mammalian species live in social groups that are kept cohesive by cooperation and social support and become disrupted in case of social conflict and competition. Social factors exert strong influences on the neuroendocrine system. The most striking illustration of this phenomenon is the inhibition of puberty and hormonal cycling that occurs in young female cotton-top tamarins (*Saguinus oedipus*) for the duration of their stay in the parental group. These animals start cycling as soon as they are separated from their parents. There is a tendency to believe that subordinate individuals are more stressed than dominant ones. However, this notion is wrong. In a dominance–subordination hierarchy, low-social-rank individuals do not always display heightened activity of the pituitary–adrenal axis compared to high-rank individuals. In fact, the hormonal pattern of subordinates depends on the behavioral strategies that dominants need to use in order to maintain their social rank, and the social support they receive from congeners. A dominant animal that always need to reaffirm its dominance because of repeated challenges by subdominant animals presents with a higher pituitary–adrenal activity than its congeners. Highly aggressive rodents that defend their home territory in an offensive manner display high sympathetic reactivity to stressors and behave in a relatively rigid manner in response to changes in their environment. In contrast, rodents with low aggressive tendencies have a high pituitary–adrenal reactivity and are more flexible in their cognitive strategies when confronted with a new environment. The existence of important individual variations in response to social factors makes the use of generic terms such as social stress ecologically nonrelevant. This does not prevent researchers from developing animal models of social stress or defeat to study the pathophysiology of psychiatric disorders and the mechanisms of action of neuroactive drugs.

Social Support and Other Stress-Buffering Factors

Psychosocial factors are not always negative. As mentioned above, cooperation and support are the rule rather than the exception in most social groups. Social

support refers to the physical and emotional comfort that we receive from others, especially in case of need, and it is dependent on the social network that is available to us and on the type of event we are exposed to. There is a general consensus that health is better in individuals who have high social support compared to individuals with limited or no social resources. It is important to note that the effect of social support can be due at least in part to only social proximity with familiar individuals. As an illustration of this, individuals who are exposed to stressors alone or in the face of an unfamiliar subject do less well than individuals who are exposed to stressors with individuals they already know. The emphasis by the American Psychology Association placed on positive psychology has favored the emergence of research on individual traits that buffer the impact of stress, such as hardiness, optimism, and resilience. However, these traits that are often valued by our social environment are not always beneficial. Optimism is a good example since its impact on another measure of the organism response to stress, immunity, depends not on just the tendency to have positive thoughts. As pointed out by Segerstrom, dispositional optimism that is defined by positive expectations about outcomes can be detrimental in the face of serious adversity that cannot be really mastered.

Neuroendocrine Influences on Psychological Functions

Influence of Stress Mediators on Emotion

Cannon had the intuition that the stress hormones that are released in response to stress are responsible not only for the somatic component of negative emotions but also for their psychological components, the feelings. However, his efforts toward demonstrating that the adrenalin, which is released during fear, can itself induce fear were not very successful. The psychologists who followed him in this enterprise did not achieve more success than he had. Injection of adrenalin to naive subjects so as to mimic circulating adrenalin concentrations during the emotion of anger and rage was unable to induce any emotion of this type. At the best, subjects reported feelings of a cold emotion in which they were not really engaged. Based on a limited set of experimental data collected from a series of experiments consisting of varying the socioemotional context in which subjects treated with adrenalin or a placebo were tested, Schachter and Singer proposed in 1962 that adrenalin increases arousal in a nonspecific manner. This nonspecific arousal sets up the stage for the occurrence of the specific emotional state that is triggered by the context in which the subject is immersed. In other words, specificity of the emotion caused by adrenalin is dependent on the context, not on the dose of adrenalin. Although widely accepted, the two-factor

theory of emotion of Schachter and Singer is plagued by many approximations in the analysis of the original data set and poor reproducibility of the experimental results.

Baseline versus Feedback Actions of Stress Mediators

Since these pioneering studies, many stress mediators produced not only by peripheral endocrine glands but also by the brain have been found to influence the neuronal circuits that underlie behavior. These actions are exerted both in a baseline manner and in a retroactive manner. The effects of corticosterone on submissiveness in mice submitted to repeated defeat by an experienced opponent provide a good example of the distinction between baseline versus feedback action of stress mediators on behavior. Administration of the natural adrenocortical hormone corticosterone to adrenalectomized mice facilitated the development of submissiveness, as measured by the number of attacks by the opponent that is necessary to trigger a submissive posture in the mice under study. However, this effect was more marked in the second confrontation with the opponent than in the first one. This difference indicates that an experience of defeat facilitates the effect of corticosterone on future submissiveness. This defines the feedback effect of hormones on behavior. The behavioral action of the hormone under consideration requires a prior critical experience. The best way to demonstrate a feedback effect is to modulate the intensity of the hormonal response that is triggered by the prior experience of defeat, which can be done by administering various doses of corticosterone immediately after the first defeat session to adrenalectomized mice and assess their submissiveness in a second test carried out 1 or 2 days later. The higher the corticosterone response to the experience of defeat in this experiment, the faster did the intruder mouse display submissive behavior. These results indicate that the hormonal response, the nature of which depends on the way the situation is perceived and represented and the individual behaves, influences by its feedback effect on the brain the way the individual will adapt to the same situation on further occasions.

Neuropeptides

Neuropeptides that are produced in the brain to regulate endocrine systems also have profound effects on the brain. The first example of such an effect was obtained by David de Wied. Working with Bela Bohus in Utrecht, the Netherlands, he observed that rats that had acquired an active avoidance response extinguished this response faster when treated with corticosterone but retained it longer when treated with adrenocorticotropic hormone (ACTH). The posterior pituitary neuropeptide

vasopressin was later found to have a similar effect to that of ACTH. Furthermore, peptides containing only part of the amino acid sequence of ACTH or vasopressin were found to have similar effects as the parent peptide, despite the loss of neuroendocrine effects. These results indicate that the amino acid sequence that codes for the behavioral activity of a neuropeptide is not necessarily the same as the one that codes for the endocrine activity of the peptide.

This field of research has seen a boom with the identification of a growing multitude of peptides in the brain, including peptides originally discovered in the gut. The search for behavioral activity of neuropeptides tends to be constrained by phrenology-like approaches that assign distinct roles to specific peptides, often in relation to their originally discovered activity. For instance, vasopressin was originally seen as a memory-enhancing peptide, in line with its enhancing effects on retention of passive avoidance. However, vasopressin has turned out to be involved in the formation of social memory and to control pair bonding in voles, commonly known as field mice. Prairie voles (*Microtus ochrogaster*) are highly social and monogamous, whereas montane voles (*Microtus montanus*) are solitary and polygamous. Both species have similar levels of the circulating neurohypophyseal hormone vasopressin. However, montane voles lack vasopressin receptors in some critical areas of their brains in contrast to prairie voles. Artificial insertion of the gene for this receptor into the brains of montane voles causes them to change their phenotype from promiscuity to monogamy and behave like prairie voles.

In the same manner, corticotropin-releasing hormone (CRH) is usually described as the mediator of stress-induced arousal and anxiety. However, it also acts as a modulator of immunity with opposite effects depending on its site of production. In the brain, CRH downregulates inflammation through its effects on the pituitary–adrenal axis and the sympathetic nervous system. In the peripheral nervous system and accessory cells of the immune system, CRH promotes inflammation through direct effects on macrophages and lymphocytes.

Conclusion

Psychoneuroendocrinology of stress is a very active field of research that is covered by two specialized journals, *Psychoneuroendocrinology* and *Stress*, and can be found in more general scientific journals as well. This article has been restricted to the presentation of the way psychological factors influence neuroendocrine systems and, vice versa, the way neuroendocrine systems influence psychological functions. However, the field is much richer than what this presentation might indicate. At the anatomical level, the neuronal circuits that are involved in information processing of stressful stimuli can now be examined thanks to the

development of neuroimaging techniques. Using functional magnetic resonance imaging, for instance, it is possible to study the relationship between the salivary cortisol response to an emotional visual scene and specific brain structure activity based on signals dependent on blood-oxygen levels. The way this association between the hormonal response and specific brain region activity is modulated by various conditions, such as depression or posttraumatic stress, is important to understand how attentional resources to potentially threatening stimuli are affected by the condition under study. Another important development is the consideration of temporal variations in sensitivity to stressors. The study of possible alterations in the bidirectional relationships between hormones and behavior over the life span has become an important theme of research in psychoneuroendocrinology. In particular, currently, there is much interest in understanding how activation early in life of the stress hormonal systems can shape coping strategies and physiological response to adversity at adulthood.

Glossary

- Dispositional optimism** – A trait that reflects generalized positive expectations about the future.
- Hostility** – A stable personality trait characterized by cynical mistrust, aggressive responding, and an overly antagonistic attitude.
- Negative affect** – The feelings associated with negative engagement with the environment, which include anger, distress, and fear; can be conceptualized as a state (reflecting short-term emotional responses) or as a trait.
- Positive affect** – The feelings associated with pleasurable engagement with the environment, which include happiness, excitement, and enthusiasm; can be conceptualized as a state (reflecting short-term emotional responses) or as a trait.
- Sociability** – A stable personality trait reflecting a tendency to affiliate that has been found in a variety of species; is similar to extraversion in the human.
- Type A behavioral profile** – A personality type comprising impatience, time-consciousness, competitiveness, hostility, and aggressiveness; was once thought to be a risk factor for coronary heart disease (CHD), but newer evidence implicates only the hostility component in CHD.

Introduction

Only within the past three decades has it been generally appreciated that the immune system is not an isolated system of the body, but rather is in intimate and continuous interaction with the central and peripheral nervous systems, and that this interaction is bidirectional. This realization has led to empirical support for the long-suspected idea that psychological and social factors are associated with disease processes, and has given rise to a new scientific discipline, psychoneuroimmunology (PNI). The focus of much of this research has been on establishing links between psychosocial factors (including personality, psychopathology, coping, and environmental events) and disease-relevant immune processes, such as inflammation and immunization; in understanding the physiological mechanisms associated with those links; and recently, on using this information therapeutically.

Brief Overview of the Immune System

There are two broad types of immune responses, typically referred to as innate (natural or nonspecific are synonyms) versus acquired (adaptive or specific). Innate immune responses are the first line of defense against pathogens, allowing the organism to combat the microbe while more targeted, specific, immune responses develop over days. For example, within hours of becoming infected with a virus, a cell will produce high levels of interferons (IFNs) – proteins that inhibit viral replication. IFNs also activate natural killer (NK) cells, which kill virally infected cells. Inflammation is another aspect of innate immunity. In acute situations, injured cells release substances that alter vascular permeability locally, and that recruit phagocytic cells. Innate immune responses such as NK-cell activity and inflammation develop automatically and with consistent strength. This is in contrast to acquired immunity, whose main cell type is the lymphocyte. When a pathogen is first encountered, the few lymphocytes that can detect that pathogen become activated and then differentiate and clonally expand. Over the course of the next several days to weeks, a highly specific response develops to a protein portion of that pathogen, referred to as an antigen. Once the pathogen has been eliminated, specific immune responses retain a memory of the encounter. Should that same pathogen be encountered a second time months or years later, memory lymphocytes will be able to rapidly upregulate their responses, and so this very intense and targeted immune response will occur much more rapidly with succeeding exposures. This provides the rationale for vaccination.

Specific immunity comes in two varieties – humoral and cell-mediated. Humoral immunity results from the production of antibodies by B lymphocytes (also referred to as immunoglobulins (Ig)). Antibodies are proteins that are secreted by B cells and are specific to a single antigen. Antibodies attach themselves to the pathogen for which they are specific, and neutralize the ability of that pathogen to infect or cause disease in the host. There are five broad types of antibodies, but the type that provides the bulk of humoral immunity in the blood compartment is the G subtype, referred to as IgG. Antibodies do not enter infected cells; consequently, they are most effective against extracellular microbes like bacteria. Cell-mediated immunity, on the other hand, involves development of a specific immune response designed to kill the infected cell. The main effector cell is the

CD8+ T-cell – often referred to as a cytotoxic T lymphocyte (CTL). (CD refers to a set of proteins on the surface of the cell that can be used to identify the type of immune cell.) The function of this cell is similar to that of the NK cell, but an NK cell will kill any virally infected cell, whereas a CTL will only kill a cell expressing its specific antigen.

It is important to note that the two distinctions made so far – namely, between innate and acquired and between humoral and cell-mediated immunities – are, in reality, much less distinct. Both the innate and acquired arms of the immune system typically work together – a specific immune response can amplify, focus, and direct the innate immune response, for example. Moreover, cells of the innate system, such as the phagocytic macrophages, serve as antigen-presenting cells – they kill foreign microbes and present peptide fragments of them (i.e., antigens) on their surface to cells of the specific immune system. A particular pathogen may also activate both cell-mediated and humoral responses. Viruses, for example, are obligatory intracellular parasites, requiring a cell's machinery to replicate. While they are inside a cell, they cannot be reached by the IgG; rather cell-mediated immune responses focus on killing the infected cell. Once the virus has replicated within a cell, however, it will spread itself by leaving the cell and circulating to target other, as-yet uninfected, cells. During this extracellular stage, it is susceptible to neutralization by antibody. In addition, it is also important to recognize that one very important T cell – the CD4+ T lymphocyte, referred to as a helper T-cell – helps facilitate a variety of immune responses, both innate and specific, as well as both cell-mediated and humoral responses (via different subtypes, referred to as T-helper 1 (Th1) and T-helper 2 (Th2) cells, respectively).

There are a number of ways that immune responses can be measured. One of the easiest is simply to draw a blood sample and determine the numbers of specific types of cells in the circulation. Unfortunately, enumerative measures such as these bear little relationship to immune function – the ability of the cells of the immune system to respond to an antigen. Only a small percentage of immune cells are present in the circulation; most of the action in an immune response takes place in lymphoid tissue such as lymph nodes or spleen, and there is generally little relationship between cell numbers in peripheral blood and the ability of the organism to mount an effective immune response to a pathogen.

Most contemporary studies focus on functional immune measures. One simple functional measure of humoral immunity is to immunize (vaccinate) an animal and measure the amount of IgG that is produced several weeks later. This *in vivo* measure reflects the integrated response of an individual's immune system, and can assess a primary response (if this is the first time the animal has

been immunized with that antigen) or a secondary response (how well the immune system responds to an antigen to which it had previously been exposed). A second, related measure is to assess the amount of antibody to a latent herpes virus. Normally, the immune system manages herpes virus infections, but under certain conditions – including stressful conditions – viral antigens reappear, stimulating B cells to produce more antibodies. Thus, unlike in the first example, where a high antibody titer is (presumably) beneficial, increased antibody to a herpes virus reflects the immune system's inability to successfully manage the latent infection. A third measure of immune function involves isolating the peripheral blood mononuclear cells (PBMCs; mostly lymphocytes) from a blood sample, and stimulating them with either mitogens or antigens (an antigen stimulates a small, specific set of cells, whereas a mitogen stimulates numerous sets of cells) in order to assess mitosis (proliferation). A variety of mitogens are used, including concanavalin A (ConA) and phytohemagglutinin (PHA) – both of which are T-cell mitogens – and pokeweed mitogen (PWM), which stimulates B and T cells. Once stimulated, a marker is incorporated into the culture that allows the amount of proliferation to be measured. A fourth functional measure assesses the ability of NK cells to lyse cells from defined human tumor cell lines. A fifth measure focuses on cytokines – proteins that are produced by a variety of cell types and have many functions, including promotion of inflammation (proinflammatory cytokines) and facilitating communication both within the immune system (e.g., between cells of the innate and adaptive immune systems) and between the immune and other physiological systems. Cytokines can be measured in plasma, or in the supernatant of mitogen-stimulated PBMCs. Finally, an *in vivo* measure of cellular immunity is the delayed-type hypersensitivity (DTH) response. This involves measuring the inflammatory response 48 or 72 h following exposure to a previously encountered antigen. DTH is typically performed using a skin-prick test, and the response that is measured is the size of the resulting wheal.

Mechanisms of Nervous–Immune System Interactions

It is now known that cells of the immune system such as lymphocytes contain a variety of receptors for non-immune-related ligands, including serotonin, opioids, and various neuropeptides (e.g., substance P, corticotropin-releasing factor (CRF), and somatostatin). The bulk of research in PNI that has focused on how psychosocial factors affect immunity, however, has focused on interactions between the two major stress-response systems and the immune system.

Sympathetic Nervous System (SNS) Influences on Immunity

Perhaps the most direct mechanism by which an organism's experience can get translated into an immune outcome involves innervation of primary (thymus, bone marrow) and secondary (lymph nodes, spleen, gut-associated lymphoid tissue, etc.) lymphoid organs by catecholaminergic fibers of the SNS. Of importance, there is no anatomical evidence of efferent parasympathetic innervation of any lymphoid organ, suggesting that there may have been survival value in having the immune system responsive to increased activity of the SNS. These sympathetic fibers enter in conjunction with the vasculature, but spread into parenchymal tissue and release norepinephrine (NE) non-synaptically in the vicinity of immune cells. NE binds to β_2 -adrenergic receptors (the predominant type of adrenergic receptor on immune cells), which are present on nearly all types of immune cells, the principal exception being the Th2 cell. Stimulation of the β -receptor elevates cyclic adenosine monophosphate (cAMP), initiating a cascade of intracellular signaling events. Epinephrine, produced and released by the adrenal medulla in response to SNS activation, serves as an endocrine mediator that stimulates the same receptors.

Functionally, activation of the SNS results in a variety of complex effects, depending on when cells of the immune system encounter NE relative to their being stimulated by an antigen. In terms of innate immunity, though, *in vitro* studies suggest that NE generally suppresses NK-cell and macrophage activity, and production of the proinflammatory cytokine tumor necrosis factor-alpha (TNF- α) by stimulated macrophages appears especially affected. NE also has effects on specific immunity, such as enhancing antibody production and suppressing CTL activity. Activation of the SNS can have disease-related consequences as well. For example, suppression of NK-cell activity by NE is associated with enhanced tumor metastasis – both of which effects can be prevented by administering a β_2 -adrenergic receptor antagonist. In addition, in lymph nodes, active replication of the simian immunodeficiency virus (the monkey form of human immunodeficiency virus (HIV)) occurs nearly fourfold higher in the vicinity of catecholaminergic nerves compared to areas devoid of SNS innervation. Finally, growing evidence indicates substantial plasticity in lymph node-innervation patterns. Stress can increase the density of innervation, which is associated with increased expression of neurotrophic factors such as nerve growth factor.

HPA Axis

Should a stressor persist for more than a few seconds, activity in the HPA-axis system is likely to be increased. Areas of the brain involved in processing emotion-related

information, such as the limbic system, influence release of CRF from neurons in the hypothalamus. CRF, acting as a hormone, mediates release into the circulation of adrenocorticotrophic hormone (ACTH) from the anterior pituitary, with consequent release of glucocorticoids (GCs; primarily corticosterone in rodents and cortisol in primates) from the adrenal cortex. Long before their mechanism of action was known, GCs were used clinically as anti-inflammatory agents. These and other effects of GCs result from the fact that they are steroid hormones, fat-soluble molecules that can traverse the cell membrane, attach to intracellular receptors, and act as transcription factors to activate or repress gene expression. The principal receptor type for GCs is the GC receptor (GR) – a protein that exists in virtually every nucleated cell. GRs can affect transcription directly, acting via GC response elements in promoter regions of genes, or indirectly, through interactions with other transcription factors, such as NF- κ B, a transcription factor that upregulates expression of proinflammatory genes.

Glucocorticoids exert numerous effects in the immune system. They decrease the numbers of leukocytes in peripheral blood, in contrast to catecholamines, which often lead to an immediate increase in numbers. GCs also downregulate genes that code for proinflammatory cytokines, such as interleukin (IL)-1 β , IL-6, and TNF- α , as well as the expression of cytokine genes associated with other aspects of the immune response such as specific immunity. Moreover, GCs can also affect expression of a variety of cytokine receptors. For example, during an immune response, local production of IL-12 by antigen-presenting cells can facilitate the differentiation of naive T cells into Th1 cells, which promote a cell-mediated immune response involving CTLs and macrophages. GCs can decrease the expression of the IL-12 receptor as well as the production of IL-12. Because Th1 and Th2 responses tend to be reciprocally regulated, the effect of GCs is to generally shift the balance toward a Th2 phenotype, facilitating humoral and allergic responses and inhibiting cellular responses. In addition, because mRNA expression of the GR is itself affected by GCs, typically in a negative fashion, the effects of chronic stress, in which GCs may be elevated for days, weeks, or longer, can alter regulatory processes that lead to adverse outcomes, particularly with respect to viral infections.

Examples of Topics under Active Study

Timing of Stressors: Prenatal Effects

Events occurring early in life typically have disproportionate influences on many different outcomes, largely because of the increased sensitivity to the environment during periods when biological systems are organizing. A recent emphasis on fetal programming in biology and

medicine has shown that the experience of the pregnant female can have consequences for offspring that last well into adulthood. While animal models for study of the effects of prenatal stress on immunity are invaluable, it is important to note that the major models – rodents and primates – differ substantially on when, relative to birth, the immune system develops. This fact – along with differences between laboratories in the nature and timing of the stressor, as well as the timing of the postnatal immune assessments – may explain the many conflicting results in this new field. Nevertheless, in general terms, the effects of prenatal stress on immunity are negative. In rodent models, prenatal stress has been associated with decreased cytotoxic function of NK cells, decreased phagocytosis by macrophages, and reduced IgG in serum. Effects on cellular immune function – as indexed by measurement of proliferative responses to mitogen stimulation – have been mixed, with increased proliferation reported in response to PHA and PWM, but decreased proliferation to ConA, relative to nonstressed controls. In nonhuman primate studies, prenatal stress during midgestation has been associated with a decreased proliferative response in a mixed lymphocyte culture compared to nonstressed controls, and this difference in immunity persisted through 2 years of age. Moreover, when PBMCs were stimulated *in vitro*, lower production of the inflammatory cytokines TNF- α and IL-6 was found in prenatally stressed animals.

The primate studies also included assessments of GC sensitivity, by incubating stimulated PBMCs with varying concentrations of the synthetic GC dexamethasone. As expected, dexamethasone inhibited TNF- α and IL-6 production in a dose-dependent fashion. However, addition of dexamethasone to the wells for the control animals resulted in cytokine concentrations that were similar to those found in the prenatally stressed animals' wells that did not contain dexamethasone. This suggests that the effects of prenatal stress on infant immunity may be mediated by the effects of the stressor on the mother's HPA-axis system. GCs are known to cross the placental barrier, and are considered a major candidate for mediating the effects of stress on fetal immune development. Demonstration of the importance of GCs as mediators has been shown in primate studies in which ACTH (the peptide that stimulates release of cortisol, but which itself does not cross the placenta) was administered to pregnant females. Offspring born to such females show reduced responses in mixed lymphocyte cultures and reduced proliferative responses to ConA. Other molecules have been proposed as possible mediators of the relationship between stress in the prenatal period and postnatal immune function. These include catecholamines, opioids, cytokines, and other steroids. Whether these potential mediators exert direct effects (e.g., by crossing the placenta and influencing development of

fetal immune organs) or indirect effects (e.g., by acting on nonimmune organs in the fetus, by altering placental function) is a source of continued interest.

Duration of Stressors: Acute versus Chronic Stress

Up to the past decade, stress was generally considered immunosuppressive. Recent evidence, however, suggests that acute stress (generally lasting minutes to hours) can be immunoenhancing, while immunosuppression is typically seen when stress is chronic (lasting for hours per day over a period of months to years). The immunoenhancing effect of acute stress has been conceptualized as adaptive – in the human's evolutionary history, many short-term stressors would have been encountered that could result in injury or infection. It would make sense that natural selection has shaped physiology to overcome such natural challenges (e.g., from an encounter with a predator); individuals capable of doing so would have greater reproductive success. Given this view, it is not surprising that the immunoenhancing effects of acute stress are more often seen in localized tissues that are likely to encounter challenges such as wounding or infection. For example, acute stress has been shown to enhance the cell-mediated skin DTH response to a previously encountered antigen.

In contrast to some of the data from studies of acute stress, chronic stress typically leads to immunosuppression. This is due, in large part, to chronic activation of the HPA axis and subsequent release of GCs which, as described above, suppress inflammation and promote a Th2 response. Why might GCs serve a suppressive function? It is important to recognize that immune responses can be destructive to normal tissue as well as to damaged/infected tissue. The HPA axis is an important regulator of immunity. This has been demonstrated in studies of adrenalectomized rodents who can die within a day or two following simple immunization – but the effects can be reversed if the animals are given corticosterone replacement treatment. These studies provided some of the strongest early evidence for the idea that there is a bidirectional relationship between the immune system and the HPA axis – infection can activate the HPA-axis system, which can then serve as a brake on the resulting immune response. Chronic stress taps into this system, not only by virtue of the elevated levels of GCs that can occur during chronic stress, but also by stress's ability to alter regulation of the HPA axis (and the HPA-immune axis) through its impact on GR number and binding in target cells.

Host Factors: Personality and Immunity

Links between personality and disease have been suspected for centuries, although mechanisms have been

unclear. Certainly, personality can affect health through non-immune-related mechanisms. Conscientious individuals, for example, may be less likely to smoke, more likely to take their medications regularly, and have more health check-ups that could result in earlier disease detection. The effects of personality on immunity can also be mediated via coping behavior. For example, in a study of the simian immunodeficiency virus infection in rhesus monkeys, some monkeys experienced socially stressful circumstances. Animals that were low in sociability – a stable personality trait reflecting a tendency to affiliate – showed more submissive behavior, and also greater expression of genes that are induced by IFNs. Animals high in sociability showed the opposite pattern. Mediational analyses, however, revealed that the effect of sociability on IFN-stimulated gene expression in PBMCs was mediated completely by display of submissive coping behavior.

Other research has focused on determining whether individuals with different personality characteristics are merely built differently. For example, hostility – a major component of the type A behavioral pattern – has long been associated with increased risk for heart disease, and there has been a growing recognition that heart disease reflects an inflammatory process. However, is hostility related to inflammation outside the context of heart disease? Evidence indicates that it is – healthy, middle-aged individuals scoring high on indicators of hostility had higher concentrations of inflammatory markers such as IL-6 and C-reactive protein in peripheral blood even after controlling for health practices, demographic factors, and a closely related psychological construct – negative affect. Animal studies have also provided evidence that personality is associated with constitutional differences. Monkeys that are low in sociability had a nearly threefold higher density of NE-secreting nerve fibers in their lymph nodes, compared to monkeys that were high in sociability. Low-sociable monkeys also showed greater expression of IFN- γ and of IL-4 mRNA in lymph nodes, and, functionally, low-sociable monkeys showed a lower IgG response 9 months after tetanus toxoid immunization. Of course, data like these are largely correlational and do not address the origins of the relationship between personality and immunity, or the nature of the mechanisms linking the two.

Positive Emotionality: Positive Affect and Optimism

While the bulk of research studying psychosocial influences on immunity have focused on stress, distress, and negative emotion, there is an emerging research area examining how positive emotional states impact immune function and health. Two constructs that have been examined include positive affect and optimism.

Positive affect refers to the feelings associated with pleasurable engagement with the environment, which include happiness, excitement, and enthusiasm. As with many emotion-related constructs, positive affect can be of brief duration (often referred to as state positive affect) or can reflect a stable disposition (trait positive affect). When considered as a trait, positive affect tends to be independent of negative affect, while state-like measures of the two constructs typically reveal strong negative correlations. In general, measures of state positive affect (e.g., induced by having subjects watch a humorous film) are associated most strongly with higher levels of secretory IgA measured in saliva. This antibody type is found principally on mucosal surfaces where it serves as a first line of defense against microbes. Interestingly, similar results have been found when negative affect has been induced, suggesting that it is activation of emotions – rather than the valence of the activated emotions – that affect immunity. The similarity in results may be related to activation of the SNS in both positive and negative emotional states. Longer-term assessments of trait positive affect have generally revealed positive effects. For example, the level of dispositional positive affect was found to be positively correlated with the *in vivo* antibody response to hepatitis B vaccination, even after controlling for dispositional negative affect. Other studies have suggested that trait positive affect is associated with greater NK-cell activity, better control of latent herpes viruses, and increased Th1 cytokine responses to antigenic stimulation *in vitro*.

Like positive affect, optimism can be considered as either short term (situational optimism) or more trait-like (dispositional optimism). It is the latter construct that has been examined in immune studies. Dispositional optimism is often defined as involving generalized positive expectations about the future, and several studies have shown that dispositional optimism is generally associated with positive health outcomes such as blood pressure and self-reports of health. Studies of immune function have been mixed, however. It has been suggested that the key to understanding the conflicting results relates to the qualities of the stressor – in general, when stressors are straightforward, brief, and controllable, dispositional optimism is associated with better immune function, and when stressors are difficult, prolonged, and uncontrollable, higher dispositional optimism is related to poorer immunity. Measures that have been examined include NK-cell activity and DTH responses. Psychological explanation of these results has suggested that during difficult tasks, those low in dispositional optimism typically disengage, while optimists – who typically show higher motivation compared to pessimists – remain engaged, which can result in greater effort, fatigue, and stress.

Treatments: Behavioral Interventions

Many PNI studies have demonstrated causal relationships between psychosocial factors and immune outcomes. A few studies are utilizing this information to try to identify behavioral interventions that can palliate existing disease conditions and promote better adjustment to diagnosis and treatment for major conditions. The principal pathways by which behavioral interventions such as exercise, relaxation training, biofeedback, massage, and cognitive behavioral stress management (CBSM) work is through modulation of the stress-response systems described above. In general, research has focused on medical conditions in which the immune system is implicated, such as acquired immune deficiency syndrome (AIDS), and conditions that are relatively long term, such as cancer and persisting inflammation. Application of basic PNI results to the clinical setting is in its infancy, but will be of increasing importance in the future.

One example of a successful application has been use of CBSM in HIV-infected people. The focus of this treatment is to provide the patient with techniques that affect appraisals of stressful events, facilitate more effective coping with stressors, and promote better interpersonal interaction (e.g., through anger management). Compared to controls, individuals assigned to CBSM treatments have been shown to have reduced emotional distress and increases in CD4+ and NK-cell numbers upon notification of their seropositive HIV status – a highly significant stressor. Other studies have also shown the CBSM can result in reduced depression and anxiety, as well as lower urinary cortisol and NE levels in HIV+ males. Six- to 12-month follow-ups of these males showed improvement in immune measures – including CD8+ numbers in peripheral blood – and these improvements were most evident for men who had shown the greatest reductions in hormone levels during the original CBSM intervention. Massage therapy has also shown significant effects in HIV+ males: increases in the number of CD8+ cells and NK cells in peripheral blood, increased NK-cell cytotoxicity *in vitro*, as well as reduced cortisol output and decreased anxiety. As with the CBSM study, follow-up again revealed that the men that had shown the greatest reduction in distress during the original intervention had a smaller reduction in T-cell numbers at the 24-month follow-up.

Glossary

Altricial – This refers to animals that are relatively undeveloped at birth and require intensive parental care for survival. Both humans and rats are altricial.

Amygdala basolateral complex – The amygdala encompasses several nuclei with distinct functions. Among these nuclei are the basolateral complex, central, medial, and cortical nuclei. The basolateral complex can be further subdivided into the lateral and the basal nuclei, which are associated with plasticity and fear learning.

Attachment and developmental psychology – While no strict definition can be given for attachment, several research areas use this word differently. The animal literature, including neurobiology, views attachment as a bond that can occur rapidly between the infant and mother or any two individuals. Attachment with respect to the human literature and developmental psychology, which is generally synonymous with attachment theory, views attachment as a protracted process occurring over the first year of life and suggests a very complex cognitive representation of the bond between two individuals. To ensure no confusion, this article is from the viewpoint of the neurobiology of attachment. However, to ensure translation across disciplines and how attachment relates to humans, attachment and attachment theory will be briefly outlined.

Classical conditioning – Also called Pavlovian conditioning, this is a form of complex learning involving the association between two stimuli based on their contingency and predictive value. Procedurally, a neutral conditioned stimulus (CS, i.e., a tone or odor) is repeatedly paired with an unconditioned stimulus (US, i.e., a shock or food). During conditioning, the animal learns that the CS is associated with or predicts the occurrence of the US and the animals will behave toward the CS as though it is the US or prepare for the onset of the US. In fear conditioning, where a tone or odor predicts the occurrence of a shock, the animal will learn to avoid or freeze with fear when the learned CS is presented, suggesting the animal is preparing for the arrival of shock or danger.

Electroencephalography (EEG) – A technique that measures the brain's electrical activity produced by the electrical activity of neurons during their communication

with one another. This technique requires electrodes to be placed on the scalp and measures the neural activity of groups of neurons.

Freudian psychoanalysis – Psychoanalytic theory originated with Sigmund Freud and was based on his interactions with patients with mental illness. Freud believed that childhood experiences and the unconscious influenced the patient's mental health.

Functional magnetic resonance imaging (fMRI) – A brain scan used to measure the neural activity of the brain. It measures changes in brain hemodynamics that correspond to the increase in blood flow in the local vasculature that accompanies brain neural activity.

Imprinting – A phase of potentiated learning temporally limited to a particular age range or sensitive period. Here, we describe filial imprinting since the learning involves the social bond formed by the young to its mother, which results in the young following the mother.

Limbic system – A group of brain areas distributed in cortical and subcortical areas in both humans and rodents. The limbic system's roles include emotional and cognitive function. Brain areas typically included and their functions are: amygdala (emotional regulation, especially fear; learning, and stress regulation), hippocampus (learning and memory, as well as stress regulation), prefrontal cortex (decision making, attention, and autonomic function including stress regulation, learning and memory, and emotional regulation).

Magnetic resonance imaging (MRI) – A technique that can be used to image the brain and visualize the brain's structures. It uses a magnetic field to align the nuclear magnetization of hydrogen atoms in water/blood in the body.

Major histocompatibility complex (MHC) – A large gene family found in most animals and has an important role in the immune system. In mammals, including humans and rats, the MHC contributes to unique, genetically determined body odors. The volatile odors are transmitted through body fluids, such as sweat and urine.

Sensitive period – A temporally limited period or age range of accelerated learning, experience, or development.

Stress system – This system coordinates brain activity with emotional and physical stressors and controls the

release of the stress hormone corticosterone (in rats) or cortisol (in humans) from the adrenal glands. The stress hormone modulates brain activity to produce behavioral responses, adjust homeostasis, and produce an adaptive response for survival. The main components of the stress axis are the hypothalamus–pituitary–adrenal gland, and the amygdala–locus ceruleus.

Robert Hinde characterized imprinting, which suggested that attachment to the caregiver was innate or biologically determined. Specifically, imprinting was first characterized in chicks as a temporally limited sensitive period when the hatchlings learn to follow the real or foster mother. The mother then elicits a following response in the young. This early-life attachment lays the foundation for later-life choice/acceptance of a reproductive partner.

Second, research on maternal separation and social isolation in rhesus monkeys by Harry Harlow and his colleagues characterized the importance of affection and social interactions with the mother for social and cognitive development. Specifically, based on observations that human infants became distressed and ill during prolonged separation from the mother, Harry Harlow separated infant rhesus monkeys from their mothers. These infant monkeys appeared to mirror the strong emotional and physical stunting of orphaned and hospitalized infants separated from their mothers. Furthermore, both the orphaned monkeys and children showed enduring emotional and cognitive problems that continued into adulthood.

This early work was quickly followed by focused studies on rodents and nonhuman primates to better understand how and why the infant showed such dramatic effects when separated from the mother. Interestingly, attachment was first studied by the removal of the attachment figure and is referred to as the maternal deprivation or maternal separation paradigm. In general, within a few hours of separation, the stress axis is engaged and shows increases in the stress hormones, corticosterone and cortisol, and in adrenocorticotropic hormone (ACTH), which controls the stress response at the level of the pituitary, although recent research suggests there are ubiquitous effects throughout the brain.

In the 1981 book, *Roots of Human Behavior*, Myron Hofer described the unique role of sensory stimuli in controlling pup behavior, brain, and physiology and provided a clearer understanding of the infant's response to separation from the attachment figure. Hofer defined the mother as a 'hidden regulator' of pup behavior and physiology through her sensory stimulation of the pups. Indeed, it is the mother that maintains pups at homeostasis, with different stimuli and her temporal patterning controlling specific behavioral and physiological systems. Thus, maternal separation could be viewed as removal of sensory stimuli that were controlling homeostasis. For example, tactile stimulation increases growth hormone, warmth increases the neurotransmitter norepinephrine (NE), and maternal odor increases behavioral activity. Thus, removal of one or all of the regulating sensory stimuli produces deregulation in pups' behavior and brains. The long-term effects of maternal separation appear to produce an animal that is more behaviorally

Introduction

Humans are social animals, relying on emotional attachment to others for emotional well-being. Attachments are made throughout the life span and include the bond between any two organisms, although a particularly important attachment exists between an infant and the caregiver, as well as reproductive partners. Here, we focus on the attachment between the infant and the caregiver, and briefly review its psychology and neurobiology.

The Infant's Attachment to the Mother

At birth, the newborn infant transitions into a world filled with new sensory experiences, including new sights, sounds, textures, and temperatures. Beginning just moments after this dramatic transition, the infant must rapidly reorganize fetal behavior to postnatal behaviors that elicit nurturing from the caregiver. Indeed, the mother and infant rapidly engage in a finely tuned dance of social behaviors that enable both the infant and mother to learn about one another and support bonding and attachment. Two words have been used, almost interchangeably, to describe the infant's relationship with the parent or caregiver – bonding and attachment – which relate to a strong emotional bond between the infant and caregiver.

The importance of childhood for emotional well-being was first highlighted by Freud. However, it was not until the 1950s, with animal studies on maternal separation in primates and rats, as well as clinical observations of maternally separated hospitalized and orphaned children, that the study of early-life attachment and its importance for mental health came into experimental focus.

Animal Research and the Importance of Maternal Care of the Infant

The importance of the care and nurturing of infants by the mother was dramatically demonstrated around 1950 by a series of experiments in chicks, rodents, and nonhuman primates. First, Konrad Lorenz, Niko Tinbergen, and

responsive to stressful situations as suggested by increased fear, anxiety, cognitive impairment, anhedonia, and susceptibility to drug and alcohol abuse. The long-term effects of maternal deprivation also appear to alter maternal care, which is then transmitted nongenomically through the next generations.

John Bowlby and Attachment Theory

In the 1950s, the psychiatrist John Bowlby developed attachment theory and an expanded version of this theory is a critically important framework in developmental psychology. This theory was in response not only to Bowlby's training as a Freudian psychoanalyst, his personal clinical observations on disturbed children, but also to the emerging animal research of the 1950s described above, which suggested a biological system for an infant's attachment to the caregiver and its importance for mental health. Bowlby's patients and initial research project involved a group of maladjusted children and was entitled 'Forty-four juvenile thieves.' He identified a common factor in these children: all had been deprived of their mothers in childhood. A second major influence on Bowlby was Rene Spitz's and James Robertson's observations on the detrimental effects of separating the child from the mother during hospitalization and the resultant extreme emotional distress. Bowlby was also intrigued by the work of animal researchers who were characterizing the importance of early-life attachment, evolution of a biological attachment system in infancy, and the importance of maternal care on later mental well-being in other species.

Thus, through a synthesis of clinical and basic research, as well as the synthesis of research from biology

and psychology, Bowlby developed his theory of attachment. He focused on the importance of a biological system for infant's attachment to the caregiver and the importance of quality caregiving for normal development. Attachment theory's central core is that the child's relationship with the mother has profound enduring effects on cognitive and emotional development. The child seeks proximity to the mother or other caregiver, which provides protection and a sense of safety. The caregiver needs to be available to the child and provide a secure base for the child to explore the world and develop other relationships. The child builds a representational mental model of the self and others based on this early relationship, which then shapes the child's emotional and cognitive development. A caregiver that shows sensitivity to their needs, supports their behavioral expression, and is available when needed, will produce a healthy infant with a secure attachment. An unavailable, obtrusive, or psychologically or physically abusive caregiver produces an insecure attachment and disturbs emotional and cognitive development. Bowlby concluded that through evolution and due to the critical importance of attachment for survival, children are biologically preprogrammed to form attachments to their caregiver (Figure 1).

Developmental Psychology and Attachment: The Strange Situation Test

In the 1970s, Mary Ainsworth, a student and collaborator of John Bowlby, focused on the attachment quality issues of attachment theory and developed the 'strange situation' experimental paradigm. This test, which uses the infant's proximity seeking to the caregiver combined with the child's desire to explore a novel environment, was used

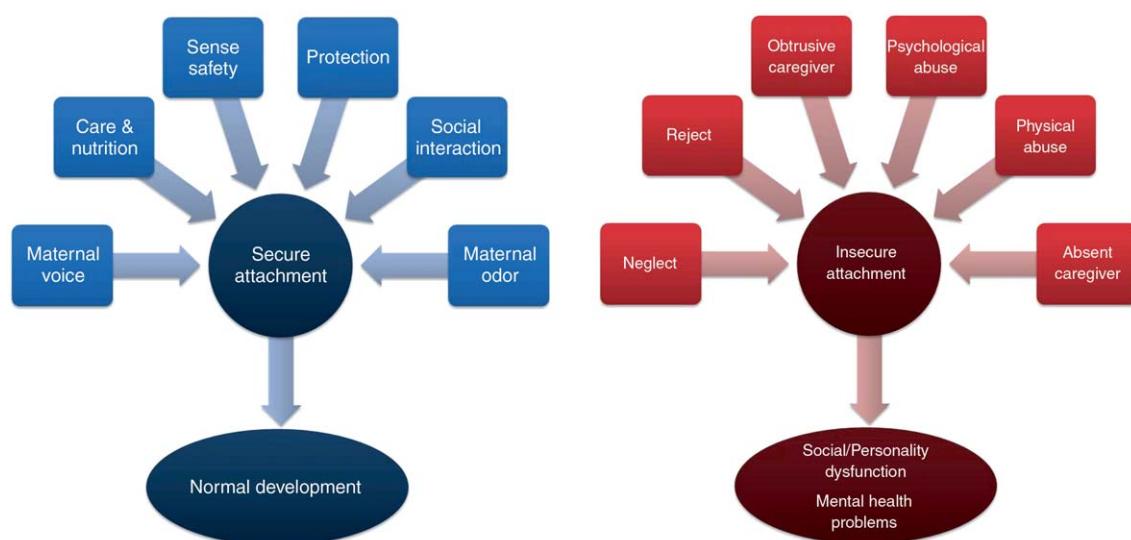

Figure 1 Environmental factors that contribute to secure (right) and insecure (left) attachment during infancy and its long-life effects.

to characterize different types/qualities of attachment. Based on this laboratory observation of mother-child separations and reunions, Ainsworth noted that most children have a secure attachment to their caregiver. This type of attachment is associated with a caregiver who is responsive and sensitive to the needs of the child, supports the child's ongoing behavior, and is available for the child. The child develops a sense of safety with this caregiver and uses the caregiver as a base for exploring the world and forming additional relationships. Ainsworth also identified characteristics of insecure attachments referred to as 'avoidant attachment,' which is associated with rejecting, interfering, or inconsistent caregiving and ambivalent attachment. An additional category of disordered attachment has been added more recently, which is most closely associated with child abuse. While attachment theory has not been without criticism, it has been a strong focus of developmental research within psychology and has greatly increased our understanding of the importance of early-life infant-caregiver attachments.

Clinical studies have found that early-life abuse is also associated with enduring effects within the brain. Although it is still unclear how attachment style in early life relates to the enduring effects of early-life abuse/trauma, caregiver abuse and neglect may be particularly damaging to the brain. These early-life events leave the child vulnerable to not only a wide range of social or personality problems such as hyperactivity, aggression, delinquency, or substance abuse, but also psychiatric problems such as borderline personality disorder, depression, posttraumatic stress disorder (PTSD), and schizophrenia. Child abuse is associated with abnormal brain responses associated with cognitive and emotional function and also in areas involved with regulation of the stress response, such as the amygdala, hippocampus, frontal cortex, and cerebellum. While a wide variety of techniques have been used to assess the relationship between abuse and human brain function, including functional magnetic resonance imaging (fMRI), MRI, and electroencephalography (EEG), due to ethical and practical restraints in human studies, these studies must rely on correlation. For a causal relationship, we must rely on animal studies that are reviewed below.

Early Translational Research: The First Postnatal Days and Attachment

In the 1980s, Marshall Klaus and John Kennell presented the concept of bonding in their classic book *Maternal Infant Bonding*, which suggested newborns had a sensitive period at birth that enabled rapid, robust learning about the mother. This idea was generated by animal research, which indicated that ewes require immediate contact with the lamb for acceptance and attachment. Klaus and Kennell asked whether mother-infant contact

immediately after birth was critical for attachment in humans and compared mother-infant dyads placed together or separated for the hours after birth. Their results suggested that mother and infant dyads that were together right after birth showed stronger attachment/bonding. This work was the catalyst for dramatic changes in hospital policies and mothers were permitted to keep their babies in their rooms. While this togetherness during the postpartum period is important, humans are resilient and infants separated from their mother at birth generally do form a strong attachment and quickly show bonding as strong as babies given immediate contact with their mother. More prolonged separations, as can occur with illness or prematurity, can require special attention for attachment. That is, unlike sheep bonding, human bonding is not a now-or-never occurrence, although more effort may be required when circumstances prevent early and consistent contact between the mother and infant. The success of adoptions, as well as the caregiver-infant relationships between the child, fathers, and other caregivers, illustrates human resilience for bonding beyond the early postpartum period and the importance of social interactions in human resiliency. It should be noted that while we now understand that human and sheep infant attachment differ, the animal work provided a new way of viewing human infant attachment and resulted in changing clinical practices in nurseries.

The Infant Shows Attachment Behavior Toward the Mother on the First Day of Life

More recent research efforts have complemented this early work on attachment and bonding by assessing the birth process and defining the events of early life. While the infant is a social being at birth, the process of building this social infant begins during the last trimester of pregnancy. The womb provides a rich auditory experience through the rhythm of the mother's heartbeat and blood flow. Due to the higher pitch of the female voice, the baby hears its mother's voice not only through the mother's abdomen but also transduced through her bones. The prenatal infant also swallows and inhales the amniotic fluid, which activates the taste receptors on the tongue and the olfactory receptors in the nose. Amniotic fluid is relatively distinctive for each mother because it has her unique olfactory signature through her diet and major histocompatibility complex (MHC). These prenatal odors appear to bridge pre- and postnatal life since the birthing room is typically filled with the odor of amniotic fluid.

At birth, the mother's voice and odors have powerful ability to guide the infant's motor patterns and emotional responses to facilitate interactions with the caregiver. These stimuli, which were learned and experienced *in utero*, lay the foundation for the infant's social behaviors

during the first few hours of birth. However, the postnatal infant quickly learns other characteristics of the mother as well as the bond and attachment between the mother and infant is strengthened. In the 1980s, DeCasper and Fifer showed that an infant just a few hours old will modify his or her sucking to hear a recording of the mother's voice. Her voice is also capable of soothing a fussy infant and bringing the infant to an optimal state for attending to the environment. The infant's visual system is also tuned to focus the infant's attention on the mother, with infants biologically predisposed to focus on the human face. Benoit Schaal and his colleagues, as well as work in our lab, have shown that maternal odors are also important to the newborn and are likely learned during late pregnancy, during birth as well as the early weeks of life. Importantly, the maternal odor is not a pheromone and can be learned by the infant. Indeed, a novel citral odor or perfume worn by the mother can become the maternal odor. The mother's odor has powerful effects on the infant's behavior: mother's odor can soothe a crying newborn and guide him or her toward the breast for feeding. Indeed, this work suggests that, when a mother holds her newborn infant, her odor can initiate a sequence of behaviors that ensure nipple attachment: cessation of the baby's crying, optimization of the infant's state, head turning toward the breast, and mouthing. Moreover, the maternal odor reduces the stress response by reducing the amount of cortisol released by the adrenal gland and helps infants develop a more organized sleep-wake cycle.

The Neurobiology of Attachment

As noted above, Bowlby's characterization of human attachment was strongly influenced by animal research, and for this reason, it is not surprising that Bowlby's attachment theory is readily applied to other species. Indeed, many altricial species must learn an attachment to their caregiver and must have a specialized biological system that supports infant attachment. Recent research on rat pups has been characterizing the attachment circuitry. While human attachment is certainly more complex than that seen in rat pups, animal models can provide insight into basic neural circuits for attachment. There are notable differences between rats and humans. First, humans rely on vision, audition, and olfaction for attachment, while pups rely only on olfaction. Second, and more importantly, the role of cognition in human attachment is more complex than that seen in rat pups. However, while rats and humans may not have identical neural circuits supporting attachment, some overlap may exist, such that general principles of the neurobiology of attachment will be useful.

Infant Rats Show Robust Rapid Learning of the Maternal Odor

Similarly to human infants, rat pups also face the daunting task of learning about their caregiver and attaching just minutes after birth. Since pups are born without vision and audition, they must rely on odors to approach the mother and exhibit appropriate behaviors, such as huddling and nipple attachment. While we initially thought the mother emitted a pheromone to control pups' behavior, we now understand that pups learn the maternal odor before and during the birth process and continue to learn the diet-dependent maternal odor throughout early development. Indeed, simply placing a novel odor (e.g., peppermint or orange) on the mother during interactions with pups is sufficient for pups to learn a new maternal odor. The maternal odor, whether natural or a peppermint odor paired with the mother, elicits approach from the pups and permits nipple attachment. Without the maternal odor, pups do not survive. This odor also retains value into adulthood, where it controls reproductive behaviors. To facilitate a neural analysis of attachment, pups are removed from the nest and maternal behavior is mimicked during pairings with an odor using a learning paradigm called 'classical conditioning.' This extra-nest attachment learning also enables the odor to take on characteristics of maternal odor, which produce approach responses and nipple attachment.

Attachment Learning Requires NE from the Locus Ceruleus

Attachment odor learning in rat pups is supported by both anatomical and physiological changes within the olfactory bulb, the brain area important in processing odor information. Importantly, the same neural response occurs to the natural maternal odor, or an artificial odor conditioned to become the maternal odor (e.g., placed on the mother or classically conditioned). This plasticity induced by olfactory-bulb learning is attributable to a large influx of NE released from the locus ceruleus (LC) into the olfactory bulb, which causes prolonged activation of the bulb's primary output neurons (mitral/tufted) and prevents habituation to repeated presentations of the odor. Notably, the abundant release of NE to the olfactory bulb is induced by the same stimuli that support attachment learning and preventing the LC from releasing NE also prevents attachment learning. Thus, enhanced NE during an odor presentation is sufficient to produce the plasticity within the olfactory bulb and pups' learning of a new maternal odor.

Sensitive Period for Attachment Learning

NE only supports attachment learning when pups are infants because the infant LC releases approximately 3 times more NE into the olfactory bulb than the adult LC. The abundant release of NE by the infant LC occurs for a number of reasons. Specifically, the LC responds to a very broad range of sensory stimuli, fails to habituate after repeated sensory stimulation, and does not have the functional LC's α_2 inhibitory autoreceptors that terminate the LC's excitatory response in adults. Indeed, a 1-s stimulus generally produces a 20–30-s response in the LC of the infant, but only a few milliseconds one in the adult. Thus, unique prolonged and robust functioning of the LC produces the abundant release of NE required to support the neural plasticity for the rapid and robust odor attachment learning exhibited by infant rats. The sensitive period ends as the LC matures and fails to release sufficient NE to support plasticity in the bulb.

Avoidance and Fear Learning Are Suppressed during the Sensitive Period by Attenuation of Amygdala Function

One characteristic of attachment listed by Bowlby was the child's persistence in learning and maintaining attachment to a caregiver, even when the caregiver inflicts the child with pain. This characteristic of attachment has also been demonstrated in rat pups. Indeed, attachment learning occurs equally well when a novel odor is paired with presumably pleasant stimuli such as milk, warmth, or tactile stimulation, or painful stimuli such as 0.5-mA shock or tail pinch. This pain-related attachment learning also exists within the natural environment of the nest.

Specifically, pups were placed with a mother rat that mistreated pups in the presence of a novel odor, yet the odor still supported a learned odor preference and nipple attachment at a level similar to natural maternal odor. That is, whether the mother nursed and groomed the pups or mistreated them by biting or trampling on them in the presence of a novel odor, all pups later showed robust approach responses to the newly learned artificial maternal odor.

Sensitive-period learning is usually characterized by enhanced learning. This paradoxical learning illustrates that limitations on learning also occur. For example, as noted above, shocking chicks during imprinting to the mother supports approach learning, while shock supports avoidance learning just hours after the imprinting-sensitive period closes. Similarly, shocking or mistreating an infant dog while interacting with a caregiver results in a strong attachment to the caregiver. This paradoxical attachment learning has also been demonstrated in non-human primates by Harlow and, more recently, when abused infant monkeys form strong attachments to an abusive caregiver. Furthermore, children tolerate considerable abuse while remaining strongly attached to an abusive caretaker. We have hypothesized that through selection pressure and evolution, the attachment system has evolved to ensure that the infant attaches to the caregiver regardless of the quality of caregiving received ([Figure 2](#)).

At least in rat pups, the neurobiology for this paradoxical attachment learning has been partially documented. Specifically, the amygdala, which is a brain area required for fear and avoidance learning in adult animals, does not participate in the infant odor learning. The assessment of

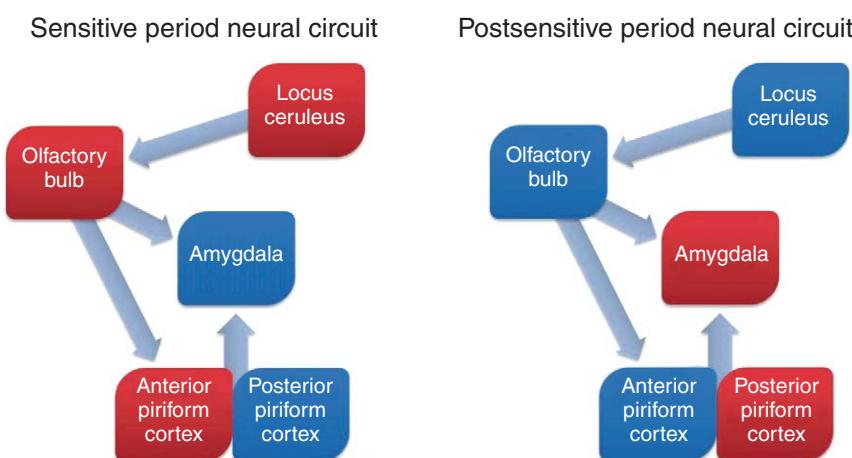

Figure 2 The unique neurobiology of infant learning and its transition to the more “adult-like” learning circuit in the brain of rat pups. Specifically, the neural basis of attachment learning with olfactory conditioning during the early life sensitive period for attachment uses the olfactory bulb, anterior piriform (olfactory) cortex and the locus coeruleus (red areas) to support approach learning regardless of the quality of care the infant receives. With maturation and the end of attachment learning, the neural circuit for learning changes so that the quality of care (pain or pleasant) becomes important in determining what is learned in older pups. The learning circuit for pain based learning then includes the posterior piriform cortex and the amygdala (red areas).

the neurobiology of infant attachment indicates infants possess a unique learning circuit that ensures rapid and robust learning of the maternal odor regardless of its association with a normally behaving mother, a mother mistreating her pups or painful stimuli presented in a classical conditioning paradigm outside the nest. Indeed, all these procedures appear to activate the same neural circuit: the olfactory bulb, anterior piriform of the olfactory cortex, and the LC. Briefly, during the presentation of a reward (maternal care, milk, stroking, etc.), the hyperfunctioning infant LC releases a huge amount of NE into the olfactory bulb. The combined stimulation of the olfactory bulb with an odor and NE is sufficient and necessary to support the neural plasticity within the bulb for learning of the maternal odor. This odor learning and the plasticity of the olfactory bulb is sufficient to produce a maternal odor that supports not only approach responses, but also the complex sequence of motor responses required for nipple attachment. However, pups' attachment learning with pain also requires suppression of the amygdala's plasticity, which is normally activated by pain and required for learning fear. It should be noted that electrophysiological studies indicate that the pain information reaches the amygdala, yet the amygdala fails to exhibit the plasticity required for fear learning.

Thus, attachment learning in rat pups not only appears to activate the attachment circuit but also inhibits amygdala plasticity if that attachment learning is associated with pain. The suppression of amygdala plasticity presumably prevents pups from learning to avoid the maternal odor and the care required for survival that is provided by the mother. This unique ability for pups to prevent avoidance/fear learning and suppression of amygdala function in early life is due to pups' naturally low levels of the stress hormone corticosterone, which is required by the infant for amygdala plasticity. Importantly, while the amygdala was suppressed during attachment learning, pups experiencing pain developed a smaller amygdala basolateral complex. Remarkably, simply experiencing the pain without attachment did not result in changes in amygdala size, indicating that pain within attachment is processed differently than pain without attachment.

Implications of Animal Studies for Understanding Human Attachment

Infant rat studies suggest that early attachment memories are formed within brain circuits that are different from those used later in life. They also suggest that the circuitry involved in attachment learned with painful stimulation is likely to be mediated by additional brain regions and hormonal facilitation. The comparison of normal attachment formation and pain-related attachment suggests similar behaviors, yet different neural

substrates that may lay the foundation for the enduring effects of early-life trauma.

The Mother's Attachment to the Infant

Birth is also a transition for the mother and requires considerable learning and adaptation that complements the infant's attachment. Unlike the infant, however, the human mother relies on years of experience of observing and experiencing infants suggesting a considerable importance of cognition and learning. Indeed, cognitive ideation of the mother's role in parenting and the attachment quality experienced in the mother's childhood have robust effects on the quality of mothering and attachment a mother provides her baby. Indeed, the social transmission of maternal behavior and its flexibility likely supports the diverse climates and cultures that support human populations. On the other hand, biology has a role in maternal behavior in humans. Remarkable consistency in emotional responses is associated with late pregnancy, and birth is associated with heightened sensory responsiveness, rapid learning about the baby, and a strong need to be with and hold the infant.

Summary and Conclusion

Attachment is a strong bond that can be formed at any stage of development in humans and other social animals. Robust attachments are formed at sensitive periods associated with reproduction, including the reciprocal mother–infant attachment associated with altricial animals such as humans and rats. While this article has primarily focused on the infant's attachment to the mother, attachment is a process of interactions between the mother and infant. While the infant's role in this relationship appears passive, minor changes in the infant's behavior toward the mother can produce confidence or weakening in the mother's nurturing skills and attachment. Indeed, the expression of appropriate responses by the infant to the mother, as well as the mother to the infant, is critical for the synchrony of attachment. Thus, both the infant and mother are active and critical participants in the mother–infant dance that requires subtle coordination between the mother and new baby. The vulnerability of bond formation in mothers of unresponsive infants, either because of illness or prematurity, illustrates the important role of the infant in this dyad.

Due to ethical and practical concerns, we must rely on animal studies to characterize a causal link between neurobiology and behavior in attachment. While humans and other animals may not use the same behaviors and neural structures for attachment, behavioral similarities suggest at least some overlapping neural circuits that may involve

amygdala suppression. More globally, cross-species comparisons may provide insight into unique ways of viewing attachment and potentials for intervening and preventing attachment difficulties.

Parental Behavior

M Numan, Boston College, Chestnut Hill, MA, USA

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Alloparental behavior – Parental behavior directed toward a conspecific infant by an individual who is not the infant's biological parent.

Amygdala – A neural region in the limbic system that is involved importantly in the regulation of fearfulness and defensive behaviors. Two important nuclei are the medial nucleus of the amygdala (MeA) and the central nucleus of the amygdala (CeA).

Corticotropin-releasing factor (CRF) – A neuropeptide produced in the brain which contributes to neural circuits regulating fearfulness, anxiety, and stress responsiveness.

Fos – A protein whose expression is increased in cells, including neurons, when the cell is affected by input signals, such as neurotransmitters or hormones. The detection of Fos expression within neurons is typically used as a marker of neural activity.

Lactogens – Peptide hormones – including pituitary prolactin and placental lactogens – which not only stimulate lactation, but also act on the brain in conjunction with the steroid hormone estradiol (produced by the ovary) to stimulate maternal behavior.

Medial preoptic area (MPOA) – A brain region located in the rostral hypothalamus that is essential for maternal behavior. It is the site where estradiol, prolactin, and oxytocin act to stimulate maternal responsiveness.

Mesolimbic dopamine (DA) system – A neural system originating from DA neurons in the ventral tegmental area (VTA) of the midbrain. These neurons have ascending projections to various parts of the subcortical telencephalon which include a projection to the nucleus accumbens (NACC). An important area to which the NACC projects is the ventral pallidum. Activation of the VTA–NACC DA system appears to regulate a variety of goal-directed or motivated behaviors, including maternal behavior.

Null mutation – A mutation produced in a transgenic mouse strain which eliminates the functional activity of a particular gene. It is also referred to as a knock-out mutation. For example, when a mouse line is produced with a null mutation of the prolactin receptor gene, then cells in the body can no longer produce the prolactin receptor protein.

Oxytocin – A neuropeptide that is produced in the brain and can function either as a hormone (when it is released into the general blood supply via the neural

lobe of the pituitary gland) or as a neurotransmitter (when it is released locally at synapses in the brain). Oxytocin (OT) acts on oxytocin receptors (OTRs) in the MPOA and VTA to stimulate the onset of maternal behavior. Estradiol can stimulate the synthesis of OTRs in the brain.

Introduction

Parental behavior in mammals includes maternal, paternal, and alloparental behavior. Most mammalian species show a polygynous or promiscuous mating system, paternal behavior does not occur, and uniparental maternal behavior is the dominant pattern. However, monogamous mating systems do occur in some mammals, such as prairie voles, California mice, and marmoset and tamarin monkeys. In such species, family groups can consist of mother, father, recently born young, and older subadult or adult siblings. In addition to the mother, the father and older siblings may care for the young for long periods of time.

Because maternal behavior is the dominant form of mammalian parenting, it will be our primary concern. The nature of maternal behavior is influenced by the development of the young at birth and the social group into which the young are born. Infants may be altricial (immature) and immobile at birth, precocial and mobile at birth, or intermediate between these two developmental extremes (semiprecocial and semimobile). Rodents, ungulates, and primates, respectively, will be used as representative examples of each case. Most rodent infants are helpless and incapable of temperature regulation at birth. They are born into a secluded nest site where the mother crouches over the young to nurse them and to keep them warm. She also licks them, which grooms them and facilitates urination and defecation. If the nest site is disturbed or if pups become displaced, the mother shows retrieval or transport behavior where she carries pups one at a time in her mouth to a new nest site or back to the original nest. Experimental studies have shown that most rodents do not form selective attachments to their own young: one can cross-foster young among litters and mothers will care for these young. The evolution of selective attachment mechanisms has not occurred because infants are not capable of wandering from one

nest to another and, therefore, confusion between own and alien young is not likely to occur. Ungulates, such as sheep and goats, give birth to precocial young which are relatively mature at birth, and these young are born into herds composed of unrelated individuals. Selective attachments between the mother and the calf occur rapidly after birth, and the mother will remain near her calf and nurse only her calf, while rejecting the advances of alien young. These attachment mechanisms prevent confusion between own and alien young under these conditions. Lastly, maternal responses in primates are adapted to young who are semiprecocial at birth. Initially, the mother is in constant contact with her offspring, nursing and grooming it, and the infant clings to its mother for transport. During movement, the mother carries the infant either ventrally or dorsally. As the infant develops it will begin to wander away from the mother, but the mother is usually aware of its location and, when necessary, will retrieve the infant. Selective maternal attachments develop in most primates, although this development is not as temporally rigid as that which occurs in sheep and goats, which is consistent with the semiprecocial nature of primate offspring.

Maternal behaviors are sometimes divided into appetitive and consummatory components. Appetitive components are proactive voluntary maternal behaviors such as approaching, guiding, grooming, and retrieving/transporting the young. The consummatory component is more reflexive and inactive in nature and primarily consists of nursing behavior. Appetitive maternal behaviors engage forebrain control mechanisms, while nursing responses may be controlled primarily by brainstem reflexive mechanisms.

There are two other important characteristics associated with the maternal condition: (1) maternal aggression, which is an increase in aggressiveness that presumably allows the mother to protect her young and (2) a postpartum decrease in fear- and anxiety-related behaviors, which may allow the mother to take reasonable risks in order to raise her young.

Hormonal Mechanisms Regulating Maternal Behavior

For most mammals, the hormonal events associated with pregnancy termination and the initiation of lactation are also involved in stimulating maternal responsiveness. Of the typical female mammal, nulliparous or virgin females do not show maternal behavior. Such females avoid infants and reject their advances. In contrast, newly parturient females will care for their own or alien young. In the case of those species which form selective attachments to specific young, learning mechanisms are involved: an ewe will act maternally to any lamb that is presented to

her at the time of birth, but once a bond is formed with that lamb, she will reject other lambs. The formation of this selective attachment is the result of olfactory learning mechanisms which allow the parturient mother to recognize the odor of the lamb to which she was exposed.

These findings from typical virgin and parturient mammals have led to the idea that hormones stimulate maternal responsiveness at parturition by acting on the brain to inhibit avoidance and rejection responses toward young infants while stimulating neural circuits which regulate approach and acceptance responses (**Figure 1**).

Most of the research on the endocrine basis of maternal behavior has been done on rats. The critical hormonal events include declining levels of progesterone and rising levels of estradiol and lactogens (pituitary prolactin and placental lactogens). Similar mechanisms are operative in sheep. In sheep, the vaginal and cervical stimulation which occurs at birth co-acts with these hormonal mechanisms.

Oxytocin is a hormone released by the posterior pituitary at parturition and it stimulates uterine contractions. Oxytocin – as a hormone – probably is not essential for maternal behavior since it has poor penetrance across the blood–brain barrier. However, oxytocin – serving as a neurotransmitter/neuromodulator – is also released into the brain of the parturient female where it acts to promote maternal behavior.

Although the endocrine events of pregnancy termination stimulate maternal behavior in the typical female mammal, other events must also be operative in those cases where paternal behavior or alloparental behavior occur, since these individuals are not exposed to those hormonal events. One proposal is that there is a basic and intact neural circuitry regulating parental behavior in all mammals of both sexes, but this circuitry is under varying intensities of inhibition, based on sex, genetic, developmental, hormonal, and experiential/environmental factors. When this parental circuitry is under low inhibition, infant stimuli may activate a certain degree of caregiving behavior in the absence of pregnancy-related hormones.

In some cases where long periods of infant dependency exist – which occur in primates, including the human – a monogamous mating system with high levels of maternal, paternal, and alloparental behavior may be important for infant survival. Evolutionary factors – including kin-selection mechanisms – may have influenced the formation of mechanisms which allow for high levels of parental behavior in the absence of the brain's exposure to the hormones of pregnancy and lactation. It should be noted, however, that in marmosets where alloparental behavior is shown by nulliparous females, when such females are treated with a hormone regimen that simulates the endocrine events associated with pregnancy termination their maternal responsiveness is further enhanced.

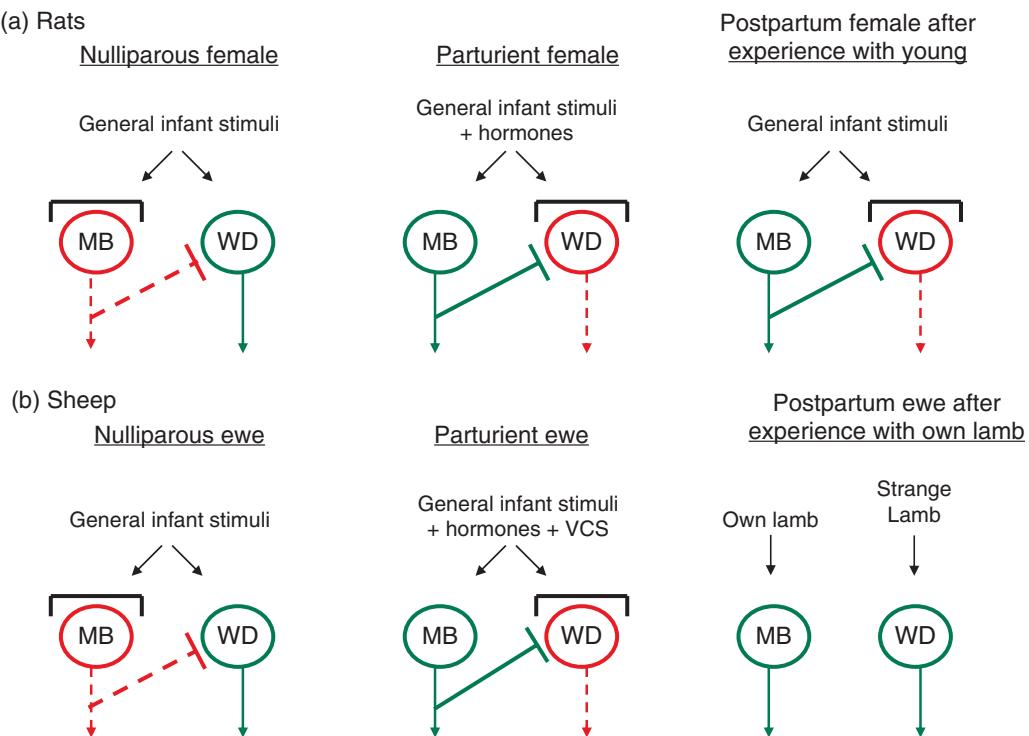

Figure 1 Neural models of the regulation of maternal behavior in rats (a) and sheep (b). Two neural systems are depicted: a maternal behavior (MB) system, which controls the occurrence of appropriate maternal responses, and a withdrawal (WD), rejection, or avoidance system, which prevents interaction with infants. A bracket over the neural system origination point indicates that the system cannot be stimulated by afferents carrying inputs from infant stimuli. When a system is shown in red dashed lines, it is not operative. When it is shown in green solid lines, it is operative. Lines ending in an arrow signify excitation and those ending in a bar represent inhibition. In rats, for nulliparous females, lamb stimuli activate the MB system, which is shown as inhibiting the WD system. In parturient and postpartum-experienced rats, general infant stimuli activate the MB system, which is shown as inhibiting the WD system. In nulliparous sheep, lamb stimuli activate the WD system. In parturient sheep that are exposed to young for the first time, a general infant stimulus activates the MB system and the WD system is not operative. After the ewe interacts with her lamb for several hours post partum, an olfactory learning process occurs so that the female's own (specific) lamb activates the MB system, while alien or strange (unfamiliar) lambs activate the WD system. VCS = vaginocervical stimulation.

Feral mice act like rats and sheep: nulliparous females avoid or attack, while parturient females care for the young. In contrast, as a result of selective breeding or inbreeding, most nulliparous females of laboratory strains of mice show maternal behavior toward young pups. These data show that experimental selection can modify the brain such that infant stimuli can activate maternal behavior in the absence of the hormones of pregnancy and lactation. Presumably, natural and kin-selection mechanisms can act similarly. Interestingly, in nulliparous female laboratory mice that would normally show maternal behavior toward the young, a null mutation of the prolactin receptor gene prevents this maternal behavior, while a null mutation of the prolactin gene does not. These results suggest a possible mechanism which might underlie alloparental behavior in nulliparous females of certain species: a brain factor other than prolactin may stimulate maternal responsiveness by activating the prolactin receptor in the brain.

In summary, although the hormonal events associated with pregnancy termination are important factors for stimulating the onset of maternal behavior in most

mammals, other factors can be involved which would allow for the occurrence of alloparental behavior in nulliparous females and also for the occurrence of paternal behavior. Some of these facts are summarized in **Figure 2**. Allomaternal behavior mechanisms in nulliparous females may allow for the occurrence of adoption in the human and other primates. In fact, even in the rat, something like adoption can occur. Although virgin nulliparous females are not initially maternally responsive, if such virgins are continuously housed with healthy foster pups, then after about 7 days of continuous exposure the virgins will show the full pattern of maternal behavior toward the foster pups even though they are not capable of lactating.

Neural Circuits Regulating Maternal Behavior

In the typical female mammal, hormones are proposed to act on the brain to depress avoidance/rejection circuits and to activate maternal behavior circuits regulating

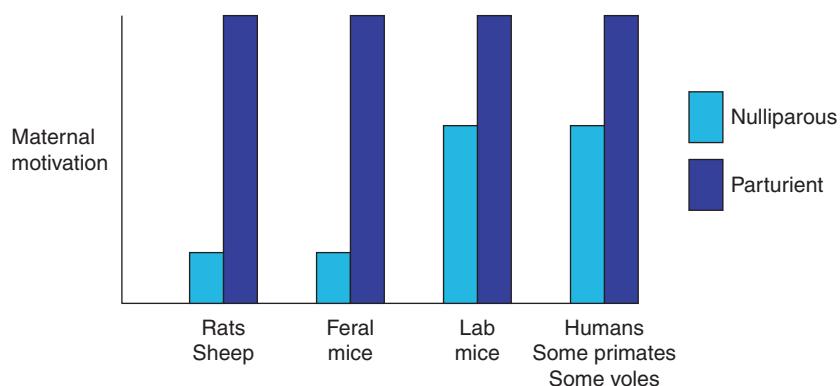

Figure 2 Comparative analysis of the level of maternal motivation or responsiveness in nulliparous and parturient females of a variety of species. For most female mammals, nulliparous females do not show maternal behavior upon an initial exposure to young, while parturient females – as a result of the neural effects of the hormones associated with pregnancy termination – do. In some species, however, nulliparous females show alloparental behavior and will care for young. However, even in these species the evidence indicates that pregnancy hormones boost maternal motivation to a level above that of the nulliparous female. For example, although nulliparous marmoset monkeys show alloparental behavior toward their young siblings, they will not perform an operant response at a high rate in order to gain access to infant stimuli. However, if such females are treated with a hormone regimen which simulates the endocrine pattern that occurs toward the end of pregnancy, they will perform the operant response at a very high rate. See Numan and Insel (2003) for the data that were used to develop this graph.

approach and acceptance behaviors (Figure 1). Research, primarily on rats, has uncovered the details of both the inhibitory and stimulatory circuits.

The Medial Preoptic Area (MPOA)

The MPOA plays a dominant role in the control of the appetitive aspects of maternal behavior in rats and other species. Electrical or excitotoxic amino acid lesions of the MPOA interfere with maternal behavior in rats, and retrieval behavior is disrupted to a much greater extent than is nursing. Such females, however, are capable of picking up and carrying other items, like candy, in their mouths. Postpartum females with MPOA lesions will not perform an operant response to gain access to pups, although they will do so to obtain food. Finally, Fos is expressed in MPOA during maternal behavior and also when postpartum females are searching in an environment previously associated with the presence of pups. All of these results suggest that the MPOA is necessary for proactive appetitive maternal responses. MPOA lesions also disrupt maternal behavior in mice, hamsters, and sheep.

The MPOA neurons contain receptors for estradiol, progesterone, and lactogens, and direct injection of either estradiol or lactogens into the MPOA stimulates maternal behavior in female rats who have been treated systemically with the other critical hormones. When maternal behavior is stimulated by hormone application to the MPOA, the full complex of retrieving, nest building, nursing behavior, and pup grooming is activated. One possibility is that hormone activation of the MPOA promotes output circuits which decrease avoidance behavior

and increase approach behavior and retrieval. Once the pups are in the nest with the female, proximal suckling and nuzzling stimuli from pups are likely to reflexively elicit nursing postures.

The Avoidance–Rejection Circuit

The typical response of the nulliparous female to young has given rise to the view that when a female is not primed with pregnancy hormones, infant stimuli gain access to a defensive circuit which promotes avoidance and rejection behaviors. Since the amygdala is involved in fear-related responsiveness, it is not surprising that it is involved in this defensive circuitry. Research has indicated that, in the absence of appropriate hormone priming, pup stimuli (including olfactory stimuli) activate a circuit from the medial amygdala (MeA) to the anterior hypothalamus (AHN) to the periaqueductal gray (PAG) in the midbrain which promotes defensive responses. The best evidence for this proposal is that lesions to points along this circuit stimulate maternal behavior in females who have been suboptimally primed with hormones (in terms of dosage and the actual hormones administered).

MPOA Output Circuits: Inhibition of Avoidance and Stimulation of Approach

The MPOA neurons which express Fos during maternal behavior project to the AHN and PAG. Since a proportion of Fos-expressing MPOA neurons also contain the inhibitory neurotransmitter γ -aminobutyric acid (GABA), the hormonally primed MPOA may inhibit the

avoidance circuit, which fosters the onset of maternal behavior at parturition.

For maternal behavior to occur, not only must avoidance be depressed, but proactive appetitive maternal responses must be stimulated. The MPOA neurons which express Fos during maternal behavior also project to the ventral tegmental area (VTA) in the midbrain. The VTA contains the dopamine (DA) neurons which give rise to the ascending mesolimbic DAergic system, and one site of termination of these DA neurons is the nucleus accumbens (NACC) in the telencephalon. Research has indicated that VTA-DA projections to the NACC are involved in the regulation of a variety of appetitive proactive voluntary responses. The proposed link between the MPOA and the VTA may form a connection between a specific appetitive system (MPOA: maternal motivation) and a general appetitive motivational system (NACC), which when exposed to DA promotes appropriate responsiveness to biologically significant stimuli.

Dopamine is released into the NACC during maternal behavior in rats and disruption of DA action in the NACC interferes with retrieval behavior without depressing nursing behavior. There are two types of DA receptors, D₁

and D₂, and research has emphasized the importance of D₁ receptors: microinjection of D₁ antagonists, but not D₂ antagonists, into the NACC disrupts appetitive maternal responses in postpartum rats. Significantly, microinjection of D₁, but not D₂, agonists into the NACC activates the full onset of maternal behavior in female rats that have been suboptimally primed with hormones. Finally, neural disconnections between the MPOA and the mesolimbic DAergic system disrupt maternal behavior.

Additional research has led to the following neural model for the regulation of proactive voluntary maternal responses: when the MPOA is hormonally primed, it can be activated by infant-related stimuli and the MPOA efferents in turn activate VTA-DA neurons. DA release into the NACC acts on D₁ receptors to depress the responsiveness of the NACC and this acts to release the ventral pallidum (VP) from inhibition. The disinhibited VP is then capable of being stimulated by afferent pup stimuli derived from limbic sources, leading to appetitive maternal behavior.

Figure 3 shows a diagram of the brain circuits which may represent the core neural circuitry for parental behavior in mammals.

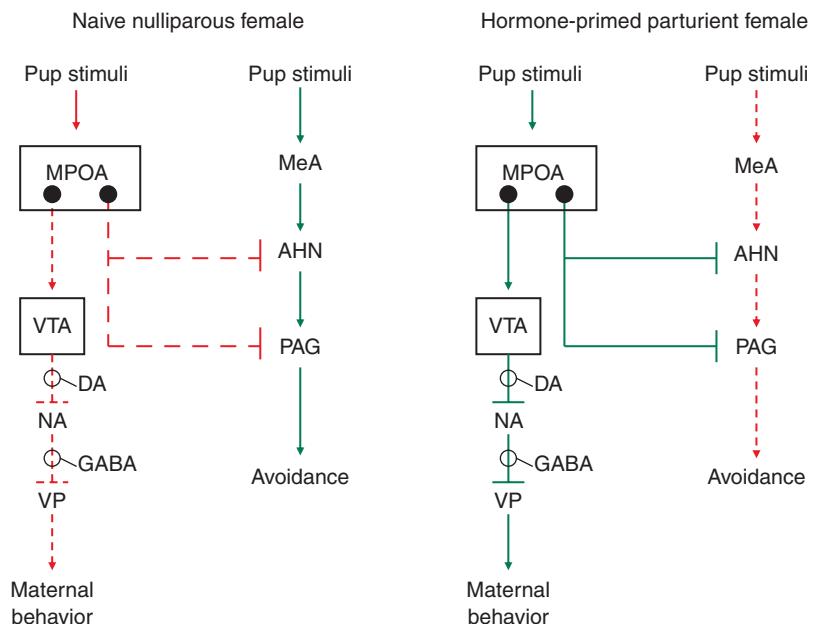

Figure 3 Neural model of a dual systems-control mechanism regulating maternal behavior in the rat. Systems represented in dashed red lines are not operative, while those shown in solid green lines are functional. Axons ending in an arrow indicate excitation and those ending in a bar represent inhibition. This figure is an elaboration of **Figure 1**, based on the findings from research on rats (see Numan, 2006). In the nulliparous female, pup stimuli activate avoidance, withdrawal, or defensive responses by activating a neural pathway from the medial amygdala (MeA) to the anterior hypothalamic nucleus (AHN) to the periaqueductal gray (PAG). As a result of exposure of the brain to the hormones of pregnancy and pregnancy termination, the maternal behavior system becomes operative. Hormones act on the medial preoptic area (MPOA), which becomes responsive to pup stimuli. The outputs of the MPOA inhibit the avoidance system and also activate proactive maternal responses via stimulation of the ventral tegmental area (VTA), which gives rise to the mesolimbic dopamine (DA) system. Subsequent DA release into the nucleus accumbens (NA) suppresses inhibitory GABAergic projections to the ventral pallidum (VP). An active VP is necessary for appropriate maternal responsiveness.

Oxytocin (OT) and Maternal Behavior

Other than DA, most of the research on the neurochemical control of maternal behavior has focused on OT, which exerts powerful modulatory influences at critical nodes within some of the neural circuits we have described. The parvocellular cells of the paraventricular hypothalamic nucleus (PVN) are one site of OT production, and some of these neurons terminate within the brain which allows OT to act locally as a neurotransmitter or neuromodulator.

The hormonal events associated with late pregnancy and the vaginal and cervical stimulation at birth influence both the synthesis and release of OT into the brain. The current view is that OT release into diverse neural sites is important for the initiation of maternal responsiveness at birth, but once maternal behavior has become established, OT no longer plays an essential role in the maintenance of the behavior. For example, PVN lesions performed during pregnancy disrupt the onset of maternal behavior at parturition in rats, but such lesions are not disruptive if produced after maternal behavior has become established. Similar results are obtained with more selective methods: intracerebral injections of OT receptor (OTR) antagonists during parturition disrupt the onset of maternal behavior, but similar injections postpartum are ineffective. Although OT is not essential for the continuance of maternal behavior, it may exert subtle modulatory influences on the degree of maternal grooming of infants and on the particular nursing postures the mother shows.

The hormonal and other events of late pregnancy, particularly rising estradiol levels, also increase the synthesis and expression of OTRs – which would allow critical brain nuclei to respond to OT. In rats, OTR expression increases in the MPOA and VTA at parturition and evidence shows that microinjection of an OTR antagonist directly into either the MPOA or VTA disrupts the onset

of maternal behavior at parturition. There is also some work on prairie voles which suggests a role for OT action on the NA in maternal behavior control. Therefore, at the time of parturition, OT may act at critical nodes along the circuitry regulating proactive maternal responses and such action may allow these circuits to work at optimal efficiency (**Figure 4**).

In addition to OT's influence on appetitive maternal responding, OT – in conjunction with MPOA effects – may downregulate activity in fear and anxiety-related neural circuitry, and this influence may continue into the postpartum period. We return to this issue in our discussion on postpartum maternal aggression and anxiety reduction.

Paternal Behavior

Although paternal behavior is rare in mammals, it does occur. Its neural mechanisms may be similar to maternal behavior, since it is unlikely that distinct paternal circuits evolved in each mammalian species that naturally displays the behavior. It is more likely that dual parental-control mechanisms exist in all mammals of both sexes: circuitry through which infant stimuli can elicit (1) defensive/withdrawal responses and (2) appetitive parental responses. The developmental effects of perinatal testosterone secretion may act to enhance the defensive circuitry in the typical male mammal when compared to his female counterpart.

Since male mammals are not exposed to the endocrine events of pregnancy and pregnancy termination, when paternal behavior naturally occurs, some other factors must be involved in downregulating the putative avoidance circuits and upregulating the appetitive parental circuits. Evolutionary forces may have operated on

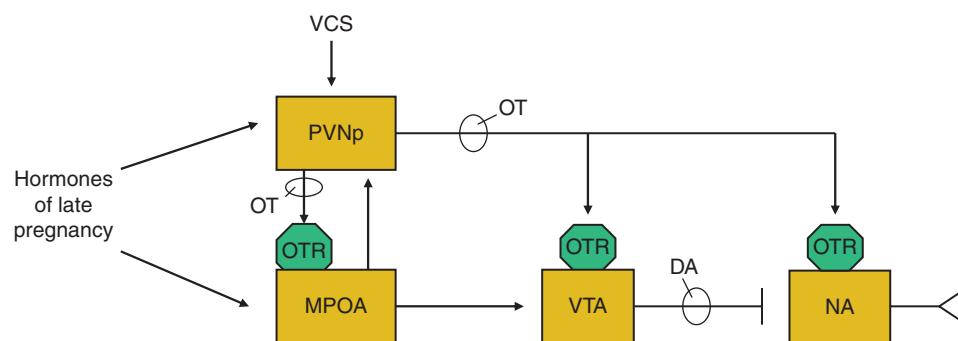

Figure 4 The coordinating role of oxytocinergic neural pathways in the regulation of the onset of maternal behavior. The parvocellular neurons of the paraventricular hypothalamic nucleus (PVNp) release oxytocin (OT) into various neural sites. The hormones of late pregnancy and the vaginocervical stimulation (VCS) which occurs during parturition promote the synthesis and release of OT. Pregnancy hormones also stimulate the synthesis of OT receptors (OTR) in the medial preoptic area (MPOA) and ventral tegmental area (VTA). At parturition, OT action on the MPOA, VTA, and, possibly, nucleus accumbens (NA) promotes the efficient operation of the MPOA–VTA–NA circuit which is essential for proactive maternal responses. DA = dopamine.

males of naturally paternal species to allow specialized stimuli and experiences to influence the critical circuitry.

Some evidence to support these views comes from rats, which are promiscuous breeders and not naturally paternal. Laboratory male rats initially avoid or attack pups, but if they are experimentally housed with healthy foster pups on a daily basis they will eventually show parental behavior after about 7–10 days as would virgin females. Furthermore, if one treats male rats with hormones which simulate the pattern that occurs in females at the end of pregnancy, their parental behavior is facilitated. Finally, MPOA lesions disrupt, and estradiol application to MPOA facilitates, parental responsiveness in male rats. Therefore, the neural mechanism underlying parental behavior exists in male rats, but under natural conditions the male is not exposed to factors which decrease avoidance of infants and stimulate parental behavior.

With respect to cases of naturally occurring parental behavior, it is known that Fos is expressed in the MPOA of paternal prairie voles, suggesting that this critical region is active. More importantly, in the naturally paternal California mouse, MPOA lesions disrupt paternal behavior.

Very little experimental research has been done on the factors which might stimulate paternal behavior in biparental mammals: hormonal factors, the experience of being biparentally reared, previous experience with young, and copulation and continued cohabitation with a mate may all play a role, and the specific factors involved may differ for different species. A popular idea with respect to endocrine influences, derived from research on avian species where paternal behavior is common, is that declining levels of testosterone and rising levels of prolactin stimulate paternal behavior. For male mammals, however, the supportive evidence is only correlational and not entirely convincing. For example, the increase in prolactin secretion which occurs in paternal marmosets and tamarins may be the result of infant contact rather than the cause of paternal behavior. In fact, in marmosets, experimental analysis has failed to support a causal link between prolactin and paternal behavior: drug treatments which depress prolactin release do not disrupt paternal behavior.

Some of the most promising ideas with respect to the mechanisms which may activate paternal circuitry in some species come from research on the domestic house mouse and on the biparental California mouse. Laboratory male mice (derived from the domestic house mouse) are not naturally paternal. However, either a null mutation of the progesterone receptor gene or treatment with a progesterone receptor antagonist depresses infanticide or avoidance and stimulates parental behavior. These results suggest that progesterone depresses paternal responding in these males, a mechanism which may also be involved in the California mouse. Unmated males of this species are typically infanticidal. However, after a

male mates with a female he becomes paternal once the female gives birth, and both copulatory stimuli and pheromones from the parturient female may be involved in this effect. There is also some evidence for the involvement of vasopressin (a neuropeptide with a chemical structure similar to oxytocin) in some of these effects. Furthermore, plasma progesterone levels are higher in nonpaternal males than in paternal males and the likely source of secretion is the adrenal cortex, since progesterone levels are not affected by castration. In addition, testosterone plays a positive role in the paternal behavior of this species and there is also an increase in aromatase activity (the enzyme which converts testosterone to estradiol) in the MPOA of paternal males.

For the California mouse, a preliminary and partial hypothetical model for paternal behavior can be offered: In unmated males, the aversive circuitry is dominant, the male attacks or avoids pups and this may be associated with adrenal release of progesterone. As a result of mating and subsequent cohabitation with a female – which includes pheromonal stimulation from the postpartum female – aromatase increases in the MPOA where testosterone is converted to estradiol, and estradiol stimulation of MPOA may then allow infant stimuli to activate appetitive paternal responses. In addition, the aversion circuitry is downregulated and progesterone levels fall.

Maternal Aggression and Fear Reduction in Postpartum Females

Postpartum females show a general decrease in fearfulness to a wide variety of novel or threatening stimuli and an increase in aggressive behavior aimed at conspecifics or potential predators that approach the infant (maternal aggression). The evidence which is currently available suggests that the hormonal events associated with late pregnancy and parturition modify the brain so that these two motivational changes occur and then subsequent proximal contact with infants maintains a high level of aggression and fear reduction.

With respect to postpartum fear reduction: it is general in nature, which distinguishes it from the specific reduction in aversion to novel infant stimuli that was proposed as necessary for the onset of infant-directed behaviors in primiparous females. Although MPOA projections to the aversion circuitry may be involved in the depression of avoidance responses to infant-related stimuli, other neural mechanisms may co-act with this MPOA effect to reduce fear-related behaviors to other stimuli. Fear reduction may be necessary for the mother to take reasonable risks in caring for her offspring, which would include displays of maternal aggression. Many studies have found an inverse relationship between levels of fearfulness and levels of maternal aggression in postpartum mothers.

Maternal aggression obviously has a neural circuitry which is independent of those circuits which regulate fearfulness and anxiety, but a reduction in fearfulness may be necessary for the maternal aggression circuitry to operate properly.

Neural projections from the central nucleus of the amygdala (CeA) to the PAG are involved in potentiating fear-related responses to a wide variety of stimuli. Corticotropin-releasing factor (CRF) action at the level of the CeA has anxiogenic effects, and intracerebroventricular injection of CRF depresses maternal aggression in postpartum mice. OT neural pathways – presumably derived from the PVN – not only facilitate the onset of infant-directed maternal behaviors, but also have general anxiolytic effects. OT is released into the CeA during maternal aggression and direct action of OT in the CeA increases maternal aggression and decreases fearfulness. Other studies have shown that OT also acts on PAG to decrease fearfulness in postpartum females. Furthermore, PAG lesions decrease fear-related behaviors and increase maternal aggression in postpartum rats. One can propose that in the postpartum female there is a downregulation of CRF neural systems and an upregulation of OT neural systems, which results in a level of fear-reduction which has a permissive effect on the occurrence of appropriate levels of maternal aggression.

Some studies have found that very low levels of fearfulness in postpartum rats are actually associated with low levels of maternal aggression. Such females may simply be passive and not concerned about potential threats to their offspring. Therefore, the relationship between fearfulness and maternal aggression is probably best described by an inverted-U-shaped curve: an optimal level of fearfulness or protectiveness may be necessary for the female to be vigilant and to display appropriate maternal aggression.

Although postpartum human females also show decreased anxiety, the occurrence of postpartum depression and anxiety is a significant problem. It can be suggested that a dysregulation of some of the systems we have just described – which may involve gene–environment interactions – can lead to high postpartum anxiety, depression and its associated anhedonia, and faulty maternal responses.

Experiential Influences on Maternal Behavior: A Window into the Mechanisms Which May Underlie Dysfunctions in Human Parental Behavior

How does animal research help us understand the neurobiological underpinnings of child abuse and neglect that are displayed by some human parents? Human children who have been abused or neglected by their parents tend to become abusive/neglectful parents themselves. Although

this could derive from genetic inheritance, it is possible that the early adverse effects of being abused and/or neglected affected the child's brain development so that, as adults, they show faulty parental behavior. Research on rhesus monkeys supports this view: motherless mother monkeys (monkeys raised without their mothers) grow up to show aberrant or absent maternal behavior to their own offspring. Such females also show high levels of anxiety. Furthermore, some rhesus monkey mothers are naturally abusive. Research has shown that infants born to nonabusive mothers who are cross-fostered to abusive mothers at birth tend to become abusive mothers when they have their own offspring in adulthood. Complete maternal deprivation in rats also results in the development of poor maternal behavior in the affected offspring.

Although gene–environment interactions are likely to be involved, these results show that early, adverse rearing conditions provide an experiential input that can lead to the development of poor maternal behavior. Possible mechanisms might include: (1) disrupted functioning of the MPOA output circuits which regulate maternal behavior; (2) increased activity in neural circuits regulating fear, anxiety, and stress responsivity; and (3) decreased activity within the mesolimbic DA system. We explore the possibility that mechanism (1) may play a contributory role in this article.

Rat mothers show variations in their maternal behavior: Some mothers are highly attentive to their pups and show high levels of licking/grooming behavior (HLG mothers), while others are less attentive, showing low levels of licking/grooming (LLG mothers). These are natural variations and we are not describing dysfunctional maternal behavior; all of these mothers rear their pups to weaning. Interestingly, when tested in a strange environment, HLG mothers are less fearful (they show more exploratory behavior) than LLG moms. HLG mothers have more estrogen receptors (ERs) and OTRs in the MPOA than do LLG moms, and during the expression of maternal behavior, more DA is released into their NA. What these behavioral and neural data suggest is that differences in the attentiveness of mothers may be due to differences in the organization of the MPOA output circuits: perhaps, because of greater numbers of ERs and OTRs in the MPOA, MPOA outputs to both the mesolimbic DA system and to the avoidance/rejection circuit are potentiated, and this leads to a more attentive and less fearful maternal style.

Cross-fostering studies show that infants develop the maternal style of the parent by which they were raised by: an infant raised by a HLG biological or foster mother grows up to become a HLG mother, expresses low fearfulness, and has high numbers of ERs in the MPOA. Just the opposite occurs in females raised by a LLG mother: as adults, such female offspring show higher fearfulness, low licking and grooming, and low numbers of ERs in the MPOA ([Figure 5](#)).

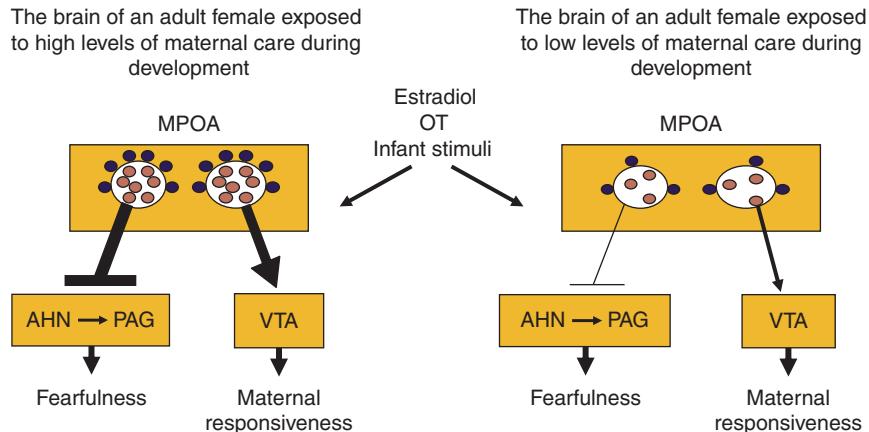

Figure 5 Experiential influences on the medial preoptic area (MPOA) development and maternal responsiveness. This figure is partly based on research reviewed by Champagne (2008) and by Kaffman and Meaney (2007). Female rat offspring that are exposed to high levels of maternal care – when compared to young that receive lower levels of maternal care – grow up to show higher levels of maternal care to their own offspring and such females are also less fearful or anxious than their low-maternal-care counterparts. Importantly, female young that receive high levels of care from their mothers develop an MPOA which contains more estrogen receptors (ERs: intracellular small circles within the MPOA cell bodies) and oxytocin receptors (OTRs: small circles on the membrane of the MPOA neurons). One can speculate that the enhanced expression of ERs and OTRs in the MPOA allows the MPOA neural circuits outlined in **Figure 3** to work more effectively. Therefore, females that have been well cared for by their mothers should grow up to show higher levels of maternal behavior to their own offspring while also being less fearful. Other abbreviations: AHN = anterior hypothalamic nucleus; OT = oxytocin; PAG = periaqueductal gray; VTA = ventral tegmental area. Axons ending in an arrow indicate excitation and those ending in a bar represent inhibition. The thickness of axons signifies the strength of the synaptic connection.

The implication of these data is that by understanding the underlying processes which influence natural variations in maternal responsiveness, one can gain insight into some of the mechanisms through which extreme adverse early-life events – such as parental abuse, neglect, or deprivation – might affect the brain of the developing child so that s/he develops truly dysfunctional parental behavior in adulthood. One possibility is that the MPOA output circuits are so disorganized by environmental insults interacting with certain genotypes that parental responsiveness to infants becomes abnormal or pathological.

Glossary

Antimuscarinics – Drugs that act as antagonists at the muscarinic class of synapses using the neurotransmitter acetylcholine. High doses eliminate playfulness without producing abnormal locomotion.

Attention-deficit hyperactivity disorder (ADHD) – A childhood disorder that has been hypothesized to result from insufficient play.

Brain-derived neurotrophic factor (BDNF) – The protein product of a gene that is upregulated during play.

cFos – The protein product of an immediate early gene that is rapidly upregulated when a neuron fires, making it a marker for neuronal activity.

Insulin-like growth factor-1 (IGF-1) – The protein product of a gene that is upregulated during play.

Mesolimbic dopaminergic pathway – One of the brain pathways in which neuronal cell bodies in the midbrain that produce and release the neuromodulator dopamine project to the forebrain. Lesions and electrical stimulation of this pathway affect play along with many other behaviors.

MK-801 – A drug that acts as an antagonist at *N*-methyl-D-aspartate (NMDA) glutamate receptors. It eliminates playfulness without producing abnormal locomotion.

Opioids – Endogenously produced neuromodulators with opiate-like effects that are involved in play through their role in social dominance.

Parafascicular complex – A region in the thalamus where nonspecific somatosensory inputs converge. Lesions of this complex reduce play by rats, as do lesions of the dorsomedial thalamus.

comparison to mammals, there is little well-established scientific information about the play of other classes of animals, aside from modest systematic behavioral work on birds. Whether other chordates and invertebrates show any playful behaviors remains unresolved. Accordingly, neuroscientific work has been conducted almost exclusively on laboratory rats. The most common variant of play in rats, distinct rough-and-tumble social engagement, is clearly an evolved function of the brain since the executive structures for such activities are situated subneocortically. There are currently sufficient high-quality data to be confident that there are, in fact, evolutionarily dedicated subcortical brain networks for the generation of social playfulness.

Historically, the scientific analysis of play has been hampered by biases ranging from the mistaken views that play simply reflects a form of exploratory activity, that it is a superfluous (excess-energy) behavior of youth, and that it may serve no adaptive psycho-behavioral functions, except perhaps for increasing physical fitness. In fact, we now know that mammalian play is functional – a basic brain–mind tool for living and learning about the social and physical environments in which young mammals find themselves. However, the neuroscientific analysis of play remains in its infancy, partly because it is not widely recognized as an easily studied fundamental emotional function of the mammalian brain that has profound societal as well as psychiatric implications.

The complexities and idiosyncrasies of play, not to mention definitional problems, discouraged investigators from initiating sustained research programs on the neural basis of play until recently. Because of conceptual and methodological advances, the experimental analysis of rough-and-tumble social play blossomed in the early 1980s. Several investigators found that it was remarkably easy, with excellent interobserver reliabilities, to obtain and quantify social play in laboratory rats, permitting rigorous neuroscientific research. This could be emulated in some other species (e.g., degus and gerbils), but has not been so far. Perhaps, the most attractive alternative laboratory species, mice, may not work well. Most strains do not exhibit clear and distinct play behaviors comparable to rats, perhaps because play has been bred out of them. (That is, it is possible that the ‘popcorn’ phase of early development reflects a play urge that was inadvertently minimized through selection practices since it was disruptive to

Play as a Basic Process of the Mammalian Brain

Playfulness is one of the most prominent behaviors of young animals across most mammalian species. However, play has remained enigmatic at a scientific level, partly because it has been one of the last primary-process emotional processes of the brain to receive experimental attention. Despite this, social play is a prominent, easily recognized, and operationalized behavior sequence in the young of most mammalian species. In

animal husbandry issues.) Several wild strains of mice, such as grasshopper mice, have been found to exhibit distinct rat-like play sequences.

We are still left with the dilemma of how to understand and discuss brain processes for complex affective behavior sequences systematically. Play is surely constituted of many highly interactive brain processes. This article focuses on the possibility that there are distinct executive, command networks for the most common social variant of play in rats – rough-and-tumble social engagement. However, there are other types of play.

Types of Play and Operational Definitions

There appear to exist several distinct kinds of play. They include most prominently, in order of ascending attention in behavioral neuroscience: object-play, locomotor-play, and, most importantly, social-play, also known as ‘rough-and-tumble play’ or ‘play-fighting.’ It is not known to what extent these forms of play are controlled by shared brain processes and whether they have distinctive functions in promoting developmental adaptations for future life challenges. To delimit the topic to the form that has the most abundant neuroscience evidence (modest though it is), the focus here is on social play, mainly as studied in laboratory rat models. However, even with this form of play, a variety of behaviors are exhibited across species – with herbivores commonly exhibiting more running, prancing, and chasing, while carnivores and omnivores exhibit play that has a much clearer pouncing attack,

predatory and wrestling-fighting character. They appear to be sham battles – tests of strength just for the fun of it.

Although the above complexities may preclude any simple universal definition of social play, rough-and-tumble play is still so distinctive that few people would mistake it for serious aggression, even though there are typically clear winners (so-called top-dogs) and losers (bottom-dogs) in play encounters. Despite this, all members of play pairs find this activity highly rewarding. Both winners and losers run down mazes to obtain play equally rapidly. Thus, a critical affective feature of play is that the social activity is highly rewarding.

Presented here is a behavioral description of play in rats that may serve as a provisional descriptive definition: when two rat pups are placed together in a nonthreatening environment, they rapidly begin to exhibit vigorous fighting. Animals chase and pounce on each other, sometimes unilaterally, sometimes mutually with rapid role reversals. They repeatedly poke and nip each other, often at the nape of the neck but also on the ventral surface when one animal is pinned.

Operational Definitions and Measurement of Play

From the above observations one can derive three main measures of playfulness that are easily quantified: chasing, dorsal contacts that seem designed to solicit play from another animal, and pinning, where one animal is on top and the other, on its back, below in a classic wrestling pose (see Figure 1). Across days, one animal of a stable play

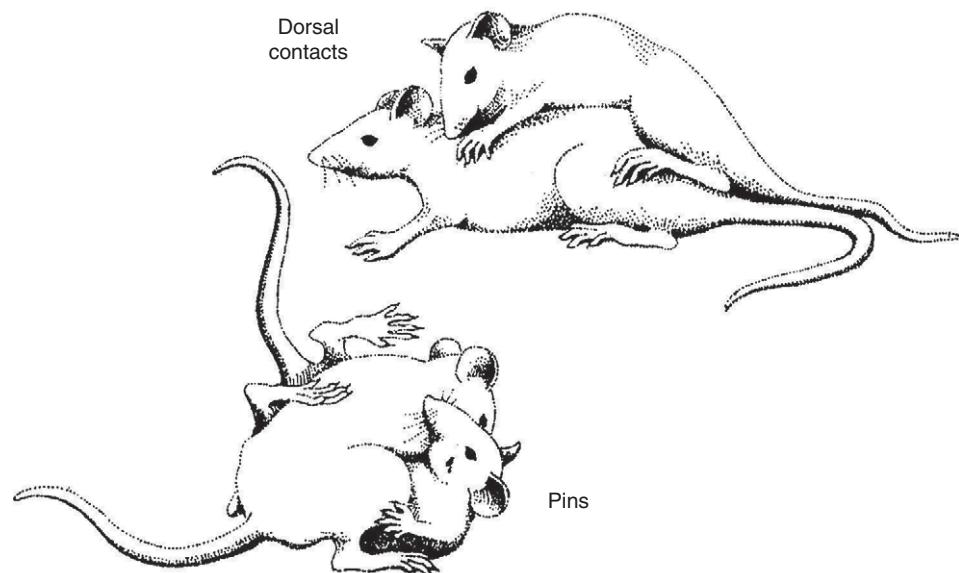

Figure 1 Two major postures that can be used as proxies to index overall amounts of rough-and-tumble play, with dorsal contacts being more related to the appetitive components of play and pins (especially the longer-duration pins) the consummatory components. Reprinted from Panksepp J (1998) *Affective Neuroscience: The Foundations of Human and Animal Emotions*. New York: Oxford University Press.

pair tends to become dominant, being the ‘top-dog’ about 70% of the time, while the other animal gets to be on top in about 30% of the pins. The durations of these indices of playfulness are quite variable, so the harvesting of behavior-duration measures is useful. Of course, as with all complex sequences of behaviors, with frame-by-frame video analysis, one can increase precision and the number of submeasures, such as quantifications of body rotations and the timing of subtle interactions, but the decision to use simple versus complex measures (e.g., pins and dorsal contacts along with overall platform activity measures vs. the many that can be obtained from frame-by-frame analysis) depends on the question one is asking. If one simply needs indices of overall amounts of play, the simple indices that can be obtained as play occurs suffice, and if the play is conducted on a sensitive activity platform one can get a measure of overall playful activity that typically correlates highly with the distinct bodily measures.

The use of such proxy measures for a complex holistic process is typical in most scientific endeavors. For instance, a biochemist typically develops a detection assay for a specific molecule, without attempting a full description of the molecule of interest. If, however, one needs ethologically complete descriptions of playfulness, then a fine-grained, slowed-down, video-analysis becomes essential.

Major Model Systems and Behavioral Descriptions

When play is studied in semi-natural, group-housing conditions, one must use a focal observation procedure where one periodically samples the behavior of designated animals. Using such procedures, it is hard to control many variables, including influences of unobserved social learning. In contrast, the paired-encounter procedure, where play-deprived animals are given short daily play periods, yields more consistent, sustained, and vigorous play activities. Play increases systematically with hours of social deprivation, closely resembling other regulated processes such as feeding and drinking.

Developmentally, play exhibits an inverted-U type of trajectory, with play indices increasing into the middle juvenile ages (days 30–40 in rats), then diminishing gradually as animals approach puberty. Playfulness continues at low levels well into adulthood, with females exhibiting generally higher levels of adult play than males. It is generally believed that juvenile males play more than juvenile females, and that this reflects a differential genetic disposition. There are reasons to doubt that, since gender differences are observed mostly in focal observation studies, where most of the social histories of animals have not been observed. Gender differences are rarely observed using the paired-encounter procedure,

where every play episode has been documented. If one allows mixed-sex play, however, males tend to prevail and remain more playful. However, this reflects the fact that the smaller and lighter females cannot compete as effectively with the bigger males. It would appear that the gender differences in play are largely socially learned. Likewise, in one of the few formal scientific studies of social physical play in like-sexed pairs of human boys and girls, no robust gender effects in the ethologically measured incidence of play behaviors were observed.

The sensory system that is most important for sustaining play in laboratory rats is the somatosensory system. Anesthetization of the anterior dorsal region of the back is the most sensitive region for obtaining play reductions as monitored by pins but not dorsal contact, suggesting that the motivation for play remains intact. Similar effects can be obtained by lesioning the spinothalamic tract carrying somatosensory information, and, at the thalamic level, the clearest and most specific lesion effects are obtained where somatosensory information diverges into nonspecific, presumably affective, projection areas (e.g., parafascicular nucleus, see below). Other equally complex behaviors such as food foraging are not disrupted by such damage.

Anything that provokes anxiety (e.g., cat smell) or induces other negative affective states (e.g., hunger) dramatically reduces playfulness. The ability of a single meal to return hunger-reduced play to normal could be used as a sensitive measure of normal satiety. Many drugs reduce feeding only because they make animals feel sick or bad in other ways. Play is one of the few behaviors that could be used as a measure of normal satiety through behavioral activation as opposed to sedation.

Play Vocalizations

During short play periods, rats exhibit abundant short (~50 ms) 50-kHz ultrasonic vocalizations (USVs), which come in two forms, the flat calls and the more complex frequency-modulated (FM) chirps which start at around 50 kHz but end with a sinusoidal FM tail. The latter are most abundant in socially rewarding situations, while the flat variants often prevail during serious fighting. Animals like to listen to the FM chirps, but they seem to be neutral about the flat calls. Rats avoid the anxiety-indicative long 22-kHz USVs.

During a half-hour play session, play diminishes systematically partly because of play satiety and partly because of an increasing number of affectively negative interactions. The changing affective balance during prolonged play sessions (15–30 min) is well indexed by gradually diminishing 50-kHz USVs, which index positive affect, and gradually increasing rates of 22-kHz USVs, which index negative affect, especially mild

anxiety. It is noteworthy that outright fear, as provoked by imminent footshock, shuts down both types of USVs.

The 50-kHz FM chirps indicative of positive affect can be most powerfully evoked by tickling (human hand-play), and the rewarding aspects of play are directly related to the amounts of this laughter-type of response. Animals become readily bonded to the human who has tickled them. This vocal marker of playfulness – 50-kHz USVs – has been genetically amplified through selective breeding, yielding lines with phenotypic differences in playfulness and a variety of related social activities.

Functions of Play

The abundance of functional theories, all with a dearth of evidence, generally agree that social play serves to practice social, emotional, and cognitive skills needed in the future. Play seems to be an experience-expectant process. Some theories specifically emphasize that play prepares animals for dealing with a variety of unpredictable events, but the evidence base is slim.

The empirical results tend to show that animals that have been play deprived are generally more aggressive and less capable of navigating complex social situations and complex learning tasks. Play-deprived animals are not deficient in simple classical and operant-conditioning tasks, nor do they exhibit deficiencies in straightforward instinctual behaviors such as copulation. For instance, adult males deprived of juvenile play approach, mount, and copulate with hormone-primed females just as rapidly as play-experienced animals. However, play-inexperienced rats are not as effective in competing with others for sexual resources as play-experienced animals.

The likelihood that play is a regulated process of the brain is indicated by highly systematic elevations of play with increasing hours of play deprivation and systematic diminishing of play with satiation. Likewise, play seems to be regulated across the life span. If animals are not allowed adequate play early in development, they play more at subsequent ages if given the opportunity.

The Neuroscience of Play

Neuroanatomy of Play

Only recently has it been recognized that there exist primary-process, genetically determined, subcortically situated play circuitries in the brain (i.e., probably genetically determined dispositions for social physical play). Playfulness seems to be an intrinsic aspect of mammalian brain organization since rats that have never been allowed to play when young (housed in isolation from 15 days of age when their eyes open until the beginning of their peak play period about 2 weeks later) play essentially normally when given their very first opportunity to play. Further

evidence for the intrinsic nature of social play is the fact that play fighting in laboratory rats survives radical neocortication of 3-day-old animals, long before play circuitry has matured in the brain. These animals exhibit as much playfulness as neurologically intact animals, even though certain measures are diminished (e.g., pins) perhaps because of modest motor abnormalities. The decorticates compete effectively with the normals, as measured by play dominance. In addition, animals that have had complete cerebellar lesions at 3 days of age still exhibit robust play urges and behaviors during juvenile development, even though their motor coordination is so poor that their social engagements are far from normal.

Using more restricted lesions, critical circuitry for play has so far only been identified in the medial thalamus, with the parafascicular complex, where nonspecific somatosensory inputs converge, having so far yielded the most specific reductions of play. Damage to many other brain areas can disrupt play (e.g., especially along the lateral hypothalamic, mesolimbic dopamine-rich medial forebrain bundle), but such damage reduces many other motivated behaviors equally. Certain forms of brain damage, such as frontal cortical and septal area lesions, can actually increase playfulness. Neuronal marker studies indicate that abundant cells in thalamic midline and dorsal midbrain regions are aroused in play, and play can promote expression of genes for neuronal growth factors such as brain-derived neurotrophic factor (BDNF) and others (see section titled ‘Pharmacological and neurochemical analysis of play’).

Electrical Stimulation of the Brain and Play

Unlike other primary-process emotional systems, play circuitry has not yet been effectively mapped with localized brain-stimulation procedures. A clear vocal marker of playfulness has been so mapped, however. Using localized brain stimulation, the simple marker for positive playful affect, namely the 50-kHz FM-USVs, has been mapped and optimal sites are situated along the trajectory of the mesolimbic dopamine pathways. Through the use of a variety of converging lesion and pharmacological manipulations, the response has been shown to be modulated positively by dopamine in the brain.

Pharmacological and Neurochemical Analysis of Play

Only a few pharmacological agents have been found to increase play. Most prominent among them are low doses of opioids such as morphine, α_2 -adrenoreceptor antagonists such as idazoxan and, perhaps, endocannabinoid facilitators. Opioids can also regulate the social

dominance that emerges in playful encounters, with opiate antagonists reducing and low doses of opiate agonists facilitating social dominance. In this context, it is interesting that opioid antagonists such as naloxone mildly reduce play, even though the animal's social motivation is increased. This may be because, without opioids, the animal feels socially insecure and is not getting as much reward from the social interaction. Indeed, it has been shown that there is abundant endogenous opioid release in the brain during social play.

A great number of pharmacological manipulations can reduce play, including dopamine- and muscarinic acetylcholine-blockade. If one wishes to make one animal of a pair unplayful so as to monitor the play-motivation (i.e., play solicitations such as dorsal contacts) of the other animal, one can use high doses of antimuscarinics or N-methyl-D-aspartate (NMDA) glutamatergic receptor antagonists such as MK-801 to generate very nonplayful animals that still locomote relatively normally. High doses of opioids and dopamine-blocking agents can produce cataleptic target animals that essentially remain immobile during the monitoring of play solicitations. These immobile targets are less socially attractive than animals that move around.

In general, every drug that makes animals feel bad – as monitored by place aversions – reduces play. Only a few agents can elevate play, and usually only at low doses, especially with opioids and alcohol. All psychostimulants that facilitate dopaminergic activity reduce play, even though dopamine release is amplified in the middle of play. This paradox may reflect the fact that dynamically modulated dopamine release is needed to sustain play; drugs that ‘freeze’ dopamine release at high, sustained levels are apparently not compatible with the dynamic, rapidly fluctuating behavior patterns that characterize play.

Gene Expression and Regulation and Play

Using the immediate-early-gene product cFos as an indication of neural activity, it is clear that only a limited number of subcortical brain areas participate in play: regions such as the medial thalamus, along with the polysensory regions of the dorsal tectum, as well as the affectively more positive regions of the medial midbrain. Although the neocortex is not needed for play, it is dramatically aroused during play. Why might that be? Perhaps because play helps program various complex social skills into the neocortex, which resembles a *tabula rasa* at birth. Preliminary genetic evidence suggests play may be important in the epigenetic programming of the higher regions of the brain; gene microarrays indicate that a great number of genes in the cortex are up- or down-regulated during play. Thus, in simple terms, play may

facilitate the developmental construction of the ‘higher social brain.’ A growth factor gene expression that is upregulated as a result of play is BDNF – which has been implicated in depressive disorders. From this, one might speculate that the positive affect from abundant play may tend to reverse depressive symptoms. At the present time, the only gene that has been studied at a functional level is that which manufactures insulin-like growth factor-1 (IGF-1). The protein products of this gene are released vigorously during play, but the amplified gene expression leads to significantly higher protein levels a few hours later. The protein, administered into the ventricular system, promotes positive affective responses, and recent functional studies have demonstrated that IGF-1 administered into the ventricular system can modify a variety of social and related emotional behaviors.

Play and Psychiatric Considerations

The genetic analysis of social behaviors, including play, remains in its infancy. What genes apparently provide are a few rough-and-ready emotional brain tools for animals to behave prosocially – for instance, to be motivated to play, have sex, and show maternal behavior – while the psychobehavioral refinements of these potentials, as in programming the neocortex, must be largely learned with the assistance of various epigenetic/developmental processes.

Although there are bound to be many higher psychological functions that can be refined through play, one possibility is that play is especially important in facilitating the maturation and refinement of frontal lobe executive functions. Attention-deficit hyperactivity disorder (ADHD) is a childhood disorder where such maturation is deficient; it is possible that this type of tendency is elevated when children do not get enough social physical play. This idea has been modeled in rats. Indeed, young animals that have been deprived of play tend to be more impulsive and playful when they are older than young rats that had abundant play. Children diagnosed with ADHD do have more slow-wave activity in their frontal lobes, which are typically slightly smaller (~5%) especially on the right side. Following imposed frontal lobe damage, rats are very much more impulsive and they play more than normal. Such symptoms are diminished if animals are allowed abundant daily access to rough-and-tumble play. In this context, it is important to recall that the psychostimulants used to treat ADHD uniformly reduce play in animal models. Likewise, sick and hungry animals and children also do not play much.

It is worth noting that animals deprived of social play throughout adolescence grow up to be more aggressive animals that are not as responsive to social cues. This has

also been evident in preliminary human studies, where violent, young, adult criminals in the Texas Prison system were found to have childhood upbringings that were very deficient in play opportunities. It is to be anticipated that play can facilitate the maturation of the fully social brain and the various sensitivities and empathetic attitudes that may go along with abundant playfulness in childhood.

Toward a Functional Understanding of Play and its Role in Society

Although the study of the functions and brain substrates of social play remains in its infancy, there are many reasons to believe that physical play is involved in the epigenetic programming of higher brain social functions. If we are to understand how the prosocial functions of the neocortex emerge in our children, we may need to devote more effort to the scientific study of play-induced epigenetic progressions in the brains of animals.

When it comes to developing new social policies related to insuring adequate physical play for our children, perhaps we should follow Plato's advice and encourage more free play – "those natural modes of amusement which children find out for themselves when they meet." In *The Republic* [section IV] he insisted that "our children from their earliest years must take part in all the more lawful forms of play, for if they are not surrounded with such an atmosphere they can never grow up to be well conducted and virtuous citizens." Pursuant to such ideas, there is a greater need to understand the functions and neuroscientific foundations of social play in animal models.

Glossary

Arginine vasopressin (AVP) – A nine-amino-acid neuropeptide synthesized in the hypothalamus, including the supraoptic and paraventricular nucleus, as well as the suprachiasmatic nucleus. AVP is also synthesized in the medial amygdala (AMY) and bed nucleus of the stria terminalis (BNST) and released in the lateral septum (LS). AVP in the AMY–BNST–LS axis is androgen dependent.

Corticotropin-releasing factor (CRF) – A secretogog for adrenocorticotropic hormone (ACTH) which has been implicated in various forms of behavior and anxiety.

Dopamine – A catecholamine neurotransmitter associated with movement as well as behavioral activation and incentive seeking.

Oxytocin (OT) – A nine-amino-acid neuropeptide synthesized primarily in the hypothalamus, including the supraoptic nucleus and paraventricular nucleus, and historically associated with birth and lactation.

Social monogamy – A social system characterized by pair bonding and biparental behavior.

Vagus – The tenth cranial nerve supplies innervation to visceral organs. The source nuclei of the motor/efferent components of the vagus are in the dorsal motor nucleus of the vagus (DMX) and the nucleus ambiguus. The nucleus ambiguus is located ventral to the DMX in an area known as the ventral vagal complex (VVC), which also contains the source nuclei of the special visceral efferent pathways regulating the striated muscles of the face and head.

Vertebrates, and especially mammals, are dependent on other members of their species for reproduction and, in some cases, for basic survival. Social relationships can be of varying intensities and durations, ranging from casual, nonselective interactions to selective comparatively long-lasting interactions or mental representations that may last for the lifetime of the individual. The purpose of this article is to describe central neurobiological processes that have been associated with the causes and consequences of mammalian sociality and selective social bonds.

Mammalian infants are nutritionally dependent for part of their lives on the mother. In addition, most

mammals produce their young through live birth. In mammals, the neuroendocrine systems necessary for birth, lactation, and maternal behavior are also at the core of the neurobiology of adult social bonds. In mammals, the most consistent social bonds are also between the mother and infant. In fact, the biology of the mother–infant interaction may be the physiological prototype for mammalian sociality. However, relationships structured around social bonds can form throughout the lifespan, and are integral to the formation of families or other social groups. The biology of social bonds probably originates from endocrine and autonomic processes necessary for very basic physiological processes such as water balance, the management of homeostasis, and reproduction.

Several neurotransmitters and neuromodulators, including compounds that are also implicated in reproduction and homeostasis, such as oxytocin (OT), arginine vasopressin (AVP), and corticotropin-releasing factor (CRF), have been implicated in social bond formation. The autonomic nervous system, comprised of both sympathetic and parasympathetic components, mediates emotional states and regulates various bodily organs. The same neurotransmitters that are involved in sociality play a role in the regulation of the autonomic nervous system, allowing integration of social behaviors with physiological and autonomic states.

Species differences in the capacity to form social bonds are common, and this variation has provided clues to the specific neurobiology of social bonding. For example, sheep, which exhibit selective maternal behaviors, and socially monogamous rodents, such as prairie voles, have proven particularly useful models for the analysis of the physiology of mammalian social bonds.

Attachment and Bonding

In the field of psychology, the term ‘attachment’ has been typically used in reference to the responses of a young child to the presence or absence of its mother or another caretaker. This somewhat narrow use of the term may also be used to describe ‘attachment theory’ which is usually restricted to human behavior. The more general term ‘bonding’ is used here to refer to selective social relationships that may occur in humans or other animals. In the context of neurobiology, social bonds may be measured by behavioral, autonomic, or endocrine responses that are differentially expressed toward one

individual versus another. The behaviors used to index social bonds may include positive behaviors, such as the preference of a mother for her own young or selective partner preferences between adults. Proximity and social contact are commonly used to index pair bonding in animals. In addition, defensive aggression, usually toward a stranger or intruder, may also be used as a measure of social bonding. In this context maternal defense or mate guarding may also be expressions of social bonds.

The first steps in the formation of social bonds, whether between a mother and infant or two adults, require social proximity, social engagement, and individual recognition. However, social cues can be perceived or interpreted as either positive or negative. Typically, positive signals elicit approach, while negative signals are followed by avoidance or withdrawal. The most basic elements of sociality are influenced by the physiological condition of the social partners, including sensory and autonomic processes which can in turn influence reactivity to various sensory cues. Sensory cues from a potential partner – such as odors, physical traits, and auditory signals – are received and filtered through neural networks that are influenced by endocrine processes. In addition, autonomic processes, necessary for social engagement, social learning, and social bonding, are dynamically affected by the same hormonal factors that regulate reproduction. Studies of maternal behavior have provided specific clues to the neuroendocrine mechanisms necessary for the formation or expression of social bonds between adults. There is strong evidence in mammals that both maternal–infant bonding and adult pair bond formation rely on neuropeptide hormones, including OT and AVP.

OT and Vasopressin

The major sources of OT and AVP are in the brainstem, including the paraventricular and supraoptic nuclei. OT and AVP are released into the blood supply at the posterior pituitary (also known as the ‘neurohypophysis’). These hypophyseal hormones act on various peripheral tissues. They are also secreted into the brain where they have their major behavioral effects. Of particular importance to sex differences in social behavior are an androgen-dependent set of AVP cell bodies in the medial amygdala and bed nucleus of the stria terminalis. Processes from these AVP secreting cells extend into the lateral septum. In this article this system is termed the medial amygdala–bed nucleus of the stria terminalis–lateral septum (AMY–BNST–LS) axis.

In general, OT and AVP are synthesized in separate cells, and tend to have dynamic, often opposing effects on both behavior and physiology. OT has only one known receptor subtype (OT receptor, OTR). The same OTR is

found in brain, uterus, and mammary tissue. AVP has three receptor subtypes; of these the AVP V1a receptor subtype is particularly abundant in the nervous system. OT and AVP are selective for their own receptors, and may also bind to and affect each other’s receptors, allowing peptidergic interactions and complexity in this system.

Social Engagement, Social Bonding, and the Autonomic Nervous System

Fundamental to the formation of pair bonds are social engagement behaviors, most simply measured by the reduction of physical distance between prospective partners. Engagement is followed by recognition of another individual as either familiar or unfamiliar. In time, especially in socially monogamous species, a social preference is expressed, usually for the familiar partner. Autonomic function is necessary for all forms of affective and emotional experience, including the interactive and contingent behaviors leading to the formation of selective social bonds.

The origins of social engagement are more fully understood in the context of the evolution of the mammalian autonomic nervous system. The mammalian nervous system evolved from phylogenetically older vertebrates. During this evolution, new autonomic mechanisms emerged that supported the metabolic needs of the complex, oxygen-dependent mammalian nervous system. Associated with the phylogenetic transition to mammals was the evolution of unique mechanisms for social communication and associated selective sociality, regulated in part by the autonomic nervous system.

It is common to divide the autonomic nervous system into sympathetic and parasympathetic branches. The sympathetic nervous system is, in general, linked to mobilization behaviors and an increase in metabolic output, while the parasympathetic nervous system is involved in calming and immobilizing behaviors. Anatomically, sympathetic pathways are integrated with nerves exiting the spinal cord, while the primary nerve of the parasympathetic nervous system exits the brainstem as the vagus or the tenth cranial nerve. Social engagement and bonding require a turning off of the primary fight and flight defense systems. The phylogenetically more recently evolved myelinated vagus dampens sympathetic activation and reduces the sense of danger associated with engaging prospective mates. Thus, social bonding and attachment are related to the effectiveness of the ventral vagus in dampening sympathetic activation, reducing defensive behaviors, and facilitating social engagement through the special visceral efferent regulation of the muscles of the face and head.

The vagus nerve is actually a bundle of fibers, including both motor/efferent and sensory/afferent components. Approximately 80% of the vagal fibers are afferent and carry information from the viscera to a brain-stem region known as ‘nucleus tractus solitarius (NTS).’ Output from the NTS contributes to the regulation of higher brain functions, including modulation of arousal and bodily state.

The two source nuclei of the efferent vagus include the phylogenetically older unmyelinated, dorsal motor nucleus of the vagus (DMX) and the more recently evolved myelinated portion of the vagus, which originates in the nucleus ambiguus. The nucleus ambiguus is located ventral to the DMX in an area known as the ventral vagal complex (VVC), which also contains the source nuclei for the special visceral efferent pathways that regulate the striated muscles of the face and head, through cranial nerves V, VII, IX, X, and XI. Actions of the ventral vagal complex allow the reduction in fear and the concurrent emergence of calm states necessary for social engagement and bonding. The special visceral efferent pathways, in coordination with the ventral vagus, form a social engagement system that integrates calming with the movements of the striated muscles of the face and head. In a context of relative safety, facial expressions and vocal intonations necessary for social engagement and social communication can emerge.

Neuropeptide receptors are found in autonomic source nuclei, where they serve to regulate sympathetic and parasympathetic functions, and in this capacity can influence social bond formation. For example, OTRs are abundant in the DMX. The DMX and the unmyelinated vagus have been implicated in various types of conditioning, such as taste aversion (e.g., nausea) and passive avoidance. The OT pathways may thus dampen both sympathoadrenal and DMX (unmyelinated) vagal reactivity, allowing reductions in anxiety and fear, and concurrently permitting proximity and social bonds. Within the brainstem, OT may act directly on the source nuclei of the DMX to protect the autonomic nervous system from surging, especially under conditions such as parturition or consensual sexual behavior, which require immobility without fear. A sense of safety may be essential to the formation of a social bond. In this context, OT may change the detection of immobilization from that of life threat to that of safety.

In contrast, both OT and AVP V1a receptors are found in the VVC and may functionally modulate the inhibitory action of the vagus on the heart. This enables the vagus to function as a bidirectional system characterized by dynamically increasing and decreasing the influence of the vagal brake on heart rate and supporting the functions of the SVE, without requiring increases in sympathetic activation. Treatment with OT and AVP has the capacity to increase sociality in general. However, both OT and

AVP (in conjunction with dopamine) may be essential to allow the expression of selective social behaviors, including social preferences, and the more mobilized states required for defense of a mate.

OT may also regulate the most primitive defensive response system, characterized by immobilization. Under stressful social conditions, in which avoidance or escape are not an option, a more primitive strategy, immobilization, based upon phylogenetically older neural systems, may emerge. For example, during subordination, the capacity to immobilize and not struggle, or even form social bonds toward a dominant partner, becomes part of an adaptive system. This primitive system is associated with an unmyelinated vagal pathway that triggers bradycardia, apnea, vasovagal syncope, and defecation as adaptive survival strategies to reduce metabolic demands and feign death. Unfortunately, this system, which functions adaptively for reptiles, amphibia, and fish, can be lethal for mammals. The neurophysiological properties of OT may also permit physical immobility without fear in prosocial settings, permitting sleep, digestion, growth, restoration, and reproduction.

Sex Differences in Sociality

Sex differences in steroid and peptide hormones, either during development or in adulthood, may be important in explaining sex differences in the factors that regulate social bonding. In general, males seem to be more capable than females of engaging in active social behaviors and may be more vigilant in response to threats, sometimes termed ‘active coping.’ Females, in contrast, are more likely to show reproductive behavioral patterns characterized by immobility, including those associated with birth, lactation, and female sexual postures such as lordosis. In females, stressors or severe threats may elicit passive coping. Based on animal models, it seems likely that an essential aspect of both parental behavior and pair bonding is the capacity to overcome neophobia and social anxiety. At optimal levels, both OT and AVP can reduce anxiety, which in turn can permit or facilitate social engagement with a novel partner. This in turn may lead to social bond formation, although the mechanisms for pair bonding may involve a more active pattern of behavior in males than females.

OT synthesis and, in some cases, the OTR are enhanced in the presence of estrogen. In addition, in females the relative absence of AVP, especially in areas such as the AMY–BNST–LS axis, may help to explain sex differences in the reaction of females versus males to stressful experiences. This axis may play a fundamental role in the sexually dimorphic expression of social behaviors.

Centrally administered AVP, acting on the V1a receptor subtype, has been implicated in social bonding in both sexes and higher levels of or increased sensitivity to AVP in the AMY–BNST–LS axis could help to explain sex differences in social behaviors. For example, following mating males of socially monogamous species become selectively aggressive toward strangers. V1a receptor stimulation may be of particular importance to active defensive behaviors associated with guarding a mate as well as an offspring. AVP also has a role in the regulation of the autonomic nervous system, including both sympathetic and parasympathetic activity. AVP helps to provide another level of integration between social physiology, emotional responses, and social behavior. The observed effect of AVP on social bonding can be mediated through shifts in autonomic regulation, providing a substrate for mobilization. Alternatively, autonomic effects of OT are associated with immobility or passive coping.

Male parental or alloparental behavior shares some features with maternal behavior. However, male parental behavior does not involve lactation and may also have a somewhat different neurochemistry, possibly requiring for expression both OT and AVP. Spontaneous alloparental behavior in reproductively naive male prairie voles is more reliably exhibited than in females. It is likely that female parental behavior reflects the dependence of females on OT which would normally be released by birth and lactation, but which may not be fully activated in nonreproductive females. This is one of the many examples of evidence for sex differences in the regulation of social behaviors, possibly because of sex differences in the roles of AVP and OT.

In humans, intranasal OT increased the willingness of human males to ‘trust’ others or to detect subtle emotional cues in pictures of human eyes. In contrast, men given AVP showed increases in frowning, and also rated neutral facial expressions as ‘unfriendly.’ Under the same conditions, women given AVP smiled more and reported more positive, affiliative responses to unfamiliar neutral faces. Reasons for this sex difference are not well understood, but may be because in females, the actions of exogenous AVP are primarily through effects on the OT (rather than AVP) receptor.

The Effect of Social Isolation

Experiments in animals provide an opportunity to examine in more depth, the physiological consequences of the absence of a social partner. Prairie voles have a human-like parasympathetic control of the heart, with high levels of vagal activity, unique in rodents. In this species, separation from a partner, followed by prolonged isolation, was associated with increases in heart rate, decreases in parasympathetic function, increased reactivity to stressors,

and increases in measures used to index anhedonia and depression. Following the disruption of a social bond increases in both central and peripheral measures of OT have been found, especially in females. Elevations in OT may provide physiological compensation and coping against negative consequences of isolation. In prairie voles, chronic OT injections were capable of preventing or reversing the cardiac and behavioral effects following prolonged separation (i.e., isolation) from a partner.

Possible Neural Substrates for Behavioral Effects of OT and Vasopressin

The full circuitry for selective sociality has not been described. However, V1a receptors in the lateral septum have been specifically implicated in social recognition in male mice. The lateral septum projects to the dopaminergic nucleus accumbens (NAcc), and through this connection may reinforce selective social behaviors.

Research in mice has also implicated OT and AVP in social recognition. For example, mice in which the gene for OT, or the OTR, or the gene for the AVP V1a receptor were ‘knocked out’ failed to show social recognition as measured by reactions to a familiar animal. In each case, these knock-out mice are not asocial, but do fail to show the selective sociality used to index social recognition. These studies support the more general hypothesis that both OT and AVP may be required for the expression of selective sociality.

The amygdala and its connections play a role in the integration of reactions to various kinds of sensory stimuli, including approach and avoidance. In human males, intranasal administration of OT inhibited the activity of the amygdala, especially after exposure to fear-associated stimuli; intranasal OT also altered downstream connections to brainstem structures involved in the regulation of the autonomic nervous system. AVP, acting centrally (especially in the AMY–BNST–LS axis), as well as other peptides, such as CRF, may elevate vigilance and defensiveness. Behaviors mediated by the central amygdala may also mediate stimulus-specific behavioral responses to fear, while the BNST has been implicated in experiences related to anxiety. At least some of the defensive actions of CRF or AVP may be downregulated by OT. Among the neural targets for OT are receptors in the paraventricular nucleus (PVN) and the posterior pituitary (neurohypophysis), where they may dampen both pain responses and defensive behavioral and autonomic reactions.

Opioids and Pair Bonding

Several other neurochemical systems, including those which rely on endogenous opioids, have been implicated in both maternal care and later sociality. In sheep and

primates, blocking opioid systems with naloxone in a mother is followed by reductions in these behaviors, although these mothers are still capable of suckling their young. Social interactions in infants are also regulated by opioids, although these effects may be species specific. In guinea pigs, which are precocial at birth, opiate injection diminished distress vocalizations. As the endogenous opioids also play a role in the regulation of the release of OT and AVP, as well as the hypothalamic–pituitary–adrenal (HPA) axis, they may also influence social behaviors indirectly.

Dopamine and Pair Bonding

Dopamine plays a role in behavioral activation and incentive seeking. Brain regions with high levels of dopaminergic input, including the medial prefrontal cortex (mPFC) and (NAcc), have also been implicated in suckling and the emergence of positive responses to an infant. Interactions between OT and dopamine in the NAcc have also been implicated in both maternal behavior and pair bonding in prairie voles. OTRs are especially abundant in the shell of the NAcc in socially monogamous species, including prairie voles, but not in nonmonogamous voles. Administration of a general dopamine receptor antagonist in the NAcc blocked mating-induced partner preferences. In contrast, treatment with a dopamine agonist facilitated pair bonding, suggesting an essential role for dopamine in pair bond formation. The action of dopamine on social bond formation and maintenance of these bonds is mediated through different subtypes of dopamine receptors. D2 receptors are necessary for pair bond formation. In contrast, D1 receptors play a role in the maintenance of social bonds, including an increase in selective and defensive aggression, which can help to protect the pair bond.

The NAcc is also a major input to the ventral pallidum and there is evidence that AVP and dopamine may interact in the ventral pallidum to facilitate pair bonding, possibly by overcoming fear or anxiety and reinforcing the bond. Prairie voles, in comparison to nonmonogamous vole species, have high levels of V1a receptors in the ventral pallidum. Blocking the V1a receptor in this region inhibited partner preference formation in male prairie voles. In addition, upregulation of V1a receptors in the ventral pallidum (using a viral vector) facilitated pair bonding in male prairie voles. Overexpression of the prairie vole, V1a receptor in the ventral pallidum of montane voles, a nonmonogamous species, also facilitated partner preferences. Species-specific microsatellites in the promoter region of the gene for the V1a receptor may alter the expression of this receptor, especially in brain regions necessary for pair bonding. Differences in the co-localization of dopamine, OT and AVP may help

to explain species or individual differences in the capacity to form pair bonds.

'Stress' Hormones and Pair Bonding

CRF is another neuropeptide that has been implicated in birth, maternal behavior, anxiety, and adult social bonding. The effects of CRF on pair bonding in prairie voles have thus far been studied only in males. The effects of CRF were dose dependent; moderate doses facilitated pair bonding, but higher doses did not, possibly because high levels of CRF can induce anxiety. Moreover, CRF receptors are sexually dimorphic, at least in prairie voles, which might also contribute to sex differences in pair bond formation. CRF and AVP are both associated with increased release of the adrenal steroid, corticosterone. It is possible that a cocktail of 'stress' hormones may facilitate pair bonding in males. CRF administered directly into the NAcc also facilitated pair bonding in male prairie voles, but was not effective in nonmonogamous vole species. Species differences exist in CRF receptors, with higher levels of the CRF type 2 receptor and lower levels of CRF type 1 receptor in the NAcc in socially monogamous species of voles. CRF may also modulate the release of dopamine, possibly contributing to the effects of CRF on pair bonding.

Developmental Factors Can Alter Social Bonding

Neuroendocrine systems involved in social bonding undergo long-lasting modifications as a function of early experience. This epigenetic model may help to explain the origins of traits, sometimes called 'personality' or 'temperament,' as well as individual differences in behavior. Understanding of these systems may also offer insights into the development of pathological or maladaptive behaviors.

Genetic differences are one source of variance in social behavior, including the tendency to form social bonds. However, genetic differences are not sufficient to explain individual variations in social behaviors. Among the behaviors and neural systems that are changed by early experience are those necessary for pair bond formation. For example, female prairie voles that were deliberately maintained with minimal disturbance during the pre-weaning period did not, in later life, form pair bonds.

Manipulations of OT and AVP in the postnatal period are also capable of programming individual differences in sociality. In female prairie voles, exposure to exogenous OT during neonatal life has a dose-dependent capacity to facilitate a later pair bond and enhanced subsequent hypothalamic synthesis of OT. In contrast, even brief

neonatal exposure to an OT receptor antagonist (OTA) disrupted subsequent social behaviors, including the tendency to form social bonds, to exhibit parental behaviors, and to manage anxiety or stress. OTA treatment also disrupted the expression of the AVP, V1a receptor, with consequences that were particularly dramatic in males. Many of the consequences of early peptide manipulations on the nervous system are sexually dimorphic and correspond to sex differences in behavior. The androgen dependence of AVP in the AMY–BNST–LS axis and the sexually dimorphic capacity of an OTA to downregulate both AVP receptors and AVP may help explain the fact that exposure to OTA was especially disruptive to male behavior. Conversely, in males (but not females), early OT exposure upregulated V1a receptors in the ventral pallidum, consistent with the finding that increases in AVP V1a receptors in the ventral pallidum can facilitate pair bonding in male prairie voles.

Early Experiences and Social Bonding

The biological mechanisms underlying traits, including the capacity to form affiliative bonds, are dynamic and capable of being influenced by early behavioral experiences. These effects are often on the same systems that regulate sociality in adulthood. For example, physiological and behavioral changes associated with pregnancy, birth, lactation, and the management of infants during the postpartum period can produce long-lasting changes in behavior. The widespread use of exogenous OT ('Pitocin') to induce or augment labor and more recently the use of OT antagonists also hold the potential to influence the parent and offspring. Even apparently simple decisions, such that the amount of time an infant is touched or receives other forms of social stimulation, can retune the developing mammalian nervous system. Human breast milk contains OT and related hormones, which may be eliminated in infant formulas. Moreover, sucking behavior engages the same neural circuits involved in social engagement. Thus, the decision to breast-feed, with both nutritional and behavioral consequences, could also be a neural exercise in the social context of nursing. Breast-feeding might strengthen the bond with the mother through the joint mechanisms of increasing OT and possibly dopamine as well. Physiological and behavioral experiences, including those associated with birth and parenting, can influence subsequent sociality and attachment. A deeper understanding of the causes and consequences of these

processes remains a major challenge for the neurosciences of the twenty-first century.

Glossary

Bottom-up – A strategy of information processing that arises from sensory stimuli present in a scene. In a bottom-up approach, physically salient stimuli, such as a bright light, bias the information to be processed.

Diffusion tensor imaging (DTI) – The structural noninvasive neuroimaging technique that enables the measurement of the integrity of cerebral white matter.

Electroencephalogram (EEG) – The electrophysiological noninvasive functional neuroimaging technique that enables the measurement of electrical brain activity by electrodes attached to the scalp.

Event-related potentials (ERPs) – The voltage fluctuations evident in the EEG recording that are induced by changes in brain activity temporally associated to the occurrence of sensory, motor, or cognitive events.

Functional magnetic resonance imaging (fMRI) – The metabolic noninvasive functional neuroimaging technique that enables the measurement of changes in cerebral blood oxygenation levels in the brain that are associated to sensory, motor, or cognitive events.

Speed of information processing (SIP) – The amount of information that can be processed per unit of time, or velocity at which a variety of cognitive processes can be carried out.

Top-down – A strategy of information processing important for guiding a goal-directed behavior. Information processing is guided in a top-down manner when expectations and goals determine what is relevant and what will be processed.

Working memory – The mental ability to maintain and/or manipulate information during brief periods of time in order to make use of this information to perform a particular task or to achieve a goal.

Definition

Attention could be defined as the mental ability to generate and maintain an activation state that allows information processing. It also allows the selection of specific

information from among multiple sources. This includes internal and external stimulation, memories, thoughts, or even actions. Attention may be considered a complex system of specialized subprocesses through which it addresses precision, speed, and continuity to behavior.

Functional dissociation between different attentional components is difficult to establish when considering everyday activities. However, researchers have traditionally described the independence of at least three functional systems that cooperate and work closely together. Current cognitive neuroscience has named these attentional networks as: alerting, orienting, and executive attention.

Alerting

Alerting relates to an increase and maintenance of the readiness response in preparation for an impending stimulus. This capacity is considered the basis of attention onto which other attentional mechanisms rest. The terms arousal, vigilance, and sustained attention have been used interchangeably to define ‘long-term attention.’ However, findings from functional neuroimaging, clinical, and animal studies have suggested the presence of neuroanatomical dissociations between the neuronal circuits underlying these attentional abilities.

The term ‘arousal’ has been defined as a continuum of physiological reactivity, sleep and excitement being the two extremes of the continuum. Arousal represents a basic attentional function that determines the efficacy of higher-level cortical attentional systems and general cognitive capacity.

The psychological construct ‘sustained attention’ is the ability to maintain attention to a particular stimulus, location, or task, for prolonged periods of time. Sustained attention has been frequently used synonymously with the term ‘vigilance.’ However, vigilance is thought of as a long-term process for periods of minutes and hours, whereas sustained attention, a shorter-term process for seconds and minutes.

Experimental Tasks

Arousal can be operationalized in terms of the degree of synchronization/desynchronization of the brain electrical

fields as measured in the electroencephalogram (EEG). In general, when the arousal state increases, a desynchronization in the recorded EEG activity is observed (i.e., small amplitudes and fast frequency rhythms). In neuropsychological and clinical practice, alerting has been also measured by different behavioral scales and tasks. Among the commonly used procedures to address alertness after brain damage, we can find the Glasgow Coma Scale (GCS), the Galveston Orientation and Amnesia Test (GOAT), the Westmead posttraumatic amnesia scale, or the Mental Control subscale from the Wechsler Memory Scale.

Vigilance tasks involve detecting stimuli with a low rate of appearance in long-lasting monotonous tasks. Prototypically, vigilance or warning tasks assess how quickly a subject can respond to certain auditory or visual warning signals.

Sustained attention tasks involve responding stimuli with a high rate of appearance such that subjects must keep monotonously responding to target stimuli. Thus, task length is not a critical variable. In a clinical context, it is common to use different versions of the Continuous Performance Test and the Symbol Digit Modality Test (SDMT).

Related Anatomy

The ability of arousal-inducing stimuli to trigger attentional processing is mediated bottom-up through noradrenergic projections from the locus ceruleus to the thalamus and the basal forebrain. This arousal system would be a lower-order system triggering, but not directly mediating, higher-order attentional mechanisms.

Visual and auditory vigilance tasks have been associated by functional neuroimaging with a decrease on right frontal activation as a function of time on task. This decrement correlates with behavioral measures of vigilance decrement, such as the slowing down in reaction times (RTs) to target stimulus.

Human neuropsychological and neuroimaging studies have also pointed to an amodal right frontoparietal-thalamic system involved in sustaining attention even for short periods of time. In addition, animal experimental research supports the basal forebrain corticopetal cholinergic projection as a major component of the circuit. Therefore, while frontoparietal regions would be related to the attentional requirements of sustained attention, thalamic signals would be related to the influence of arousal levels on sustained attention (**Figure 1**).

Clinical Impairment

Deficit in the alerting system vary from coma states to normal vigil response, and could include poor response to stimulation, lack of orienting reflexes, sleepiness, etc. Patients with severe central nervous system disease often show marked alerting difficulties.

The distinction between vigilance and sustained attention became especially relevant in the clinical context. Most patients with mild/moderate brain injury show no significant difficulties in carrying out vigilance tasks. By contrast, many patients show sustained attention difficulties when processing information presented at a high rate. These sustained attention difficulties may have a strong impact on daily activities.

Orienting

Orienting is the most studied attentional network. It is defined as the ability to select specific information from among multiple sensory stimuli or features. Selective attention is closely related to orientation of attention. While orienting of attention refers to directing attention to one particular location or stimulus, selective attention implies attending to one location or stimulus in favor of another.

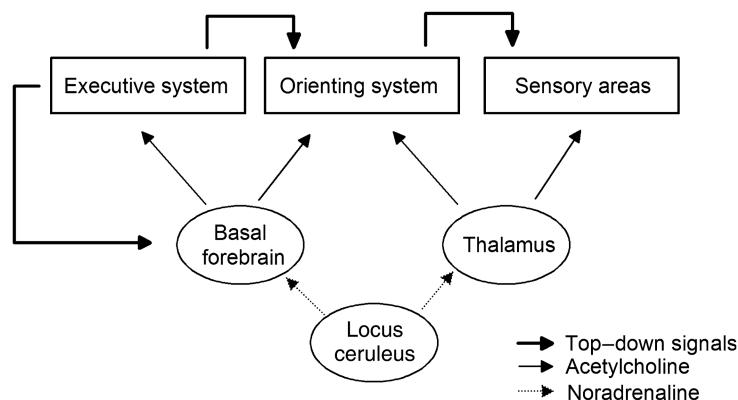

Figure 1 Schematic illustration of the major components of the neuronal network mediating sustained attention and its relation with executive and orienting networks.

Orienting attention to a stimulus enhances behavioral responses reducing RTs and error rates, as compared to nonattended features. This improved performance might be achieved by a relative increase in neural activity in a given sensory system. Accordingly, ‘bias competition’ models of attention suggest that the neural systems involved in cognitive control provide top-down signals to the different brain systems responsible for object’s representation. These signals will enhance attended perceptual objects or features and will increase the contrast with nonattended ones. Orienting and selective attention studies focus on the neural consequences of these top-down signals over the neural representations of the target attended features. These consequences may involve enhancement or reduction of the brain activation elicited by attended events. For example, orienting to a particular type of visual stimulus or to a particular aspect of the stimulus (e.g., its color) increases activity in the region where the specific task-relevant information is represented (e.g., specific color areas of the visual cortex). In this way, attention can modulate sensory processing in early stages of the visual processing stream.

Most research in orienting has been done in the context of visuospatial tasks. However, neural activity increases in response to attentional mechanisms have also been shown in the motor domain (i.e., preparatory orienting of attention toward a particular motor intention) and in the domain of working memory or long-term memory (i.e., the orienting of attention to a given number of a sequence that had to be maintained in memory).

Experimental Tasks

The oddball paradigm constitutes a classical example of selective attention tasks. Subjects are instructed to respond or to ignore stimulus presented sequentially in the center of a screen according to predetermined perceptual features (e.g., the color or shape of a stimulus). The main variables manipulated in this type of paradigm are: stimulus type and frequency. Target events are infrequent and must be covert or overtly responded by the subject. Standard events are more frequent and should be ignored. It is also possible to include other low-frequency distracting stimuli, such as deviants (similar to targets) and novelties (not previously presented or informed), allowing a variety of experimental manipulations. For instance, it is well established that RTs to targets usually increase if they occur after infrequent deviants and novel stimuli.

In a typical spatial orienting task, the experimenter cues the participant’s attention to a given location of the space before a target stimulus appears. This can be achieved by means of either visual or auditory cues. In valid trials, the cue and the target are placed in the same location; in invalid trials, cue and target positions do not

match. RTs in the valid condition are subtracted from those in the invalid condition to yield an efficiency score. Comparison between these two conditions and a no-cued condition usually shows a small benefit of orienting to a validly cued location, and a larger cost for invalidly cued locations.

Visual search tasks involve an active scan of a visual display for a particular object or feature (the target) among other objects or features (the distractors). In the visual search task, targets defined by a single feature (e.g., red dot among a number of blue dots) are easily detected in parallel, and detection time does not increase with the number of distractors in the display. In contrast, targets defined by the conjunction of two or more features (e.g., color and orientation of lines) are more difficult to detect and require serial search. For these targets, detection time increases as a function of the number of distractors in the display, suggesting that the integration of features into objects is an attention-dependent process.

Related Anatomy

Intracranial research, studies with patients with focal brain lesions, functional neuroimaging (fMRI) studies, and scalp-recorded event-related potentials (ERPs) converge suggesting that a widespread cortical network gives rise to the controlled detection of target events during the detection of targets from an oddball-like task. The temporoparietal junction, the medial temporal cortex, and the lateral prefrontal cortex (PFC) are the brain regions that have been consistently associated to target detection mechanisms.

The anatomical brain networks involved in orienting are similar for spatial orienting and visual search tasks. Posterior parietal and frontal areas are reliably involved in visual spatial orienting. This brain network is more pronounced in the right hemisphere, and its activation is independent of the direction of the attentional shifts, except at primary sensory areas. Activation in the parietal cortex is centered along the intraparietal sulcus and often extends into the superior parietal lobule. Frontal activations occur in the anterior cingulate, supplementary motor areas, and in the frontal eye fields. Other regions that frequently appear in studies of the spatial orienting network are the pulvinar, superior colliculus, temporo-parietal junction, and superior temporal lobe. These areas seem to be involved in specific subroutines in the orienting process. Further activations in the superior parietal lobule have been related to shifting attention between spatial locations as compared to maintaining attention on fixed positions. Lesions of the temporoparietal junction and superior temporal lobe disrupt the ability to disengage attention from a particular location. Finally, the frontal eye fields and superior colliculus might be

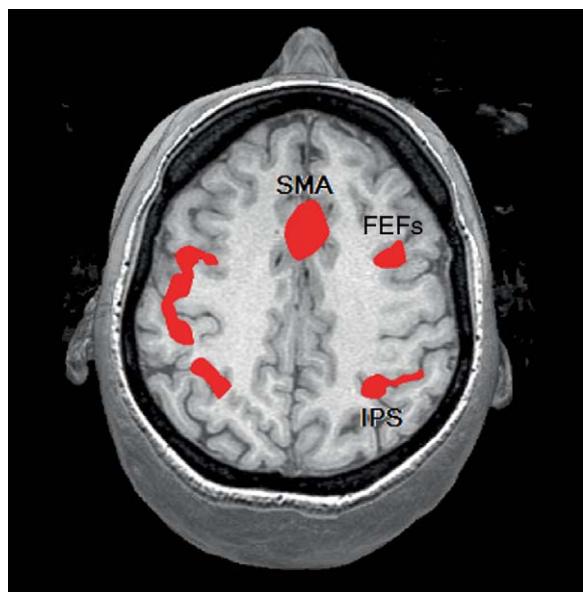

Figure 2 Brain areas involved in visual spatial orienting of attention: intraparietal sulcus (IPS), supplementary motor area (SMA), and frontal eye fields (FEFs).

primarily involved in the participation of overt eye movements in spatial attentional shifts (**Figure 2**).

Describing the brain network involved in nonspatial orienting of attention is currently an active research topic. Preliminary data on spatial and nonspatial orienting of attention seems to suggest both a partial overlap and a partial specialization of their neural systems. For instance, occipital, parietal, and frontal regions participate on spatial and temporal attention (i.e., attending to a given moment in time). However, while the right inferior parietal lobule seems specific for spatial orienting, the left inferior parietal lobule and the left inferior lateral premotor cortex seem specific for temporal orienting.

Clinical Impairment

Hemispatial neglect (or neglect) is one of the most prevalent and impairing deficits of the spatial orienting

component after brain damage. It is defined as a lack of attention for stimuli toward the side of space opposite to their unilateral lesion. Patients fail to report, respond, or orient to meaningful stimuli, suggesting that this failure cannot be attributed to primary motor (e.g., hemiplegia) or sensory dysfunction (e.g., hemianopia). Double dissociations can be found pointing to different subtypes of neglect. These are distinguished by input (attentional) or output (intentional) demands, the distribution (personal, spatial, and representational), the system affected (visual, tactile, or motor neglect), and the method used to elicit the signs (unilateral or bilateral stimuli). Patients may also exhibit viewer-centered or stimulus-centered neglect. Sensory extinctions are often considered mild forms of neglect, but are sometimes considered separate entities. According to the severity of symptoms, one cannot copy simple figures, does not eat the left side of the plate, dresses only the right half of one's body, reads only the right half of the pages or the words involving difficulties in texts comprehension, and, in most severe cases, may even deny that the left side of one's own body belongs to them (**Figure 3**). Neglect courses with lack of awareness of the deficit (i.e., anosognosia). This syndrome is observed primarily after unilateral lesions in the right parietal cortex, the supramarginal gyrus, and extends into subcortical areas. Lesions in the lateral and ventral portions of the frontal lobe and of the subcortical nuclei have also been implicated. The use of dopaminergic and noradrenergic drugs has been proposed to ameliorate neglect symptoms.

Executive Attention

Executive functions are required in situations that involve planning or decision making, error detection, novel or not well-learned responses, conditions judged to be difficult or dangerous, regulation of thoughts and feelings, and the overcoming of habitual actions. Executive attention involves effortful and controlled performance in tasks in which the response is not fully determined by the

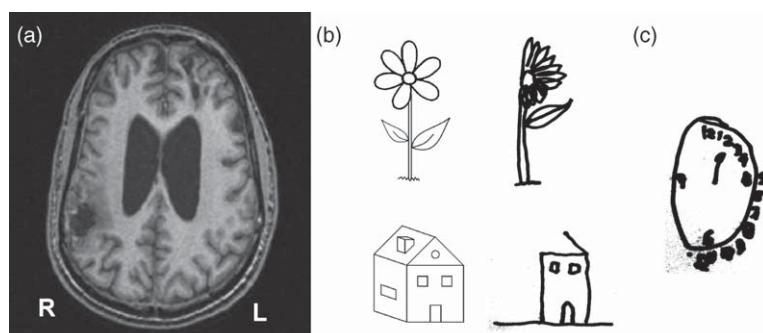

Figure 3 (a) Magnetic resonance image showing a right parietal lesion. (b) Examples of copied drawings by a patient suffering neglect. (c) Spontaneous clock drawing by the same patient.

stimulus. According to this broad definition, executive attention is not a single cognitive construct or neural mechanism but different subcomponent operations interacting within different brain regions.

A top-down mechanism for executive control must fulfill some requirements. First, it must provide a source of activity that can exert biasing signals to other structures. Second, the system must have access to a wide range of representations in other brain regions to be able to influence them. Third, it must be able to maintain information active in working memory against distractions until a goal is achieved, but should also be flexible enough to update its representations when needed. Finally, the allocation of control depends on a system able to detect conflict in processing. Conflict happens in response to the coactivation of competing representations or processing pathways.

Experimental Tasks

Several executive tasks have been used to isolate different components of executive attention and their neural basis.

Executive attention is commonly measured using tasks in which there is incompatibility between stimulus or response dimensions, as in the classic Stroop and flankers tasks. For instance, the purpose of the Stroop task is to assess one of the most fundamental aspects of cognitive control and goal-directed behavior: the ability to select a weaker task-relevant response, in the face of a competing and stronger but task-irrelevant one that the subject has to inhibit. This is generally achieved asking the subject to name the ink color of a word whose meaning is incongruent with it (e.g., to name the red ink color of the word blue).

Similarly, in the Eriksen flanker task, participants have to respond as fast and accurately as possible to a target arrow briefly presented in the center of the screen. When the target points to the right, the right button has to be pressed, and when the target points to the left, a response with the left button is required. The target arrow is accompanied by irrelevant flanker arrows displayed in the left and right sides of the target one (i.e., '> > > >' or '< < > < <' for congruent and incongruent trials, respectively). The most general finding using this task is that responses become slower under high conflict demands as compared to low- or nonconflict ones. This extra time is thought to reflect the time consumed by the operation of an executive attentional mechanism.

Research using task-switching experiments focuses on how the system is flexibly reconfigured moment by moment. A common denominator across different task-switching paradigms is that participants are asked to switch repeatedly among two or more simple tasks (e.g., classifying target stimulus according to their color or to their shape). The most general finding has been that

responses become slower and less accurate when switching than when repeating a task, a phenomenon referred to as 'behavioral switch cost.' This cost may reflect the time taken by control operations for task-set reconfiguration – a sort of mental gear changing – that must happen before the appropriate task-specific processes can proceed. Task-set reconfiguration can include shifting attention between stimulus attributes, abstract categories, goals (what to do), and condition–action rules (how to do it) into procedural working memory.

The Go/No-go task provides a simple paradigm to investigate response inhibition and response competition. In a typical Go/No-go experiment, subjects are instructed to respond by key press to the go stimulus (e.g., the letter A) and to withhold responses to No-go stimulus (e.g. the letter X). The number of correctly withheld responses to the No-go events, as well as the number of false-alarm responses and RTs, are frequently used as measures of inhibitory ability.

The novelty oddball task has been employed to study behavioral and neural responses to novel events. In this paradigm, an improbable series of unique and unexpected novel events are presented, in addition to targets and standards. As novel events are unexpected, this experimental procedure closely mimics the real-world situations of attentional shifting. Motor responses are slower and more error-prone after novels, a phenomenon that has been related to the dynamic shifting of attention from the processing of the ongoing task to the processing of the unexpected novel event.

Many of these tasks are used in the clinical context, with necessary adaptations to fit the needs of patients. Some of the most commonly used are the Stroop test, Paced Auditory Serial addition Test (PASAT), the Trail Making Test (TMT), or the Wisconsin Card Sorting Test (WCST).

Related Anatomy

Lesion and brain imaging studies using executive tasks usually describe a network that includes the anterior cingulate and supplementary motor area, the orbitofrontal cortex, the dorsolateral PFC, and portions of the basal ganglia and the thalamus (**Figure 4**). While there are evidences about functional specialization within these brain regions, several models of executive attention and prefrontal function suggest an interaction between them to achieve complex attentional functions.

The anterior cingulate cortex (ACC) is known to be an important node in the executive attention network. Different portions of this brain structure have consistently shown activation during error detection, divided attention, conflict monitoring, word generation, and task-switching performance. A fundamental executive ability related to the function of the ACC is dealing with conflict.

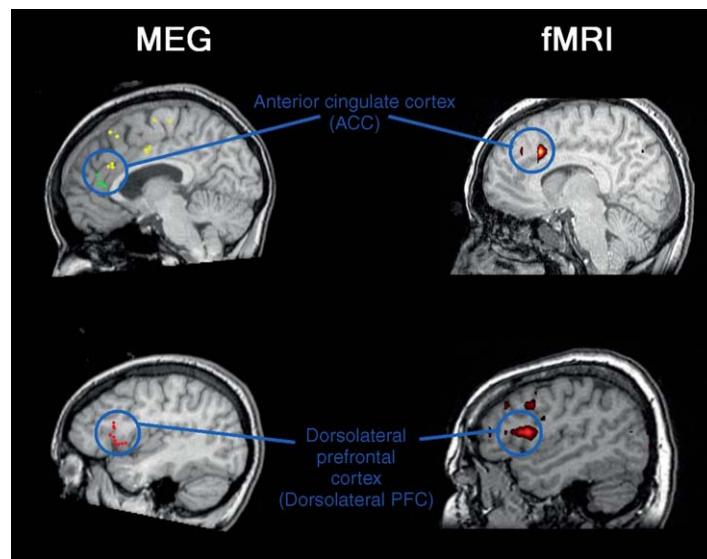

Figure 4 Brain areas activated by No-go stimulus in a Go/No-go task during magnetoencephalographic (MEG; left) and functional magnetic resonance imaging recordings (fMRI; right).

For some authors the ACC would be critical for monitoring and detecting conflict between processing pathways. According to this extended view, conflict signals would engage other prefrontal regions for conflict resolution. By contrast, other authors suggest that the ACC can subserve both conflict detection and conflict resolution directly. Recent findings have started to support the idea that different cognitive functions are mediated by different portions of the ACC.

The ACC seems insufficient by itself to achieve attentional control. Other prefrontal areas in the lateral PFC are central in creating and maintaining attentional sets. The proposal of dorsolateral PFC playing a determinant role in maintaining attentional sets is largely coherent with the well established assumption that this brain region plays a key role in the manipulation and maintaining of the contents of working memory. However, brain areas involved in working memory seem to depend on the type of information being processed. For example, functional imaging studies on humans show that verbal working memory tasks activate the ventrolateral PFC and language areas in the left temporal and inferior parietal cortex. In contrast, visuospatial working memory tasks activate the dorsolateral PFC, inferior parietal cortex on the right side, and high-order visual areas in the occipital cortex.

The inferior frontal gyrus (IFG) has been also related to the executive network by virtue of its connections with temporoparietal brain regions. This ventral PFC area seems to be active whenever low-frequency, unexpected, or previously learned relevant cues break down current processing. This is consistent with the proposed role of IFG in breaking down an outdated attended set in response to new or behaviorally relevant sensory events.

Clinical Impairment

Disturbance of different components of the executive system could lead to different impairments.

One main deficit of executive control of attention is characterized by the inability to accurately select appropriate stimuli or goals in each situation. The patient is unable to overcome salient stimuli or irrelevant responses for the present task. The most severe manifestation of this deficit is the so-called ‘utilization behavior’ where behavior is extremely guided by external stimulation.

Another deficit is the presence of perseverative responses or the difficulty to abandon a task or a *modus operandi* that is no longer adequate and does not lead to achieve goals. These patients show difficulties in adjusting their behavior to the changing requirements of the environment. At the same time, this can lead to troubleshooting difficulties, due to a rigid approach, stereotypical, and recurrent behavior. This is a complex deficit that has been related to not only cortical (e.g., prefrontal lobes and hippocampus) but also subcortical dysfunctions (e.g., caudate nucleus).

Dopamine depletions in frontostriatal circuits are thought to generate many executive deficits. For instance, it has been demonstrated that Parkinson’s disease patients usually exhibit deficits in executive mechanisms such as novelty detection, task switching, inhibiting No-go responses, and working memory. In addition, it has been shown that treatment with dopaminergic agonists improves attentional performance in Parkinson’s disease and attention-deficit hyperactivity disorder (ADHD). This constitutes evidence about the relevance of dopaminergic modulation in attentional performance.

Speed of Information Processing

Speed of information processing or SIP is not an attentional function *per se*, but a result of how information is processed, based on the properties of the system where cognition is implemented. However, an accurate attentional functioning frequently depends on how fast these mechanisms are implemented. For instance, when a potentially dangerous stimulus is to be detected, an efficient attentional system must be not only accurate, but also fast, in order to produce an adaptive response.

In addition, the relevance of studying the relationship between attentional processes and SIP became highlighted by the use of time measures in several attentional tasks. Both in clinical and experimental contexts it is often difficult to establish the extent to which a given time measure of attentional performance is mediated by proper attentional or SIP factors. However, this dissociation is very relevant to theoretical models and clinical practice.

The term SIP has been commonly used in cognitive neuroscience and while there is little debate about its meaning, it has not been clearly defined. SIP reflects the amount of information that can be processed per unit of time, or even the speed at which a variety of processes can be carried out. It can also be defined as the result of the time taken to perceive and process information, as well as the time to prepare and execute a response.

Experimental Tasks

The assessment of SIP can be achieved by different methods according to the selected level of analysis. These levels could involve measuring physiological signals of peripheral nerve conduction, the study of event-related brain potentials, timed neuropsychological tests to assess performance at a behavioral level, and specific neuroimaging techniques to study the underlying neuroanatomy.

The study of nerve conduction velocity was initiated early in neuroscience. More recently, electromyography and single-cell recordings from peripheral nerves have established a speed conduction that varies in a range between 0.5 and 90 m s^{-1} , as a function of certain physical and chemical conditions of the axon. In addition, ERPs have been used to measure the time course of sensory, motor, and cognitive brain responses, similar to the latency or the amplitude of particular components of the ERPs.

At the behavioral level, the introduction of mental chronometry allowed to measure cognitive speed using the subtraction method. This method implies the subtraction of RTs obtained in a simple task from those obtained in a similar task with an added cognitive element. Thus,

time differences between conditions reflect the additional resources consumed by the added cognitive element.

Standardized neuropsychological tests provide measures of mental slowness at a behavioral level, of which SDMT and symbol search (both configuring the speed of processing index in Wechsler Adult Intelligence Scale-III) are good examples. Whereas almost any test would serve as long as the execution time is monitored, the use of computerized methods would enhance the accuracy of time measures.

Lastly, recent advances in neuroimaging have provided new techniques to examine the neural correlates of SIP. High-spatial-resolution techniques, such as diffusion tensor imaging (DTI), are allowing for the first time to study *in vivo* the integrity of axons and validate some of the scenarios under discussion.

Related Anatomy

SIP has been related to white matter more than gray matter structures. Neuroimaging and behavioral studies have suggested a relationship between SIP and structural aspects of neural wiring, such as nerve diameter, integrity of myelin sheathing, the number of ion channels, and the efficiency of synaptic neurotransmission (**Figure 5**). Differences in speed of processing are thought to depend critically on nerve conduction velocity determined by axonal diameter and degree of myelination. As volume of brain white matter increases during development, so does the SIP.

Although white matter seems to be a key structural factor determining SIP, different cortical regions may be related to variations in speed of response. For instance, RTs usually increase after lesions in supplementary motor areas necessary to organize complex responses and activate unpracticed motor patterns. Longer RTs are also found after right frontal lobe lesions related to deficits in monitoring abilities necessary to prepare the processing of forthcoming events.

Clinical Impairment

The term ‘bradyphrenia’ defines a deficit in SIP. Particularly, patients cannot process information as quickly as healthy individuals. It is thought to be one of the most pronounced, striking, pervasive, and reliable phenomena of brain damage. Contrary to the view that suggests that bradyphrenia is a deficit of a specific information processing stage, it seems to be a general and global phenomenon.

Mental slowness seems to be a primary cognitive deficit in aging, multiple sclerosis, Parkinson’s disease, and traumatic brain-injury patients, but it is also evident in other central nervous system diseases, such as stroke.

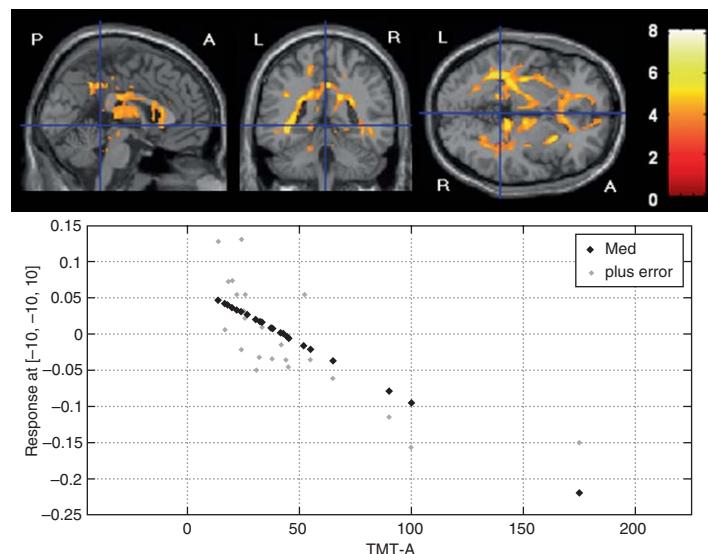

Figure 5 Correlation between trail making test part A completion time in seconds (TMT-A) and mean fractional anisotropy (FA) for main white matter structures. Line of best fit is presented for significant correlations.

Deficits in SIP impact various other cognitive abilities. As stated before, cognitive slowness may cause other attention deficits in a variety of tasks. Thus, the dissociation between attention and SIP is critical in order to detect the underlying deficit and to establish an adequate rehabilitation program for each patient.

Conclusion

Attention has been considered a complex and nonunitary process. Behavioral, functional neuroimaging, electrical scalp recording, as well as developmental and genetic studies in animals and humans provide converging evidences for the existence of at least three independent attentional brain networks. As depicted in Figure 1, alerting would relate to the activity of noradrenergic connections from the locus ceruleus to different subcortical areas, constituting one of the more basic attentional mechanisms. Through these projections, the alerting system might potentiate (generate and maintain an activation state) the efficiency of the other attentional networks. On the other hand, the orienting network relates to the ability to select (amplifying and inhibiting) specific information from both external (e.g., the environment) and internal sources (e.g., memories or thoughts). The efficiency of this network seems to rely on the integrity of a dorsal parietal–frontal system responsible of the neural representation of the attended features (e.g., spatial locations, perceptual attributes). Executive attention relates to a variety of subcomponent operations responsible for the top-down (intentional) guidance of behavior. Neural structures such as ACC, dorsolateral

PFC, or the inferior frontal cortex would interact to each other to modulate the neural activation of subordinate brain systems. SIP is not an attentional mechanism *per se*. It is a property of the system where attention is implemented and could modulate the efficiency of the attentional networks. White matter integrity seems to be a key factor for an adequate SIP. In spite of the relative independence among these networks, their interaction is continuously required for an adaptive behavior. This complex interaction can be hindered by different pathological states such as acquired brain injury, degenerative diseases, and developmental changes (in the child and in the aging process). As a result of alterations in these components, dissociations and different profiles of impairment can be observed in the clinical context.

Glossary

Apparent motion – The perceptual experience of continuous movement generated by the sequential presentation of two still images flashed in positions which are spatially offset in the visual field. This phenomenon was first studied by Max Wertheimer, the founder of the Gestalt School of Psychology, in his 1912 work: *Experimental Studies on the Seeing of Motion*.

Hallucinations and entoptic vision – Hallucination refers to a false sensory perception in the absence of an actual external stimulus. Various mental episodes can induce the vivid report by the conscious subject of activity patterns witnessing the inner architecture of specific regions of the brain, such as visual cortex. For instance, inner visions can be experienced following retrobulbar blockade of the optic nerves, during acute episodes of aura migraines (fortifications) or after taking hallucinogens such as cannabis or mescaline. Clinical analysis of these visual disturbances describes only four constant geometrical patterns, consistently reported by human subjects: (1) tunnels and funnels, (2) spirals, (3) lattices (honeycombs and triangles), and (4) cobwebs. As proposed by Christopher W. Tyler, these entoptic (vision-from-inside) geometric patterns must be regarded as indicators of some further selective process in the thalamo-cortical pathway, “a kind of functional Golgi stain by which certain neural activities are elevated into consciousness while the majority of possible discharges remain ignored.”

Mach bands – Mach bands are an optical illusion, named after the physicist and philosopher Ernst Mach. The stimulus is composed of two sectors of uniform luminance, one high (light) and one low (dark), separated by an intermediate zone with a monotonic gradient of luminance which decreases linearly when progressing from the light to the dark sector borders. Humans perceive two narrow bands of different brightness that are not present in the physical stimulus. They are situated on both sides of the gradient zone, and are perceived as respectively brighter than the light sector and darker than the lower luminance region.

Minimal discharge field – The minimal discharge field is the part of the receptive field within which the presence of an impulse-like stimulus increases the probability of firing or the number of spikes emitted by a given neuron. This definition excludes the possible recruitment of summation and interaction processes occurring across

stimuli in space and time. The surrounding zone, from which only subthreshold activity is generated (i.e., modulation of the membrane potential or changes in membrane conductance without spike activity), defines the ‘silent periphery’ or ‘surround’ of the receptive field.

Receptive field – The receptive field of a neuron is defined by the region of the sensory space within which the presence of a stimulus significantly modifies its activity. In the visual system, the receptive field is the region of the retina where a local change of luminance (relative to the background) modulates (enhances or suppresses) the firing rate or the probability of discharge of the recorded neuron. In the auditory system, receptive fields can be locations or volumes in space, and are also defined as compact regions in the temporal frequency domain. In the somatosensory system, receptive fields are regions of the body surface or internal organs. A special case of tactile receptive fields are those corresponding to the whiskers, specialized hairs which form a discretized mosaic of haptic sensors located on each side of the snout in mammals.

Sensory coding – Information in the brain, either evoked by sensory input or autonomously recalled in the form of memories, is represented by changes in neural activity, both excitatory and suppressive (although this latter case is less studied). These changes are expressed in the modulation of the firing rate of single neurons (the neuronal doctrine), which, in certain cases, becomes tuned to specific features of the sensory environment (e.g., feature detectors) or in the spatiotemporal pattern of spiking of activity distributed across neuronal populations (assembly coding). Sparse coding refers to the special case where stimulus information is encoded by the selective recruitment of a few cells active at irregular points in time. Information theory shows that sparse coding results in an independent component analysis of the sensory scene: it reduces redundancy and maximizes mutual information between the few active units.

Introduction

When facing a natural visual scene, human subjects have an immediate conscious perception of the elementary features that compose it (segmentation), as well as of the

higher-order global objects that emerge from their associations (binding), although not necessarily in this order. Contours, colors, textured surfaces, shapes, and three-dimensional objects pop out unambiguously, in a fraction of a second to seconds, according to the background context. For centuries, multiple theories have been proposed to explain the remarkable perceptual capacities of animals and humans in figure-ground segregation and identification of their immediate environment. The structuralist theory of Edward Titchener, dating back to the very beginning of the twentieth century, asserted that sensations were the basic elements of perception. In this context, sensations were considered as the simplest elementary building blocks open to introspection, on the basis of which complex perceptions could be synthesized. In this article, the concept of sensation has a different meaning than that used by the structuralists. Here we take into account the fact that the central nervous system is immersed in its environment with which it communicates through sensory channels and modalities and on which it exerts actions through specialized effectors. Closer to the enaction theory and to the spike-based computational approaches, we consider sensations as the result of the initial processing step corresponding to the transduction of the sensory input detected by the peripheral sensory organs (eye, ear, skin, etc.) into a spatiotemporally formatted spike-based input stream.

Through the example of a few sensory illusions, this article deals with the long-standing question of the link between the stimulus quantified in physical terms and the integrative process realized by the brain before any action in return takes place. Two sequential steps are classically

distinguished during low-level perception, the sequence of physiological events in central neural structures, which gives rise to the emergence of a conscious account of the percept at the psychological/behavioral level. However, animals and humans cannot be reduced to the status of passive receivers facing an external physical reality; thus, other components have to be included, such as motivation, attention, expectation, action, decision, and memory. These internally generated modulations activate top-down processes which construct unconscious hypotheses about the outer world.

We have restrained the scope of this article to neuronal correlates of perception that have been localized in the primary sensory cortices of the mammalian brain: these central networks appear as a major crossroads where feed-forward, and recurrent and feedback processing, merge to form a contextualized perception of peripersonal space. The case studies that we have chosen to illustrate offer examples of situated perception that can be related in neural terms to the Gestalt theory. They support two views which are not mutually exclusive: when driven by external sensations and bottom-up activation, the cortical neuronal machinery generates an automatic interpretation of our environment through built-in compositionality mechanisms; when driven by top-down feedback, the same network computes unconscious inferences from sensory events based on predictive knowledge derived from the past. Consequently, the primal sketch of our sensory periphery is continuously updated and modulated by the feedback or proactive context of our thoughts, intentions, and actions (**Figure 1c**).

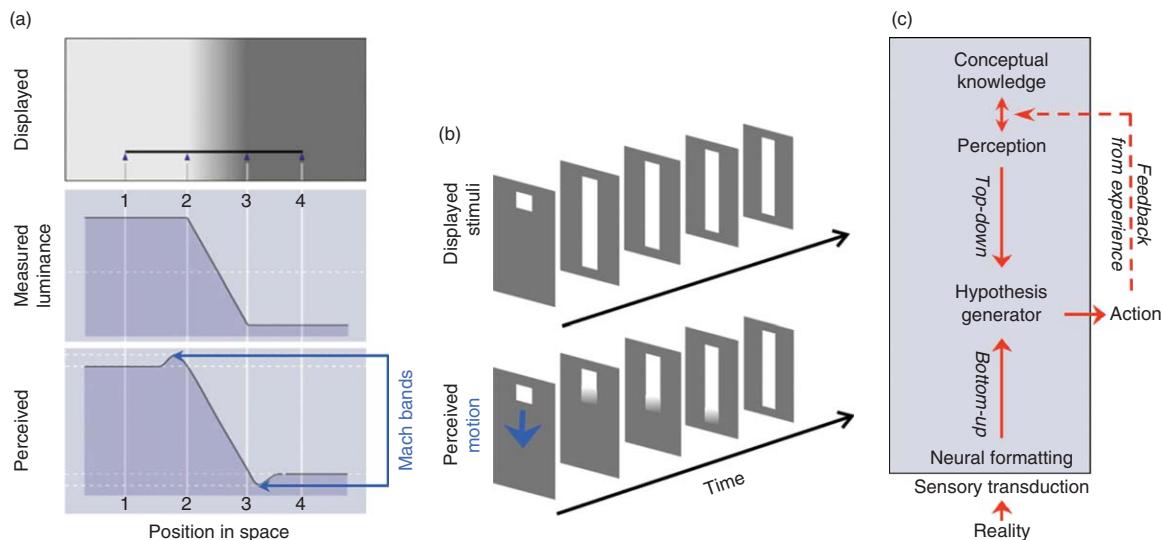

Figure 1 Sensation, perception and illusion. (a) Mach bands: from top to bottom, displayed luminance profile, measured luminance gradient in positions 1–4, perceived luminance profile. The Mach illusion (blue arrows) corresponds to the perceived lighter (position 2) and darker (position 3) bands. (b) Line-motion illusion: top, spatio-temporal sequence of displayed stimuli (square followed by a bar); bottom, perceived downwards motion (blue arrow). (c) A conceptual framework (inspired from Richard Gregory).

For more than half a century, beginning with the pioneering research on the visual system led by David Hubel and Torsten Wiesel, hundreds of laboratories throughout the world have tried to identify the neuronal mechanisms that would explain the remarkable sensory recognition performances of the mammalian brain, never equalled by any artificial device. This research initially targeted cortical primary visual areas, since they form the earliest stage in the functional hierarchy of the visual system where the emergence of high-order feature encoding (orientation, curvature, etc.) and elementary mechanisms for computing geometrical invariants were demonstrated. However, what applies to vision generally holds for the other senses too. All sensory cortical areas are considered as the seat of memory of our early sensory experience and their functional specialization has been shown to mirror the multimodal perceptual development of the organism, at least during critical periods of postnatal life.

In the case of the visual system, the bi-dimensional distribution of luminance and contrast in the retina is captured by specialized transducer cells, the photoreceptors, where light energy is translated into neural electrical activity. This electrical message is then transferred from retina to subcortical centers, including the thalamus. The ascending pathway associated with conscious perception is the retino-thalamo-cortical pathway and most of the processing in terms of segmentation and binding is thought to occur at the cortical stage. Three remarkable features of the early-perceptual pathway are: (1) the preservation of a topographic representation of space at all intermediate stages of the hierarchy, which provides some form of isomorphism between the sensory image and the feed-forward imprint formed at the next step of integration; (2) the existence of multiple loops (feedback from cortex to thalamus, feedback from higher cortical areas to primary sensory cortices) that coexist with the powerful feed-forward transmission; and (3) an overwhelming dominance (in terms of relative number of synapses per neurons) of connections (recurrent and lateral) intrinsic to each of the cortical areas, relative to the feed-forward contingent. Thus, as soon as a few tens of milliseconds after a stimulus impinges on the retina (bottom-up processing), the change in neuronal activity, departing from the level of irregular and sparse ongoing activity level, propagates through the nested thalamo-cortical architecture.

These complex activation dynamics are observed not only for exteroceptive sensations arising from the periphery, but also during interoceptive reactivation: for example, the recall of a visual memory (top-down processing) or an abnormal imbalance between cortical excitation and inhibition. In this latter case, remarkable illusions, which do not involve attention-related processes, are revealed during migraines and can be

amplified by hallucinogenic drugs. It is thought that the paroxysmal activity state of the cortex shuts off the processing of retinal activity and is interpreted by the human observer as an illusory constellation of geometrical patterns. The topological structure of these highly specific planforms is closely related to the functional architecture of the cortical analyser. Thus, central neural structures, such as the visual cortex, do more than mirroring visual experience. Entoptic hallucinations provide a vivid proof to the observer/patient that his own cortical activity generates a geometrical construct in the absence of sensory input. This construct is interpreted by the mind as a projection of an inner state expressed in retinal-encoded coordinates.

Feed-Forward Imprint of the Sensory Periphery

The predominant view of sensory processing posits that the filtering properties of the neurons that operate at the different successive steps of the functional integration ladder, from periphery to central cortical areas, become progressively more and more elaborate. This dogma is best illustrated by the hierarchical simple-complex-hypercomplex model of David Hubel and Torsten Wiesel and the grandmother concept of Horace Barlow. The critical attributes of a visual scene that trigger electrical activity of neurons in retina, thalamus, primary cortex, and higher-order cortices indeed show increasing complexity.

While retinal ganglion cells are specialized contrast detectors with a spatially isotropic, opponent (ON vs. OFF) concentric organization, simple neurons in the primary cortex show elongated receptive fields with spatially segregated ON and OFF subzones, indicative of the breakdown of circular symmetry. Consequently, their firing frequency is tuned for specific features, such as orientation and movement direction. Higher-order visual cortical areas of the dorsal pathway, such as the medio-temporal area, extract information about the motion flow by integrating information over larger areas of the visual space. Even more illustrative of this complexification is the finding of neurons in the inferior-temporal lobe of the ventral pathway that fire action potentials selectively to images of faces, animals, or other complex objects. The role of sensory experience in shaping perception is such that there exist neurons in the human medial temporal lobe that are activated selectively when reacting to the picture of famous personalities or even to the sight of their written names. This recognition performance is learned from the social environment of the human observer through different communication channels (radio, TV, movies, speech, etc.) and is dependent on various reward processes. It suggests an explicit

code, at least in superior areas of the ventral visual pathway, which might be linked to an abstract representation of iconic memories.

The ultrafast dynamics observed during pop-out recognition raises a paradoxical challenge in terms of correlation between neural structure and perceptual function. At the behavioral level in humans and monkeys, during a recognition task requiring the discrimination of animal versus nonanimals, the response onset delay measured by a forced choice saccadic paradigm can be as much as 100 ms (although it is not proven that the motor decision is based on the conscious identification and naming of the animal targeted by the saccade). Taking into account the number of integrative steps through the retino-thalamo-cortical pathway needed to reach prefrontal areas, it has been argued that most of the information processing relies on the first few evoked spikes propagating through a specialized fast pathway. Nonetheless, as we shall see in the next section, it is hard to reconcile an exclusively feed-forward processing by the thalamo-cortical pathway with our knowledge of the anatomical connectivity of sensory cortex and, in particular, the very great number of feedback synaptic contacts.

Beyond the Receptive Field of Sensory Neurons: Context Matters

In the primary visual cortex, the integrative properties of visual neurons result from the relative contributions of three sources of afferent connectivity: (1) feed-forward excitation from the lateral geniculate nucleus, the principal thalamic relay between the retina and the visual cortex; (2) feed-forward and local feedback inhibition from intracortical interneurons; and (3) recurrent excitation from other cortical neurons, both within (lateral or horizontal) and outside primary visual cortex, which provides the largest number of synaptic contacts. Geniculate feed-forward connections provide visuotopic information to the primary visual cortex that is spatially coextensive with the cortical neuron's minimal discharge field. On average, the extent of this receptive area is relatively small for neurons in the primary visual cortex, spanning only 1–4° of visual angle in the cat and 10 times less in the monkey for central and parafoveal vision. One might then suppose that primary visual cortex neurons only integrate luminance information locally. However, it has been well documented that visual cortical neurons exhibit modulation of responses from far beyond the spatial boundaries of the minimal discharge field. Quantitative analyses of anatomical data in the primary visual cortex of the cat show that axons from the principal neurons of the lateral geniculate nucleus account for no more than 5% of the total

excitatory synapses onto pyramidal neurons of layer IV, the thalamo-recipient layer of the cortex. Consequently, the large majority of excitatory synapses originate from other cortical neurons within the visual cortex and from other cortical areas that project back to the primary visual cortex. It seems unlikely then that the geniculate nucleus alone could fully control the activity of a given cortical neuron, and this seems particularly true for cortical neurons in supra- and infra-granular layers (above and below layer IV). Thus, visual cortex neurons are connected to a widespread network of horizontal and feedback connections that give access to spatially and temporally distributed information over large parts of the visual field.

There is accumulating evidence concerning the functional consequences of this distributed and recurrent connectivity scheme. For example, stimuli outside the minimal discharge field can have potent and complex modulatory influences when presented simultaneously with stimuli inside the receptive field. Neuronal responses in the primary visual areas of the alert macaque monkey to a single oriented line presented in the center of the neuron's classical receptive field are strongly modulated by the presence of textured patterns of oriented lines presented in the surround of the receptive field. This has been reported most often when the orientation of the surround elements matches that of the center element but has also been observed, although more rarely, when it does not. The first mechanism is a form of response suppression resulting from the collinearity of the stimuli, whereas the latter one appears to be triggered by the orientation contrast between center and surround.

These observations, documented at the cellular level, have their counterparts in psychophysical studies where the perception of an object's attributes depends on the spatial context in which a stimulus is presented. For instance, the finding that primary cortical neurons respond to orientation contrast supports a possible role of primary visual cortex in the mediation of perceptual segregation of texture borders and in perceptual pop-out. Low-level mechanisms can also be implicated in the perception of the apparent lightness of a surface, which is known to be strongly modulated by the spatial context in which it is embedded.

Sensory Illusions as the Perceptual Expression of Stimulus Inference by the Brain

Tout ce que j'ai reçu jusqu'à présent pour le plus vrai et assuré, je l'ai appris des sens, ou par les sens : or j'ai quelques fois éprouvé que ces sens étaient trompeurs, et il est de la prudence de ne se fier jamais entièrement à ceux qui nous ont une fois trompés.

Everything that I have learned so far, to be the most true and reliable, I have learned through my senses: and yet, I have sometimes felt that these senses were misleading, and that it is prudent to never rely entirely on that which has once mislead us. (*Méditations Métaphysiques*, Première méditation, R. Descartes, 1647.)

Hermann von Helmholtz described visual perceptions as unconscious inferences from sensory data and knowledge derived from the past. According to this view, perceptions are regarded as predictive hypotheses made by our brain, which are projected by the mind into the external physical space and accepted as our most immediate reality. The reflexive neural processes to which they correspond find remarkable counterparts in the low-level center-surround interactions that have been described by electrophysiologists in the primary visual cortex, as well as in the contextual perceptual effects described by experimental psychologists. Some of the best-known illusions, such as Mach bands (Figure 1a) and apparent motion, open explanatory windows on the inner functioning of the brain, since they result in an apparent contradiction between the physical nature of the stimulus present at the periphery and that reported consciously by the subject (here, luminance bands and continuous motion). The Mach band was a key to the elucidation of center-surround antagonism in retinal and higher-order sensory receptive fields. Its signature, in terms of neural correlates, is that of a Mexican hat where focal excitation is surrounded (or opposed) by widespread inhibition. Another example is apparent motion, where the percept of continuous motion emerges from sequential static activations. Max Wertheimer, who was one of the founders of the Gestalt school of psychology, proposed a seminal theory of perceptual grouping in his *Experimental Studies on the Seeing of Motion* (1912). This theory predicts the emergence of coherent percepts of global shape and motion from the temporal staggering of static presentations of elementary spatial features. It assumes the existence of mental processes which favor associations of visual elements in space (according to spatial proximity and similarity in contrast polarity) as well as in time (continuity and common fate). Originally called the beta phenomenon by Wertheimer, the apparent-motion illusion is a powerful dynamic effect induced when a visual target is flashed successively, immobile, in different positions in the visual field ordered along a virtual trajectory. Although, at each moment in time, the image that is presented to the observer is stationary, the subject reports the perception of the continuous motion of the object along the trajectory defined by the association path, which links the various positions explored in succession. The strength of the percept depends on the complexity of the test stimulus, including its shape and texture, on the duration of the static presentations, on the inter-stimulus

interval, and on the spatial offset between the explored positions.

A series of experimental observations makes it likely that these psychophysical effects are the result of activity waves propagating laterally across the layer plane (which is the projection plane of the periphery) within the primary visual cortex. At the single-unit level, the principal orientation axes of the receptive field of neurons that communicate through long-range horizontal connections are often co-aligned. Horizontal cortical connections are thought to facilitate the response of cells with collinear orientation preference and to reduce their response otherwise. At a more integrated level, recent local field potential studies show the spontaneous propagation of horizontal travelling waves that most often link cortical loci sharing the same orientation preference. Similarly, at the psychophysical level, numerous studies have described facilitatory or suppressive changes in the ability to detect a central target when adding a contextual periphery. They showed, in particular, that low-contrast visual contour elements are easier to detect when presented in the context of collinear flankers, confirming that lateral connectivity in visual cortex may participate in establishing such facilitation. Interestingly, the subthreshold synaptic integration field, recorded intracellularly at the cortical level, is within the same range as the perceptual association field reported by psychophysicists, and thus it is most likely that it provides a cellular substrate for these perceptual effects.

Case Studies for Visual and Haptic Perception: Apparent Motion and Funnelling

While the spatial contextual effect described above can be easily interpreted in the framework of the association field, the temporal determinants of this collinear facilitation have been less well explored. The perception of speed can be differentially modulated during apparent motion sequences of oriented stimuli by adjusting the collinearity and alignment of the local orientation with respect to the motion axis. When observers are asked to discriminate during a forced choice task between the relative speeds of two apparent-motion sequences composed of three identical Gabor patches (an oriented sinusoidal luminance grating whose modulation is weighted by a bi-dimensional Gaussian function) with positional offset, whose orientation is either collinear to the apparent motion axis or cross-oriented to it, a speed-up illusion is observed. For the same physical speed of the two apparent-motion sequences, a Gabor patch moving along its orientation axis appears much faster than a Gabor patch oriented at an angle away from the motion axis.

This psychophysical effect may be quantified by the ratio between the speed of the test sequence and that of the reference sequence for which the subject reports equality in perceived speed. The perceptual bias is as strong as threefold in humans, and its strength explains why observers find in the great majority of the cases that collinear sequences are faster than noncollinear ones even if the two composite stimuli have the same physical speed. The hypothesis that the speeding up is induced when the horizontal wave travels ahead or in phase with the feed-forward inputs from the thalamic stage is supported both by computational models and by intracellular observations made in cat primary visual cortex for the same stimulus configurations. These different data strongly support the hypothesis of a dynamic neural association field: oriented contours should propagate facilitation across space (collinearity) as well as across time (common fate). In this latter case, synergy should be observed when the feed-forward flow travels in phase with the lateral intracortical activity wave evoked by the apparent motion sequence.

The line-motion effect is another illusion from the same family, induced by asynchronous static presentations (**Figure 1b**). In this latter case, the cue feature is a uniform luminance square, followed by a bar of the same luminance, one end of which encroaches on the previously flashed square. For adequate inter-stimulus intervals and presentation durations, the human subject reports a continuous movement of one border, perceived as the smooth morphing of the square into the elongated bar. The line-motion illusion has been studied using voltage-sensitive-dye imaging of activity propagation, in a secondary visual cortical area of the anesthetized cat. The aim was to obtain a direct visualization of the spatial spread of the facilitation induced by the cue stimulus. For this purpose, the responses to a flashed small square and a long bar alone were compared with a stimulus configuration producing the line-motion effect, that is, a square briefly preceding the bar. In the associative condition, a spreading, low-amplitude activation wave was induced, extending far beyond the retinotopic representation of the initial cue. The observed propagation speed was consistent with the conduction velocity of horizontal axons reported in electrophysiological experiments or inferred with voltage-sensitive-dye techniques. Furthermore, this work demonstrated that the cue square, even though physically immobile, induced a propagating wave of cortical depolarization, indistinguishable from the spatiotemporal pattern produced by continuous motion of the same square. Although it is likely that similar low-level mechanisms may underlie both the speeding-up and line motion effects, it should be noted that the temporal parameters that maximize the line-motion effect (a delay of 100–200 ms between the presentation of the inducing spot and the flashed bar) are longer than the

fast and brief (<100 ms) motion sequences used for the speeding-up effect.

Context-dependent modulation of cortical activity has been observed in other sensory modalities as well. These modulations and the presence of neuronal signals correlated with the direction of apparent tactile motion have been explored in the whisker-to-barrel cortex system of the rat. Rodents localize objects and discriminate textures by scanning their surface with their facial vibrissae. The exploratory movements of the vibrissae generate spatio-temporally complex sequences of tactile contacts. The sensory whiskers in the mystacial pad of the rat are mapped onto the thalamo-recipient layer of primary somatosensory cortex as distinct units, named barrels. The detailed description of the organization of the cortical barrel field into discrete architectonic modules has triggered a large number of functional studies in recent decades. In particular, numerous anatomical and extracellular electrophysiological studies have demonstrated a one-to-one correspondence between a mystacial vibrissa and its matching cortical barrel, leading to the concept of a structural as well as functional imprint of the sensory periphery in the cortical representation. Recent observations, using whole cell and intracellular recordings of synaptic responses evoked by individual whisker deflections, have challenged the original notion of a segregated mosaic cortex in the primary somatosensory cortex of adult rats. The cortical spread function, which measures the pattern of divergence of information, is in fact extensive, encompassing several barrels. The spatial extent of subthreshold receptive fields in the vibrissal cortical representation is similar to that we have previously described in the visual cortex: it suggests that the rat barrel cortex has a wide array of cortico-cortical horizontal connections that, together with the multi-whisker thalamic input, provide a potential substrate for complex nonlinear temporal and spatial interactions. Consequently, context-dependent modulations of responses through the cortico-cortical network might have profound effects on neuronal receptive fields.

Recently, the dynamics of spatiotemporal integration in the somatosensory cortex (S1) were reevaluated by using experimental stimuli similar to those encountered naturally during tactile (haptic) exploration. This study took advantage of a newly developed stimulation device that, in the rat, allows the controlled application of large-scale spatiotemporal patterns of stimulation, by the parallel and independent activation of the almost-complete mystacial pad (stimulation matrix of 25 macrovibrissae). It compared two modes of stimulation: in the first, the vibrissal system was probed with random sequences of independent single-whisker deflections in one direction in the second, the stimulation of several whiskers was coordinated so as to generate an apparent global motion in a given direction. The electrophysiological recordings in S1 cortical neurons showed that the

second stimulus (global motion) drove the neurons with a direction preference that could not be predicted from the responses generated from single whiskers when moved independently. These results suggest that individual neurons have the capacity to integrate and extract collective information from the entire whisker pad. As in the visual cortex, we conclude that tactile perception emerges from collective invariants or global properties of the full field input as well as from local independent features.

Another famous illusion, still related to lateral intracortical interaction, but expressed with a sensory modality other than vision, is the tactile funnelling effect. This is characterized by the percept of spatial mislocalization and increased tactile intensity at a central skin location that is not directly stimulated. When stimulating the skin at three co-aligned points, inputs at lateral sites are funnelled centrally so that the perceived intensity at the central site is greater than that perceived when stimulated alone. With two-point stimulation, a funnelled sensation is produced and extends to an unstimulated part of the skin. This illusion has been reported on the forearm, palm, and fingers. A recent functional correlate has been reported in area 3b of the primary somatosensory cortex (S1) of monkeys, where optical imaging showed that simultaneous stimulation of two fingertips produces a single focal cortical activation between the single fingertip activation regions. Thus, in contrast to the traditional view of an isomorphism between the body and its cortical imprint in S1, the topography of the functionally evoked map reflects the perceived rather than the physical location of the peripheral stimulation. Such contextual influences from beyond the classical receptive field are likely to be determined by mechanisms dependent on intracortical distance, center and surround interactions, and cortical feedback as described earlier in the case of visual cortex.

Adaptation of Cortical Sensory Processing to the Statistical Structure of Our Natural Environment

As beautifully expressed by William James, the founder of the American School of Experimental Psychology, one hallmark feature of perception is the “constant fit between the mind and the world” in which we dwell. Continuous immersion in a natural environment irregularly updated by motor exploration causes cortical neurons of different modalities to adapt their function to process specific spatiotemporal power spectrum statistics ($1/f^\alpha$). Neural representations of our peri-personal sensory environment in the cortex are the result of an ever-active optimization of the fit between brain representations and the physical features of the environment that are experienced during

epigenetic development. For instance, during natural vision, informative sensory input is generally gained from the whole visual field and there is now ample evidence that the activity patterns of neurons in the primary visual cortex evoked by full-field exposure to natural scenes differ radically from the activity elicited by simpler and local stimuli. In particular, the most evident qualitative change in response to natural stimuli is the induction of a sparser regime of activity spatially distributed across the cortical network.

Intracellular recordings and voltage-sensitive-dye imaging in the mammalian primary visual cortex show that stimulus-locked variability and network correlations (a measure of information redundancy) both decrease with stimulus complexity, whereas the temporal precision and sparseness of the neural code increase. While drifting gratings evoke highly variable and dense visual responses, stimuli with richer spatiotemporal structures force the cortical network dynamics to become more reproducible at the subthreshold-membrane-potential level and sparser and more reliable at the spiking level. Thus, the precision of the neural code changes with the complexity of the visual input statistics and their closeness to those of natural scenes. These findings contradict the frequently asserted view that the neural code used to represent sensory information in mammalian visual cortex is noisy and redundant. This apparent low efficiency could be due partly to the choice of visual stimuli used in most previous studies: luminance spots, bars, and gratings are typically of low dimension when compared with the high dimensionality of the natural sensory environment and of limited neuroethological value.

The sparsening of activity produced by natural scenes results from the recruitment of dynamic nonlinearities linked mostly to center-surround interactions. A dramatic contextual reformatting of sensory cortical representations has been reported in awake behaving macaques, when extending the presentation of natural-like scenes beyond the classical discharge field. The concomitant stimulation of the silent surround results in a selective increase in mutual information and spike-based efficiency.

Experimental evidence for sparse coding of natural stimuli has been found for other sensory modalities as well, as demonstrated in the auditory cortex. Here again, stimuli that have high probabilities of being encountered in the natural environment of the animal are optimally encoded by sparse activity. Evidence is much scarcer in the somatosensory modality, although neural activity in the upper layers of the barrel cortex is particularly low, consistent with the requirement of a sparse regime, where each neuron should be active only rarely. Furthermore, intracortical electrical micro-stimulation experiments, where only one or a very few neurons are selectively recruited, have been reported to bias the perceptual judgement of the observer during a behavioral recognition task

in a predictable way. This last set of data strongly suggests that each spike seems to count in the sparse mode regime. Consequently, when our sensory cortices operate in an activation state adapted to the most likely input statistics, any discrete activity change can dramatically influence our perception. This holds, whether the change is produced externally by a sudden discontinuity in the sensory input (that cannot be predicted by our own motor activity) or internally by top-down processes.

Top-Down Processing and Cortical Correlates of Expectancy

In previous instances, we have observed that evoked responses in primary sensory cortices can be modulated by concurrent activation of surround regions, beyond the limits of the classical receptive field. We also presented evidence indicative of strong correlates between cortical center–surround neural nonlinearities and biases or illusions in perceptual judgment. While these contextual effects originate partly from the underlying horizontal connectivity intrinsic to the primary sensory cortices, they also depend on the feedback connectivity of higher cortical areas onto the primary sensory cortex. Top-down influences in sensory processing take many different forms, for instance, cross-modal interactions produced in synesthesia, attention-related modulation, and belief propagation or expectancy. In the latter case, templates of sensory stimuli that occur in a highly reproducible way are continuously updated and constantly compared with incoming sensory information. Detection errors in assessing the presence of a sensory stimulus or incorrect identification might arise from the match or mismatch between bottom-up information from the sensory periphery and the top-down feedback arising from stored internal representations and working memory.

Expectancy can be viewed as a dynamic process which prepares the organism to react in an adapted way to sensory inputs which have been primed by the immediate history of the brain. In music cognition, melodic expectation is the tendency for the listener to predict what might come next in the stimulus train, a continuity-in-time feature predicted by the Gestalt theory. Expectancy allows the system to respond – or not – in due time by taking into account the recent presentations of a similar sensory context. It has been studied within two major frameworks. The first, linked to probability theory, posits that in uncertain situations (close to the absolute threshold), responses to highly probable elements are faster and/or more precise than those to rare ones. The second one is more concerned with the impact of the local sensory context and is less directly connected to long-term probabilistic assessments of events. Different dimensions of the stimulus pattern, for example, temporal, spatial, and

multimodal, can be critical in anticipating the timing as well as the identity of future sensory events.

Expectancy-related physiological signals have been observed in the case of the sudden omission (hence, unexpected absence) of a stimulus during a repetitive sequence of stimulation. This omitted stimulus induces characteristic signatures in human cortical evoked potentials in the visual and auditory modalities. Such a detection of a change within a sequence of temporally discrete events requires computing, representing, and retaining for some interval of time the temporal interval between the events, together with the event itself. Following this line of argument, the detection of a change or of a violation of expectancy occurs when there is a mismatch between the representation of the current event and the stored representation of the expected event. As illustrated in the case of the cortical mismatch negativity, the characteristic evoked potential associated with such a violation essentially reflects a pre-attentive, preconscious task-independent process that does not require directed attention.

The cortical imprint evoked by new stimuli interacts with spontaneous or attention-gated recall of internal templates stored for the most frequent sensory events. The neural processes through which these bottom-up and top-down representations interact might be supposed to have a distinctive electrophysiological signature. For example, a neural response to the expected event should be available to recording during the omission of a stimulus. Such expectancy processes have been studied in the rat vibrissal system. The array of specialized vibrissae is the input stage of an extremely sensitive tactile system, comparable in resolution to the human fingers. Moreover, the natural stimuli in this system are strongly conditioned by the arrangement of whiskers on the mystacial pad that follows a precise geometrical pattern in rostro-caudal rows and dorso-ventral arcs. During the whiskers' exploratory behavior, rats move their vibrissae rostro-caudally, creating a *de facto* functional asymmetry between rows and arcs: whiskers in the same row will tend to contact an object successively, whereas whiskers in the same arc either will contact the object nearly simultaneously, or will not contact the object at all. Therefore, the natural whisking movement generates a repetitive pattern of rostro-caudal stimulation that might generate an expectancy wave of activity in the cortex. By defining stimulus conditions as being either predictable or unpredictable, and by recording different neuronal responses across the two types of stimuli, one can infer whether expectancies of the organism account for the observed differential responses. A clear expectancy response can be detected in humans by measuring auditory evoked potentials during repetitive stimulation with a low rate of omission (around 10%). In the somatosensory barrel field, omitted stimuli

protocols reveal neural correlates which can be recorded even in anesthetized animals, consistent with the pre-attentive nature of the mismatch negativity reported in the auditory cortex. In conclusion, these results are in agreement with the idea that the somatosensory cortex is generating hypotheses about stimulus characteristics on the basis of stored representations which are compared with the ever-updated information stream coming from the sensory periphery.

Other forms of expectancy are used by the brain to filter out the sensory perturbation produced by the self-generated motor activity which serves to gather relevant sensory information. The best-known examples have been described in the visuo-oculomotor system in mammals and in the electrosensory system in the electric fish. Both provide examples, at the functional and structural level, of the existence within the brain of internal copies (outflow and efferent copy) of motor signals (saccades or electric discharge). These contextual signals prepare the sensorium to ignore the expected recalibration of the sensory space produced by the sudden shift in gaze fixation or the generated electric field.

Conclusion

From this overview, we conclude that low-level perception can be defined as a cortical-based computation, constantly building unconscious or self-generated inferences during the processing of sensory events. The outcome of the perceptual process is highly conditional on the context of predictive knowledge derived from the past sensorimotor experience. In many cases, perception departs from the physical reality, but this is what ultimately feeds and guides our interactions with the world.

Glossary

Bimodal neurons – A particular class of neurons that presents receptive fields for stimulations coming from different sensory modalities. For instance, a visuotactile neuron is driven by a tactile stimulus on the tactile receptive field as well as by a visual stimulus presented in the visual receptive field close to the tactile one.

Deafferentation – The elimination or interruption of sensory nerve impulses by destruction of or injury to the sensory nerve fibers. The level at which the disruption happens defines the type of deafferentation: central if the lesion involves the central nervous system, and peripheral if the lesion involves the peripheral nervous system.

Double dissociation – Term that was introduced by H. L. Teuber in 1955. This is the demonstration that two experimental manipulations each have different effects on two dependent variables; if one manipulation affects the first variable and not the second, the other manipulation affects the second variable and not the first. If one can demonstrate not only that a lesion in brain structure A impairs function X but not Y, and further demonstrates that a lesion to brain structure B impairs function Y but spares function X, one can make more specific inferences about brain function and function localization. In cognitive neuroscience, double dissociation is an experimental technique by which two cerebral areas are functionally dissociated by two behavioral tests, each test being affected by a lesion in one zone and not the other. In a series of patients with traumatic brain injury, one might find two patients, A and B. Patient A has difficulty performing cognitive tests for, say, auditory memory but has no problem with visual memory. Patient B has the opposite problem. By using neuroimaging (or neuropathology post mortem) to identify the overlap and dissociation among lesioned areas of the brain, one can infer something about the localization of visual and auditory function in the normal brain.

Multisensory integration – The way information from the different sensory modalities, such as sight, sound, touch, smell, self-motion, and taste, may be integrated

by the nervous system. Such integration may result in unified perceptual experiences that are coherent across sensory modalities. Multisensory integration also concerns how different sensory modalities interact and alter each other’s processing.

Neuroplasticity – Neuroplasticity (also referred to as brain plasticity, cortical plasticity, or cortical remapping) is the changing of neurons and the organization of their networks and thus their function by experience. This idea was first proposed in 1892 by Santiago Ramón y Cajal – the proposer of the neuron doctrine though the idea was largely neglected for the next 50 years.

Proprioception – The sense of the relative position of neighbouring parts of the body. Unlike the six exteroceptive senses (sight, taste, smell, touch, hearing, and balance) by which we perceive the outside world, and interoceptive senses, by which we perceive the pain and the stretching of internal organs, proprioception is a third, distinct sensory modality that provides feedback solely on the status of the body internally. It is the sense that indicates whether the body is moving with required effort, as well as where the various parts of the body are located in relation to each other.

Receptive field – The receptive field of a sensory neuron is a region of space in which the presence of a stimulus will alter the firing of that neuron. Receptive fields have been identified for neurons of the auditory system, the somatosensory system, and the visual system. The concept of receptive fields can be extended to further up the neural system; if many sensory receptors all form synapses with a single cell further up, they collectively form the receptive field of that cell. In the somatosensory system, receptive fields are regions of the skin or of internal organs. Some types of mechanoreceptors have large receptive fields, while others have smaller ones. Large receptive fields allow the cell to detect changes over a wider area, but lead to a less precise perception. Thus, the fingers, which require the ability to detect fine detail, have many, densely packed mechanoreceptors with small receptive fields, while the back and legs, for example, have fewer

receptors with large receptive fields. Receptors with large receptive fields usually have a hot spot, an area within the receptive field (usually in the center, directly over the receptor) where stimulation produces the most intense response.

The Peripersonal Space

The peripersonal space consists of a region immediately surrounding the body, characterized by a high degree of multisensory integration among visual, tactile, and auditory information, which differs from farther regions of space. Although we perceive the space as something continuously defined and unitarily represented – as in the Descartes' geometrical definition we are used to – space derives from the perceptual space and it is composed of different neuronal representations, each built in relation to the behavior we can perform in the environment. The peripersonal space representation can thus be added to the classical triadic space taxonomy that can be described from a phenomenological point of view: The personal space, occupied by the body itself, whose representation is mainly built via proprioceptive and tactile information, but also with the contribution of visual input about body parts in the space; the extrapersonal space, principally based on visual and auditory inputs that convey information from the far space; the reaching space, within the extrapersonal space but proximal to the body, functionally defined according to the distance at which an object can be reached by the subject's hand without moving his/her trunk. The peripersonal space, mainly based on the integration of tactile and visual information coming from the body and the space immediately around the body, constitutes a privileged interface for the body to interact with nearby objects (see **Figure 1**).

Neurophysiological Basis of Peripersonal Space in Nonhuman Primates and the Human

One of the first scientists to formulate the concept of a special area of space around the body was Hediger, director of the Zurich Zoo from 1954 to 1973. In his formulation, this region of space was called the flight zone and corresponds to a margin of safety around the animal's body. When a threatening object enters this safety margin, the animal escapes. In a more psychological context, many researchers noted that the human behaves as if s/he had an invisible bubble of protective space surrounding her/his body. Whenever this proximal

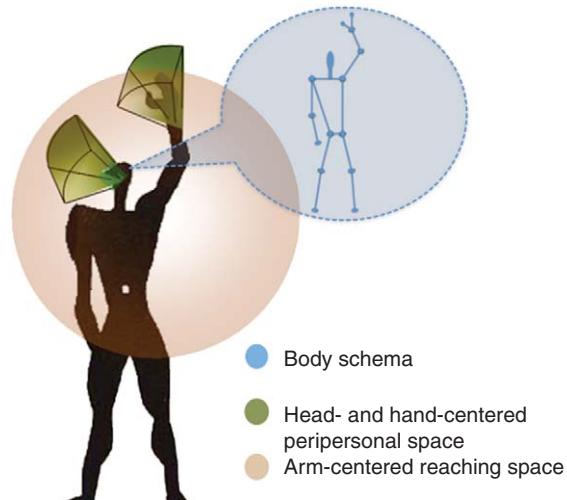

Figure 1 The figure depicts the body schema, the head- and hand-centered peripersonal space and the arm centered reaching space. The head- and hand-centered peripersonal space (green area) is mainly based on the integration of tactile information (from the skin) and visual information and it constitutes a privileged interface between the body and the external world. The body schema (in light blue) is a representation of the body parts dimensions and position the brain uses to plan and execute actions.

space boundary is violated, the person steps away to reinstate the safety margin. The size of this region of space is supposed to increase in a potentially threatening context with respect to friendly company.

With the discovery of bimodal visuotactile neurons in the monkey brain, the peripersonal space found both a more precise definition and its physiological basis. Hyvärinen and Poranen in the 1970s reported that some neurons in the parietal area 7 of nonanesthetized macaque monkeys were activated by a tactile stimulus delivered onto the tactile receptive field on a specific body part, as well as by a visual stimulus whenever presented close to the same body part. However, it is only in the 1980s that the systematic studies of Rizzolatti's group revealed the properties and the distribution of these neurons in an anterior region of the monkey brain, namely the ventral premotor cortex (area F4). Most of these neurons respond to stimuli in one or two sensory modalities. According to the particular modality activating the neurons, they were classified as somatosensory, visual, or bimodal (visual and somatosensory) neurons. Visual neurons are located rostral to the arcuate sulcus (area 8, or frontal eye field (FEF)), whereas somatosensory and bimodal neurons are found predominantly caudal to the sulcus (area F4). The parts of the body most represented are the hands and the mouth. According to the location of their visually responding region (i.e., their receptive field (RF)), bimodal neurons were subdivided into percutaneous (54%) and distant peripersonal neurons (46%). The former responded best to stimuli presented a few centimeters

from the skin, the latter to stimuli within the animal's reaching distance. The visual RFs were spatially related to the tactile ones. Therefore, an important property of these neurons, as with other cells in different multisensory areas (see below), is that the extent of their visual RF is limited in depth to a few centimeters (in most cases from ~5 to ~50 cm) out of the tactile ones. Moreover, when the arm is moved under the monkey's view, the visual RF follows the body part, being anchored to the tactile RF of that particular body part. A peripersonal region is similarly coded around the monkey's head. In particular, some neurons in the ventral intraparietal area (VIP) have visuotactile receptive fields mostly localized on the animal's face and head. As for other body parts, VIP neurons may thus build a multisensory representation of the head-centered peripersonal space. Through this interconnected network of bimodal areas, as Graziano pointed out,

the visual space near the animal is represented as if it were a gelatinous medium surrounding the body that deforms whenever the head rotates or the limbs move. Such a map would give the location of the visual stimulus with respect to the body surface, in somatotopic coordinates.

(see below for the functional role played by peripersonal space).

An important characteristic of the bimodal neurons is the dynamic property of their visual RFs. Iriki's group studied bimodal neurons of the postcentral parietal gyrus, somewhat extending into the intraparietal sulcus, that code for the peripersonal space of the hand-arm in monkeys. They showed their visual RF is not fixed, but can be expanded. Indeed, Iriki and colleagues trained monkeys to use a rake to reach for food pellets placed out of the animal's hand-reaching distance. Following this tool-training, the visual RF of some bimodal neurons coding for the hand peripersonal space was elongated toward the tool-tip, such that the tool appeared to be included within the visual RF. A few minutes after the training, the visually responsive area changed again, apparently shrinking back to its original size. These modifications were not observed if the rake was just passively held by the animal, suggesting that for such a change to occur, the tool has to be actively employed to perform an action. In other words, the dynamic aspect depends on the execution of a specific motor action. In a similar vein, Fogassi and colleagues also found that the visual RF of F4's visuotactile neurons expand when the visual stimulus velocity increases while approaching the cutaneous RF, a property that could be crucial for preparing and/or executing actions toward nearby objects.

Several studies support the existence of a similar representation of the space around the body in the

human. In this respect, the study of a neuropsychological condition called 'extinction' provided considerable insight into the behavioral characteristics of multimodal spatial representation in the human brain. Extinction is a pathological sign following brain damage whereby patients may fail to perceive contralesional stimuli only under conditions of double (contra- and ipsi-lesional) simultaneous stimulation, thus revealing the competitive nature of this phenomenon. A number of studies have shown that extinction can emerge when concurrent stimuli are presented in different sensory modalities: a visual stimulus close to the ipsi-lesional hand can extinguish a touch delivered on the contra-lesional hand. These studies reported the presence of stronger cross-modal visual-tactile extinction when visual stimuli were displayed in the near, as compared to the far, space, providing a neuropsychological support to the idea that the human brain represents peripersonal space through an integrated multisensory visuotactile system. Moreover, as described in monkey studies, even in the human the visual peripersonal space remains anchored to the hand when this is moved in another hemi-space, suggesting that peripersonal space is coded in a hand-centered coordinate system. As for the hand, a multisensory mechanism is involved in representing peripersonal space in relation to the human head. By showing stronger visual-tactile extinction for homologous (left and right cheek) than nonhomologous combinations of stimuli (e.g., left hand and right cheek) we demonstrated the modular organization of peripersonal space, different regions adjacent to different body parts being represented separately. Further support to this view has been recently provided by neuroimaging findings showing a human parietal face area representing head-centered visual and tactile maps. Finally, we have shown that human peripersonal space also features plastic properties, akin to those shown in the monkey. A similar re-coding of visual stimuli located in far space, as if they were closer to the participants' body, has been documented behaviorally in extinction patients following the use of a rake to retrieve distant objects. In this study, cross-modal visual-tactile extinction was assessed by presenting visual stimuli far from the patients' ipsi-lesional hand, at the distal edge of a 38-cm long rake passively held in their hand. The patients' performance was evaluated before tool-use, immediately following a 5-min period of tool-use, and after a further 5–10 min resting period. The authors found that far away visual stimuli induced more contra-lesional extinction immediately after tool-use, than before tool-use. Therefore, near and far space are separately represented and what is near or far is not aprioristically defined, but depends functionally upon movements that allow the body to interact with objects in space. Several authors have since suggested that tool-use-dependent changes in multisensory processing

may reflect changes occurring in another brain representation, namely the body schema.

The Body Schema

The body schema is a representation of dimension and position of body parts in the external space (see **Figure 1**) whose conception can be traced back to 1883, when Pierre Bonnier suggested the existence of an organized spatial representation (or ‘spatial sense’) of the body. However, is the ‘postural schemata’ introduced later by Head and Holmes (1911–12) to be universally considered as the first model of a plastic representation of the body. The main characteristics of this representation are to be finalized to action, to be dynamically updated, and strictly internally coherent.

Body Schema for Action (Executed and Imagined)

To accurately reach-to-grasp an object the brain needs to compute not only the position, shape, and dimension of the target, but also of one’s own body and, in particular, of the body part one wants to use to execute the action (the arm, in this example). The body schema is the representation of the body and its parts the brain uses to do this, among other aims. The spatial position and dimension of body parts are computed by combining information derived from different sensory modalities, such as proprioception, kinesthesia, touch and vision, in a sensory-motor schema. Head and Holmes suggested that the main function of the body schema is to appreciate the execution of active and passive movements, in contrast with another representation – a ‘Superficial Schemata’ – involved in tactile stimuli localization on the body surface. This dichotomy will remain in the subsequent literature, bringing to the fore more commonly used terms of body schema and body image (see below) that, however, do not unambiguously relate to the originally proposed two-faced representation. Several studies have been undertaken to provide evidence supporting this idea, and in particular showing the existence of a double dissociation, that is, the possibility of observing a deficit that is limited to one body representation in a (group of) patient, with the inverse pattern being observable in another (group of) patient. Deafferented patients, for example, have been shown to be able to localize a touch on their own hand despite a deficit in localizing the hand’s position in space, or vice versa. More recent work proposed the existence of three different levels in which the body is represented. In these models, the body schema is presented in contrast to other body representations such as the body image and the body structural description. The body image is a semantic and lexical representation of the body and its

relationship with external objects, while the body structural description is a topological map of locations derived primarily from visual information. Contrary to the body schema, these representations operate at a conscious level. Schwoebel and Coslett have recently tested this model’s validity on a large group of stroke patients. The authors developed a battery of tasks to examine the prevalence and anatomical substrates of the deficits of body representations. Patients with a deficit of the body schema succeeded in tests assessing the body image and body structural description, such as localizing isolated body parts and tactile inputs, matching body parts by location (a target body part was visually presented and subjects were asked to point among three pictures of body parts to the one that was closest on the body surface to the target body part), to match body parts by function (e.g., Is the knee more akin to the wrist or thumb? What body part wears the watch?). However, the same patients were impaired in performing tasks impinging in the body schema, such as imagining the execution of a series of hand movements with different levels of difficulty, and then actually executing those same movements. When response times for both imagined and executed movements were analyzed, the results showed a poor correlation between the two measures, thus suggesting a deficit of the body schema. In the same study, these patients were also unable to perform the hand-laterality task that requires a mental rotation of the hand. Patients were presented with a picture of a hand and asked to indicate if the stimulus was the right or the left hand. To solve the task the participant needs to mentally rotate his/her own hand until it matches the position of the stimulus picture, but this was not possible for patients with deficits of body schema. The lesion analysis suggested that the body schema is dependent on the dorsolateral frontal cortex and posterior parietal cortex.

Body Schema Representation is Plastic

As the body changes continuously in position and dimension throughout life, its cerebral representation needs to be updated for the brain to correctly plan and execute actions. Changes in body-part dimension develop relatively slowly, normally taking years, whereas postural changes are quicker and more frequent. Despite this difference in timescale, both need to be taken into account in the updating of the body schema. Actually, even abnormally fast changes in bodily dimensions are taken into account. Di Russo and colleagues showed a rapid cortical reorganization in the primary somatosensory cortex (SI) and in the associative parietal cortex after surgical extension of lower limbs. Acondroplastic dwarf subjects were tested before undergoing a progressive extension (PE) that increased the length of their legs by about 15 cm in 6 months. The authors observed an expansion and a shift

of the area responding to the foot-tactile stimulation in the SI 15 days after the PE, which disappeared at the follow-up (6 months later). Crucially, a change in activation was also observed in the superior parietal lobule (SPL) that was still present at the follow-up examination. SPL is thus suggested to be a crucial area in the parietal cortex involved in coding the relationship among body parts and between the body and the environment.

The notion that the body schema is plastic can be traced back to the seminal paper by Head and Holmes, where they wrote:

By means of perpetual alterations in position we are always building up a postural model of ourselves which constantly changes. Every new posture or movement is recorded on this plastic schema, and the activity of the cortex brings every fresh group of sensations evoked by altered posture into relation with it. Immediate postural recognition follows as soon as the relation is complete.

Two fundamental ideas are exposed here. First, the body schema is essentially a multisensory motor representation, as proprioceptive, kinesthetic, tactile, and visual information contribute in building it. Second, updating it takes place at an unconscious level, without needing an attentive effort. So, we do not need to think about the position of our feet at every step, or of our arm length to decide if we can reach for an object. Once the update is completed, we can consciously report the position of our body, verbally or by pointing to a body part. In the same paper, Head and Holmes added:

It is to the existence of these "schemata" that we owe the power of projecting our recognition of posture, movement and locality beyond the limits of our own bodies to the end of some instrument held in the hand. Without them we could not probe with a stick, nor use a spoon unless our eyes were fixed upon the plate. Anything which participates in the conscious movement of our bodies is added to the model of ourselves and becomes part of these schemata: a woman's power of localization may extend to the feather in her hat.

In this plastic feature of the body schema related to tool-use seems to reside the origin of the potential overlap with the concept of peripersonal space. As reported above, a large amount of studies relating skilful tool-use to the plasticity of the body schema actually refers to findings that pertain to the multisensory processing of peripersonal space. Irikis' findings in the monkey – showing enlarged visual RFs of bimodal neurons in the parietal cortex after training with a rake – as well as the human tool-use studies showing changes of multisensory interactions in the peripersonal space both of healthy subjects and neurological patients, have been taken as evidence that tool-use modifies the body schema. Similar instances

of such a conceptual overlap can be found in apparently remote domains, such as that of time perception. Yamamoto and Kitazawa asked a group of healthy subjects to perform a temporal order judgment task of two subsequent vibratory stimuli delivered on the tip of two hand-held sticks. When subjects were asked to cross the tips of the sticks without crossing their hands, they observed an alteration of the performance that was comparable to that obtained when subjects crossed their own hands. This finding provides evidence for a proprioceptively mediated referral of tactile stimuli to the tip of hand-held tools. It is unclear, however, to what extent the multisensory effects reported above can be ascribed to a change in the body schema and/or in the peripersonal space processing. We provided more direct evidence for a modification of the body schema following the use of a tool. We recorded, in healthy participants, the kinematic of freehand movements before and after training with a mechanical grabber – used to grasp objects. After the use of the tool, subjects performed the same freehand movement with a different kinematic profile. In particular, they took a longer time to achieve the maximal acceleration, velocity, and deceleration and the amplitude of these parameters was reduced. This particular kinematic pattern, involving only the transport component of the movement fits the kinematic difference that is naturally present in subjects on the basis of their morphology. Indeed, when a given movement is performed by subjects that have a different arm length, 'long-arm' subjects will show longer latencies and reduced amplitudes compared to 'short-arm' subjects. When we use a tool, the representation of our acting body changes so that the tool becomes a part of the body. This modification takes place rapidly, without requiring learning processes. However, the tool-use-dependent plasticity does not vanish immediately, the kinematic changes being present at least up to 15 min after the training with the mechanical grab. This direct measure of changes in the body schema may thus provide a new sensitive test to verify whether changes in the body schema invariably imply changes in the multisensory processing of peripersonal space, or they can be dissociated.

Internal Coherence

The body schema does not accept any incoherence. This means that when a conflict occurs between two inputs, the brain solves it in the direction of one of them. This mechanism is responsible for many perceptual illusions as, for example, the kinesthetic fusion illusion, the rubber-hand illusion, or the tendon-vibration illusion. The kinesthetic fusion illusion has been described by Craske and colleagues in 1978. Blindfolded subjects were seated with their arms stretched in front of them and separated by a plexiglas panel where a button and a probe were fixed.

Subjects had to press the button with their right index finger, which made the probe touch the left arm. In the experimental condition, the button and the probe positions were not coincident, so that pushing the button delivered a tactile stimulation through the probe that was displaced 12 cm away from the button. This paradigm induces a conflict between the proprioceptive and kinesthetic information (from the right-finger movement) and the tactile stimulus (on the left arm). The brain solves this conflict by initiating the feeling in the subject that the two spatial positions are coincident and, consequently, of the left arm being longer than it actually is. Similarly, in the rubber-hand illusion a conflict between visual and tactile inputs is solved in favor of the first one, ensuring that the subject feels the seen rubber hand as his/her own hand. The tendon-vibration illusion arises when a vibration is applied to the biceps or the triceps of the subject's arm. This vibration elicits a kinesthetic illusion of passive extension or flexion of the elbow, respectively. If the vibration is applied when the subject is holding with the vibrated hand the tip of his index finger of the opposite hand, an illusion of elongation, or shrinking, of the held finger is induced. de Vignemont and colleagues used this illusion and asked subjects to perform a perceptual judgment of the distance of two tactile stimuli delivered on the elongated/shrunk finger. They found that the tactile distance feels greater when the stimulated body part feels temporarily elongated. Interestingly, the contrary is not true as the perceptual judgment is not affected when the finger is perceived as shorter. The authors explained this result as caused by anisotropy of the body surface: ontogenetic changes are in the direction of a growing body and cannot normally be reversed. The body schema seems to have the ability to quickly change in the direction of a growing body (ontogenetic changes, rapid body-part elongation, tool-embodiment, etc.), but is resistant to modification in the opposite direction as they are not biologically plausible.

Space and Body for Action

Can the body schema and the peripersonal space be conceived of as the two faces of the same concept and cerebral representation? The former, classically action related, would be referred to the represented structure and position of the body used by the brain to perform an action; the latter is also action-oriented and refers to the multisensory space immediately surrounding the body, which could be used for performing freehand actions as well as using a functional tool. A large corpus of findings indeed supports the involvement of peripersonal space in the guidance of involuntary defensive movements. In the monkey, electrical stimulation of multisensory areas evokes complex pattern of hand-arm movements

compatible with avoidance or defensive reactions, such as withdrawal of the hand, turning of the head, or lifting the hand as if to defend the side of the head. It would thus be adaptive that responses possibly evoked by multisensory neurons are fast and mainly outside the control of top-down mechanisms. However, these multisensory interfaces might be adaptive, in addition, for producing voluntary actions toward objects, such as grasping a glass of water. Bimodal neuronal properties allow the brain to represent an object in a coordinate system centered on the body that can be continuously updated during bodily movements. Remarkably, some bimodal neurons also respond when the arm is voluntarily moved within the reaching space and have been proposed to code goal-directed actions. We provided evidence that voluntarily acting on objects triggers hand-centered remapping of multisensory perception by asking healthy participants to discriminate touches on the hand they used to grasp an object that contained task-irrelevant visual distractors. This provides a measure of how the visual-tactile interaction varies in real time with the action unfolding. Compared to a static condition, the start of the grasping action selectively increased the interference exerted by visual inputs originating from the far target object on tactile stimuli delivered to the grasping hand. This modulation reveals a re-mapping of the peripersonal space that, besides being time-locked with the action onset and regulated in real time with the action itself, does not require any tool-use to occur. The multisensory-motor neural machinery acting as an anticipatory interface between the body and nearby objects may thus have been selected throughout evolution to drive both involuntary avoidance reactions and voluntary approaching movements, with common adaptive advantages for defensive and manipulative actions.

Conclusions

The plastic feature of spatial and bodily representations, together with their involvement in motor control, have raised the possibility that the peripersonal space and the body schema are tightly related concepts, if not a unique one. The central point is to understand how the two concepts of peripersonal space and body schema are operationally separable. Although it is logically conceivable that a modification of one of them may occur leaving the other unchanged, no definitive evidence is yet available to support neither their dissociation nor their association. In this respect, future research is awaited to definitively answer the question of whether talking about body schema is the same as talking about peripersonal space.

Glossary

Cibarial sense organ – cibarium – Food pocket of the insect's external mouth cavity between the base of the hypopharynx and the undersurface of the clypeus, in which food is chewed.

Labral sense organ - labrum – Upper lip, covering the base of the mandibles and forming the roof of the mouth. The labrum is a small sclerite articulating with the lower margin of the insect's face. It helps to hold food in place during chewing by the mandibles.

Papillae – foliate – (Papilla: small protuberance, Folium: leaf) Bilateral structures with the appearance of a leaf, irrigated by the lateral lingual glands. Foliate papillae are found on the posterior edges of the tongue and made of a succession of invaginations embedded in the epithelium. The lateral walls of these invaginations are filled with taste buds opening into the trench. The total number of taste buds found in human foliate papillae varies between 15 and 1500.

Papillae – fungiform – (Papilla: small protuberance, Fungus: mushroom) Small mushroom-shaped structures spread over the anterior two-thirds of the tongue and protruding slightly from the dorsal surface. Each papilla can contain up to 20 taste buds (human); however, it is estimated that up to 60% of fungiform papillae lack taste buds. There are around 200 fungiform papillae on the tongue with a higher density at the tip (150 taste buds per square centimeter).

Papillae – circumvallate – (Papilla: small protuberance, Circum: around, Vallum: rampart) Structures distributed along a chevron-shaped line in front of the sulcus terminalis on the dorsal-posterior surface of the human tongue. Each circumvallate papilla has the appearance of a horseshoe-shaped invagination opening a trench under the surface of the tongue. The trench is irrigated by the

ducts of the von Ebner gland, and the walls are covered with up to 800 taste buds opening into it. In mice, there is only one circumvallate papilla whereas in humans the total number varies between 3 and 13 per individual.

Pheromone – A chemical (or cocktail of chemicals) that triggers a natural behavioral response in another member of the same species. Their use among insects has been particularly well documented. In addition, some vertebrates and plants communicate by using pheromones. Pheromones are produced by various glands and their chemoreception can initiate social responses (e.g., sex, aggregation, alarm, and food-trail) and eventually endocrine changes.

Proboscis – Elongated appendage from the head of an animal, either a vertebrate or an invertebrate. In general, this refers to the tubular feeding and sucking organ of insects (e.g., moths, flies, and butterflies), worms, and gastropod mollusks. This composite organ is formed of the maxillae and labium brought together to form a tube through which liquids are drawn up to the mouth by the cibarial pump.

Sense organ – A structure, which is a receptor for external or internal stimulation. A sense organ is often referred to as a receptor organ. A specialized organ or structure, such as the eye, ear, tongue, nose, or skin for vertebrates and the sensory sensilla for invertebrates, where sensory neurons are concentrated and that functions as a receptor.

Taste sensilla – Sensilla (sg.= *sensillum*) are insect sensory organs protruding from the cuticle, or sometimes lie within or beneath it. They are divided into chemical, mechanical, thermal, and visual sensilla. A sensillum is a simple sense organ consisting of one or a few receptor cells at the end of a nerve connection generally responsive to a common modality.

The identification of food sources is a prerequisite to survival. This task involves the integration of information coming from several senses. Sight, hearing, and smell can all provide long-range cues about the putative location of a prey or food source, but somatosensation and taste will ultimately decide on the ingestion of the food. Because the main function of the gustatory system is to distinguish the good (nutrient rich) from the bad (toxic), taste information collected in the peripheral structures and processed in the higher brain centers is wired to evoke an appropriate behavioral response.

Anatomy of the Gustatory System

Peripheral Structures: Taste Buds and Taste Sensilla

In mammals, the structures monitoring the chemical composition of foods are called taste buds. Although taste buds are mostly concentrated on the dorsolateral surface of the tongue in the fungiform, foliate, and circumvallate papillae (**Figure 1**), others are judiciously distributed in the oral cavity on the palate, the epiglottis, the pharynx, and the larynx. Taste buds are small oval-shaped arrangements of 30–100 elongated cells of three distinguishable types. Type I cells operate as supporting cells. Taste receptors for sweet, umami, and bitter compounds reside on the apical microvilli of type II cells. Type III cells are thought to express a candidate sour receptor and have the distinct characteristic of making synaptic connections with afferent sensory fibers. The precise role of the various cell types in tastants detection is still under investigation. Two important features characterize the elongated cells composing the mammalian taste bud. Unlike in flies where taste receptors are found on primary sensory neurons, mammalian taste bud cells (TBCs) are polarized neuroepithelial cells with functionally distinct apical and basal regions. On the apical side, TBCs are in contact with the saliva by means of microvilli protruding through the taste pore. Below the pore, tight junctions create a selective intercellular barrier thereby isolating the basal region dedicated to cell–cell communication. Gap junctions, paracrine secretions, and synapses indicate that cells within the taste bud communicate with each other and with the cranial nerve fibers through the release of neurotransmitters (ATP); at the same time, sensory nerves are thought to provide TBCs with trophic factors necessary for their survival. It is estimated that taste cells are renewed every 2 weeks from a pool of progenitor cells found at the base of the bud.

In *Drosophila*, the gustatory system has been investigated in both larvae and adults. During these two developmental stages, insects display very different lifestyles: larvae develop directly on their food source whereas adults can fly over a large distance to find both an appropriate nutritive source and a mate. This can

explain the higher complexity for the organization of the adult taste system. The head of the adult carries about 4 times more gustatory receptor neurons (GRNs: 300) than that of the larva (80). However, this difference is less marked than for the olfactory system.

The larva carries three principal chemosensory organs on its head, each of which contains multiple sensilla. The dorsal organ (DO) consists of a multiporous dome housing 21 olfactory receptor neurons (ORNs) surrounded by a ring of six sensilla, mostly containing GRNs. The two other external organs, the terminal organ (TO) and the ventral organ (VO), contain predominantly GRNs but also some neurons likely involved in thermo-, mechano-, or hygrosensation. The pharynx is also lined with three paired organs: the dorsal, ventral, and posterior pharyngeal sense organs (DPS, VPS, PPS), which mostly contain taste sensilla.

In the adult, the peripheral structure dedicated to detecting tastants is called the taste sensillum. There are three types of sensilla according to their size: small (s-type), long (l-type), and intermediate (i-type). A large number of taste sensilla are found on the labial palps, at the tip of the proboscis, the equivalent of the tongue in mammals (62 taste hairs each housing two (i-type) or four GRNs (l- and s-types) and about 60 taste pegs housing one GRN each) (**Figure 1**). These organs allow the fly to sample tastants before their ingestion. Some other taste hairs are distributed on the outer edges of the wings and also on the legs and ovipositor. Three pairs of bilateral internal taste organs are symmetrically disposed around the pharynx: the labral sense organ (LSO), and the ventral and dorsal cibarial sense organs (VCSO, DCSO). These internal organs contain several sensilla housing GRNs. They allow the fly to sample the food after ingestion, but before it enters into the digestive tract. Taste sensilla have an opening or pore at their distal end allowing tastants to come into contact with the lymph that fills them. Each sensillum contains either two or four gustatory neurons depending on the type of sensilla (see above) and a mechanosensory neuron. Gustatory neurons extend a dendrite into the shaft of the sensillum lymph cavity. The lymph is produced by the supporting cells surrounding the gustatory neurons, including the thecogen, tormogen, and tricogen, which are also thought to play a role in mechanosensation. Electrophysiological recordings of gustatory neurons and immunohistological localization of taste receptors in the sensillum are beginning to provide a clear picture of the composition and sensitivity of receptor neurons in each type of sensillum, but substantial work remains to reach a complete and comprehensive map. Four main types of gustatory neurons are distinguished based on their electrophysiological features: gustatory neurons responding best to sugars (S cell), to water (w cell), to low salt (L1 cell), or high salt and bitter compounds (L2 cell).

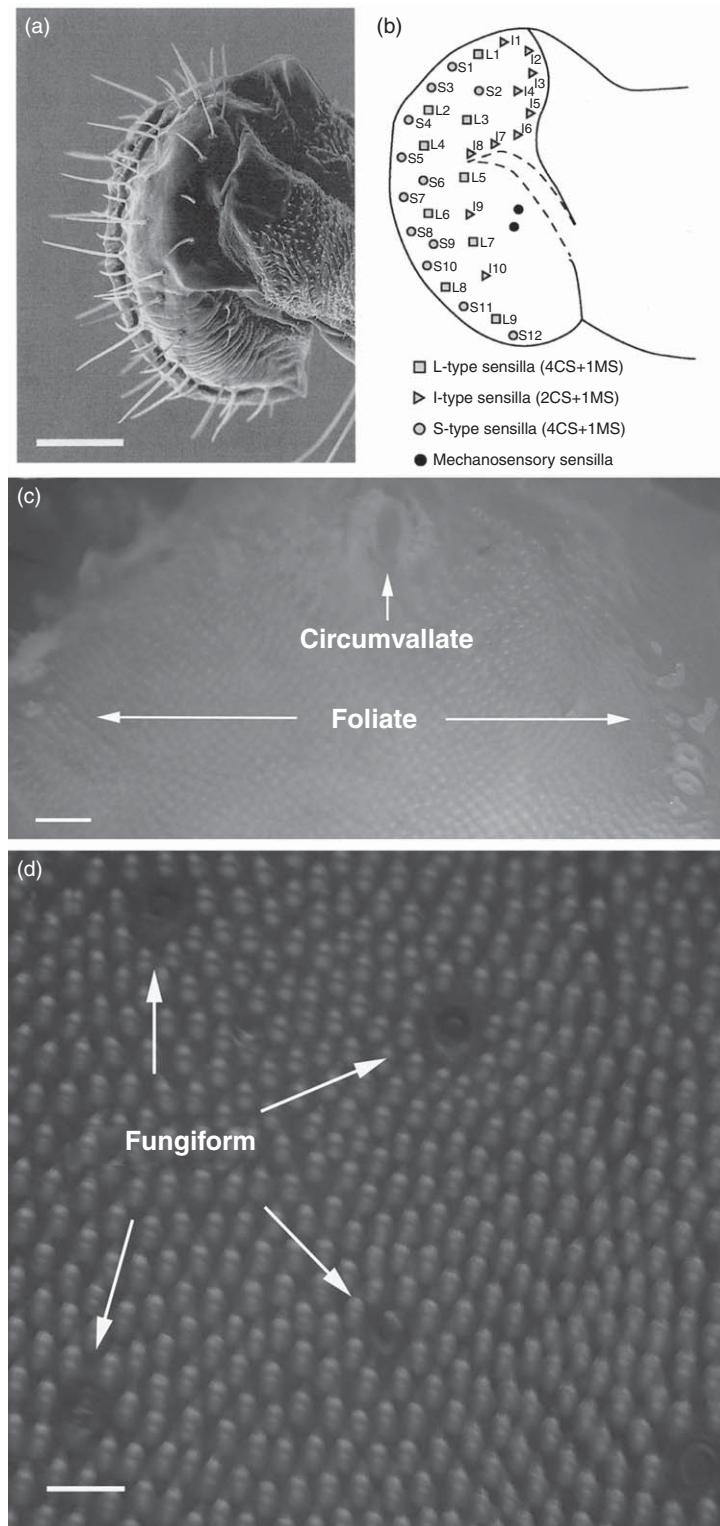

Figure 1 Location of the main taste sensitive organs in *Drosophila* and mouse. (a) Surface image of a left labellar lobe on the proboscis showing the distribution of the chemosensilla. Scale = 30 μ m. (b) Diagram illustrating the arrangement of sensilla on the lobe. Each lobe or palp contains 12 short bristles (S-type: open circles) each with four chemosensory (CS) + one mechanosensory (MS) neurons, nine long bristles (I-type: squares) with four CS + one MS, 10 intermediate bristles (I-type: triangles) each with two CS + one MS as well as two mechanosensory sensilla (filled circles). (c) Transmission image of an unfolded sheet of posterior mouse tongue epithelium showing the location of the unique circumvallate papilla and the two foliate papillae on both lateral edges. Posterior is top. Scale = 400 μ m. (d) Transmission image of a sheet of anterior mouse tongue epithelium showing the location of fungiform papillae surrounded by filiform papillae (pegs). Filiform papillae cover the entire dorsal surface of the tongue and do not contain taste buds. Posterior is top. Scale = 125 μ m. Projections to the Brain

In mammals, the gustatory information collected by the taste cells travels through primary sensory neurons from cranial nerves VIIth, IXth, and Xth via the geniculate, petrosal, and nodose ganglia, respectively, before forming a synapse with neurons in the rostral-lateral part of the nucleus of the solitary tract (rNST). Fibers carrying gustatory information from the chorda tympani branch of the cranial nerve VIIth innervate taste buds in the fungiform and anterior part of the foliate papillae, while the greater superior petrosal branch innervates the palate.

The posterior region of the foliate as well as the circumvallate papillae is innervated by the lingual branch of the glossopharyngeal nerve (IXth), whereas the superior laryngeal branch of the vagus nerve (Xth) contacts the taste buds in the larynx. It is thought that single nerve fibers from the cranial nerves contact a few taste buds and that each taste bud is in contact with several fibers.

In rodents, the taste information travels through the rNST to the medial parabrachial nucleus of the pons on the ipsilateral side, then via the ventroposteromedial nucleus of the thalamus before reaching the gustatory neocortex. Inputs from the parabrachial nucleus and rNST also reach the basal forebrain areas, such as the hypothalamus and the amygdala. This system is likely involved in the hedonic aspect and autonomic functions linked to feeding, whereas information processing in the thalamocortical areas determines perception of taste intensity and quality.

In *Drosophila*, the cell bodies of the sensory neurons housed in larval sense organs are collected in the ganglia located beneath each organ. The sensory inputs

originated in their GRNs are conveyed through four nerves, each of which projects into a distinct region of the subesophageal ganglia (SOG; located at the ventral side of the central brain complex). However, in the larval SOG, there is no spatial segregation by GRN type, indicating that the same tastant can induce different behavioral response according to the sensilla it has been processed by. In the SOG, a set of 20 interneurons expressing the *bugin* gene seems to modulate different aspects of larval feeding. These interneurons establish dendritic arborization with the GRNs and send processes to several neural and endocrine centers involved in feeding. Moreover, the genetic blocking of *bugin*-positive neurons in adults dramatically increases feeding.

In adults, all GRNs are targeted to the SOG. Although there is no morphologically apparent substructure dividing the SOG, the projection of gustatory afferents from different appendages project in distinct SOG regions: the GRNs from labial, tarsal, and internal taste organs, respectively, end in the central, posterior, and anterior-dorsal part of the SOG. Similarly to the taste system of larvae, adults show no segregation by type of GRN but rather by type of appendage, suggesting that the same tastant can induce distinct behavioral effects if it is detected by different gustatory organs. However, the two principal types of GRN, carrying either Gr66a or Gr5a receptors (see below), mediate, respectively, repulsive or attractive stimuli, and show nonoverlapping projection patterns in the SOG (Figure 2). Other putative bitter GRNs expressing Gr32a or Gr47a show a projection pattern that largely overlaps with that of Gr66a-expressing neurons. Therefore, the separation of repulsive and attractive stimuli seems to occur at the first neuronal level.

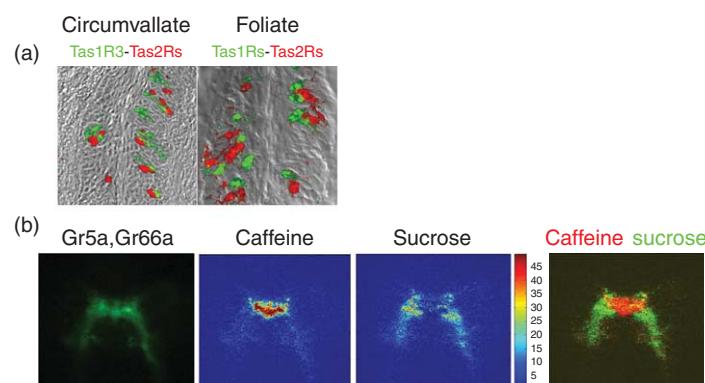

Figure 2 (a) Expression patterns of Tas1Rs and Tas2Rs on the mouse tongue define two subsets of taste cells. Double-label *in situ* hybridization on sections of mouse circumvallate papillae (right panel) with probes specific for Tas2Rs (red) or Tas1R3 (green) or foliate papillae (left panel) with a mix of probes specific for Tas2Rs (red) or Tas1Rs (green). (b) Central projections of the Gr5a and Gr66a GRN are spatially segregated. G-CaMP fluorescence imaging of sweet-responsive Gr5a and bitter-responsive Gr66a neurons in the SOG (first panel from the left) after stimulation with 100 mM caffeine (the ligand of the Gr66a receptor; second panel from the left) or 1 M sucrose (third panel from the left). Overlay of the caffeine- (red) or sucrose-induced (green) response. (a) Reprinted from Nelson G, Hoon M, Chandrashekhar J et al. (2001) Mammalian sweet taste receptors. *Cell* 106: 381–390 with permission from Elsevier. (b) Reprinted from Marella S, Fischler W, Kong P et al. (2006) Imaging taste responses in the fly brain reveals a functional map of taste category and behavior. *Neuron* 49: 285–295 with permission from Elsevier.

Despite some quantitative differences, there are many similarities between the larval and the adult taste systems, suggesting that many elements persist throughout the complete metamorphosis of this insect. Some stage difference can nevertheless be observed as for the projection pattern of Gr66a-expressing neurons, which is exclusively ipsilateral in the larval brain and bilateral in the adult SOG.

Tastants Detection and Behavioral Output

Taste Modalities and Associated Behaviors

Taste cells harbor receptors recognizing a wide variety of soluble chemicals with extremely variable structures, including ions, carbohydrates, alkaloids, small proteins, and amino acids. In humans, the taste sensations evoked by these compounds can be categorized into five primary modalities known as bitter, salty, sour, sweet, and umami. Behavioral responses associated with each of these modalities are related to the biological relevance of the compounds connected with each category.

Several behavioral assays are available to assess and quantify the response of rodents to soluble chemicals. The two-bottle choice test is a simple and robust assay to evaluate attraction or aversion to chemicals in solution. In this test, after a period of training and starvation designed to promote absorption and reduce apprehension, rodents are offered a pair of bottles containing the solutions to be tested. If the test period is short (<10 min), the total quantity sampled and the ratio of solutions consumed is considered to be reflecting palatability and orosensory factors while longer testing period also reflects postigestive effects. An alternative strategy involves presenting food-deprived animals with a choice of solutions and computing the number of licks produced over a very short period of time (10–60 s). By allowing such transient access to the solution, the brief-access test is thought to completely exclude postigestive events known to influence intake and preference; therefore, it is suitable to determine the contribution of oral factors and intensity thresholds.

Perceptual discrimination can be assessed with conditioning paradigms during which an animal is trained to perform a specific task after tasting one of two solutions. Typically, only solutions that can be discriminated will allow the animal to learn the task. Another paradigm involves pairing a given taste stimulus with a gastric malaise induced by the simultaneous intraperitoneal injection of LiCl. The very robust resulting conditioned taste aversion is applied to the study of perceptual categorization of taste compounds.

Using these tests and the others more elaborate in rodents, it was determined that salty, sour, sweet, and umami compounds tested at or just above detection thresholds are preferred over water, while bitter-tasting

compounds are strongly aversive. Detection thresholds for bitter compounds are generally lower than that of preferred compounds. At high concentration, salty, sour, sweet, and umami compounds elicit an aversive response.

Behavioral tests carried out with larvae or adult flies aim to measure not only the attractive or repulsive effect of varied food molecules but also that of adult contact pheromones mostly perceived by the gustatory system. Behavioral tests performed with larvae are designed to measure individual or group responses exclusively to food compounds. Basically, starved larvae taken at the end of their second instar (period during which the maximum feeding response is shown) are placed on a Petri dish at the frontier between two media. These media always consist of a choice that can involve either an attractive (sugar) or a repulsive substance (high salt, bitter) or one of these substance combined with a neutral medium (agar). The precise behavior (individual) or the distribution on each medium (group) is measured during a test period generally lasting between 10 and 30 min.

Adults can be tested for three major behavioral paradigms to measure their feeding or sexual responses. For feeding tests, they are kept fasting during a few hours; for mating tests, they are kept in isolation during all adult development to prevent inter-individual experience. Feeding response can be measured with groups of flies kept, in darkness, in a small box containing a choice of two types of food colored with different dyes. The preference is subsequently assessed by looking at the transparent abdomen of the fly and scoring the tint of the food ingested. The second feeding assay takes advantage of the proboscis extension reflex, which individually measures the aversive or appetitive effect of a stimulus deposited on the fly leg. Typically, feeding tests have shown that bitter and high salt concentration are aversive while sweet and water stimuli are attractive to both larvae and adults.

Pheromonal gustatory perception is measured by the intensity of courtship and the willingness to mate that individual male direct to various target flies either alone or paired. These tests, which involve target flies carrying various quality and quantity of contact pheromones, can last between 5 and 60 min.

Detection and Transduction of Sweeteners and Amino Acids

In mice, a small family of GPCRs comprising three members (Tas1R1, Tas1R2, Tas1R3) mediates the detection of most of the sweeteners and amino acids. These GPCRs assemble as pairs to produce functional receptors for sweet-tasting compounds (Tas1R2–Tas1R3) or L-amino acids (Tas1R1–Tas1R3). Their expression pattern defines two subsets (Tas1R1–Tas1R3- or Tas1R2–Tas1R3-expressing cells) of type II taste bud cells.

The gene coding for Tas1R3 is found at a genetic locus (*Sac* locus) influencing behavioral responses to sucrose and saccharine in several mouse strains; consequently, naturally occurring polymorphisms in the amino-terminal extracellular region of the receptor have been associated with saccharine preference. Tas1R2–Tas1R3 is broadly tuned to a large range of sweet-tasting compounds, including D-amino acids, peptides, natural sugars, and artificial sweeteners, whereas Tas1R1–Tas1R3 is activated by L-amino acids and potentiated by purine nucleotides, a distinctive feature of umami taste (Table 1).

The coupling of these receptors to the transduction machinery appears to involve a common signaling pathway whereby G $\beta\gamma$ subunits released from the heterotrimeric G protein coupled to the receptors leads to the activation of phospholipase C beta-2, which, in turn, hydrolyzes phosphatidylinositol-4,5-bisphosphate (PIP2) into inositol 3-phosphate (IP3) and diacylglycerol (DAG). IP3 then causes the release of Ca²⁺ from intracellular stores, subsequently leading to the activation of TRPM5, a member of the TRP family of ion channels. Gating of TRPM5 by intracellular Ca²⁺ allows entry of monovalent cations into the cell and subsequent depolarization. The role of other second messengers, such as cAMP, thought to be important for sugar signal transduction remains unknown.

In *Drosophila*, a family of 60 GPCRs called Grs for gustatory receptors is thought to be responsible for tastant detection. Grs were found to be expressed in larvae's terminal taste organ as well as in GRNs of the labial palp and legs. Gr5a, a member of this family found in about 50% of the labial palp's GRNs, is activated by the sugar trehalose but not maltose or sucrose. Neurons carrying Gr5a mediate responses to appetitive stimuli such as trehalose as well as low salt concentration. Mutant flies without a functional Gr5a are able to detect sucrose, suggesting that other yet unidentified receptors are involved in sugar detection. It has been proposed that the Gr64 subfamily of receptors of which Gr64f is present in sugar-detecting sensilla (long and small) are such candidates.

Detection and Transduction of Bitter

A family of about 30 divergent GPCRs called Tas2Rs has been tied to bitter detection in mammals. The genes coding for the Tas2Rs are located at genetic loci associated with bitter sensitivity in human and mice. In fact, genetically inherited modifications in the human Tas2R38 and mouse Tas2R5 receptor proteins are linked with variation in sensitivity to the bitter compounds phenylthiocarbamide (PTC) and cycloheximide, respectively. The divergence in sequence identity among members of the Tas2R family is expected to reflect the

structural diversity of bitter-tasting compounds with which they interact. Tas2Rs characterized so far display high selectivity to bitter-tasting ligands (Table 1).

In rodents, TBCs expressing Tas2Rs are found in all tongue papillae as well as on the palate. They define a subset of type II cells separate from that expressing Tas1R2–Tas1R3 or Tas1R1–Tas1R3 (Figure 2). Multiple intracellular signaling components have been detected in Tas2Rs expressing cells, including the G-protein alpha-subunit gustducin as well as the receptor for inositol triphosphate type 3. Behavioral evidence emanating from knock-out mice supports a role for gustducin, phospholipase C beta-2, and TRPM5 in bitter detection but evidence exists for additional signaling pathways.

Drosophila small and intermediate sensilla are thought to contain bitter receptors. More than 20 Grs have been reported as expressed in bitter sensilla, including Gr66a a receptor activated by the bitter compound caffeine. Gr66a-expressing GRNs in the labial palp emanate from s-type and i-type sensilla and represent a subset of neurons distinct from that expressing Gr5a. Gr66a-expressing neurons seem to respond to a wide variety of tastant molecules, including bitter molecules, wasabi, and, more surprisingly, 7-tricosene, which is a long chain hydrocarbon known to act as a male inhibitory pheromone. While it has been shown that caffeine binds to the Gr66a receptor, the receptor for the male pheromone has yet to be identified. Both substances induce similar repulsive effect on feeding and sexual behavior. They can also act additively and cross-stimulate the same taste neuron (which corresponds to the L2 cell). This indicates that taste neurons inducing a typical behavior (repulsion) can respond to very different molecules. The signaling pathways downstream of Gr66a are presently unknown.

Detection of Salts and Acids

Sour and salty stimuli are thought to be detected by ion channels in mammals. A heteromer composed of two members of the transient receptor potential (TRP) family of ion channels (PKD2L1 and PKD1L3) has emerged as a strong candidate sensor for sour stimuli in mice. PKD2L1 is confined to type III taste bud cells.

Salty sensation is thought to be mediated, at least in part by an amiloride-sensitive sodium channel (ASSC), which belongs to the epithelial sodium channel (ENaC) family of ion channels.

In *Drosophila*, two members of the DEG/ENaC ion channel family, pk11 and pk19, are likely involved in the response of flies to high salt concentration that are normally repulsive. Intriguingly, another ion channel of the same family (ppk25) seems to be also involved in the response to putative female contact pheromones, which elicit an attractive response in males.

Table 1 Receptor–ligand relationships for taste receptor

Taste quality	Receptor	Species	Ligand	Assay
Bitter	Gr66a	<i>Drosophila</i>	Caffeine Theophylline Denatonium Cycloheximide	Behavioral response
	Tas2R5	Mouse		Calcium imaging GTP γ S
	Tas2R8	Mouse	Denatonium PROP	Behavioral response Calcium imaging
	Tas2R9	Rat	Cycloheximide	Calcium imaging
	Tas2R4	Human	Denatonium PROP	Calcium imaging

Additional Taste Modalities

The mechanism of water detection and the identity of the receptor of the water cell found in *Drosophila* sensilla remain largely unknown, although a genetic marker (NP1017) specific to the W cell has been identified. Interestingly, in the hamster, the superior laryngeal branch of the vagus nerve innervating chemosensory receptor cells within the laryngeal epithelium present the particularity to be responsive to water.

In flies, Gr21 and Gr63 are important for the detection of CO₂, a gustatory stimulus signaling the presence of fermentation. In larvae, the response to CO₂ depends on Gr21a-expressing neurons, which project in a specific SOG region distinct from the four subregions described above. In adults, Gr21a and Gr63a should be simultaneously present to allow an acute response to CO₂, suggesting that both receptors function together as a membrane-bound CO₂ receptor.

Taste Information Coding

Over the years, tremendous progress in our understanding of the functional organization of the gustatory system has been achieved. The expression patterns of the rodent receptors involved in the detection of tastants strongly

suggest that, within the taste bud, distinct subsets of TBCs are specialized for the detection of bitter-, sweet-, sour-, and umami-tasting compounds. Whether the signal is processed in the taste buds or specific connections with afferent nerve fibers are established remains a debated issue. Nonetheless, gustatory nerve recordings indicate that single fibers carry the information from several taste qualities, although their sensitivities vary according to the taste stimulus. In the rat, fibers of the chorda tympani and glossopharyngeal nerve can be classified into NaCl best, quinine best, sucrose best, and HCl best based on their relative sensitivity to four types of taste stimuli. Glossopharyngeal taste fibers are predominantly responsive to HCl and quinine, while those of the chorda tympani nerve are mainly responsive to sucrose and NaCl. In adult *Drosophila*, the two principal types of taste receptors are located in nonoverlapping sets of GRNs and project to different areas much like GRN emanating from different peripheral taste organs do. Thus, both quality and position are represented in the fly SOG. In rodents, a clear map of taste quality in the NST remains to be seen. Nevertheless, behavioral evidence emanating from genetically modified mice expressing a bitter taste receptor in sweet taste receptor-expressing cells supports a linear system for the detection and associated behavioral response of attractive and aversive compounds as that apparent in *Drosophila* (Figure 3).

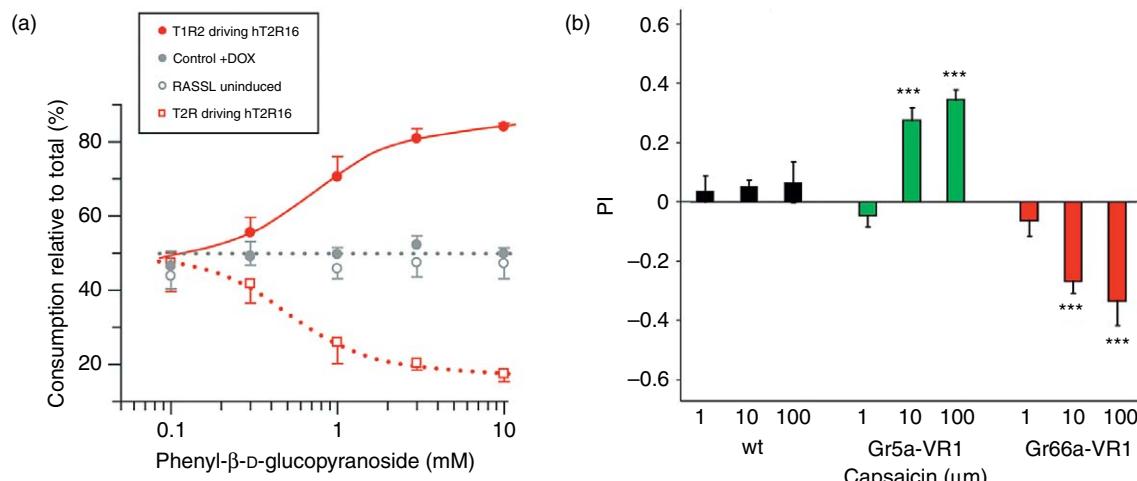

Figure 3 Specific sets of taste receptor cells in mice or GRNs in *Drosophila* mediate attractive or aversive behaviors. (a) Targeted inducible expression of the human Tas2R16 receptor in Tas2R19 expressing taste bud cells elicits a dose-dependent aversive response to phenyl-β-D-glucopyranoside, the ligand of the Tas2R16 receptor (red circles) as measured by standard two-bottle preference assay. By opposition, expression of the human Tas2R16 in Tas1R2 expressing taste bud cells produces mice attracted by phenyl-β-D-glucopyranoside (red squares). Control mice without the Tas2R16 receptor display no behavioral response to the same molecule (gray circles). (b) In *Drosophila*, a similar experiment was conducted with VR1, an ion channel activated by capsaicin and expressed in Gr5a- or Gr66a-expressing GRNs. Behavioral taste preference assays in these genetically engineered flies show that capsaicin does not elicit a significant behavioral response in control flies (black bars) whereas expression of VR1 in Gr5a neurons induced a robust dose-dependent attraction to capsaicin (green bars). On the contrary, VR1 expression in Gr66a neurons made flies strongly aversive to capsaicin (red bars). (a) Reprinted from Mueller K L, Hoon M A, Erlenbach I et al. (2005) The receptors and coding logic for bitter taste. *Nature* 434: 225–229 with permission from Macmillan Publishers Ltd. (b) Reprinted from Marella S, Fischler W, Kong P et al. (2006) Neuron, 49, Marella et al., Imaging taste responses in the fly brain reveals a functional map of taste category and behavior. *Neuron* 49: 285–295 with permission from Elsevier.

One can envision that such a system providing straight information about the quality and position of nutrients might be beneficial for the efficient control of the ingestive behavior, while integration of multisensory information and perhaps processing of temporal patterns are required for behaviors linked with reward, appetite, and emotion. Future research investigating the topography of projection to the NST and beyond and processing of the information in various brain regions will undoubtedly provide valuable insight into taste-guided behaviors.

In conclusion, although sucrose or denatonium elicit similar behaviors in *Drosophila* and mice, their sweet and bitter taste receptors have no sequence similarity. Nevertheless, in these two species, aversive or attractive behaviors appear guided by neuronal or neuroepithelial chemosensory receptor cells specialized in the detection of palatable or unpalatable compounds. Further research into the central mechanisms of taste processing in these species will address whether evolutionary conserved mechanisms take place at this level as well.

Tinnitus: Processing of Auditory Phantom Sound

J J Eggermont, University of Calgary, Calgary, AB, Canada

Glossary

Audiometry – Behavioral measurement of hearing thresholds at octave-spaced frequencies between 125 and 8 kHz.

Hair cells – Receptor cells in the cochlea (inner ear) comprising inner hair cells (true receptor cells) that act like microphones and outer hair cells that have an amplifying function on the mechanical vibrations in the inner ear. Outer hair cells are especially susceptible to damage by excessive noise and certain drugs, resulting in hearing loss.

Ménière's disease – A clinical disorder characterized by the combination of (low-)frequency hearing loss, roaring tinnitus, fullness in the ear, and vertigo.

Neural synchrony – More or less coincident firing of nerve cells, resulting in enhanced evoked potentials and efficient stimulation of other neurons downstream that are innervated by the synchronously firing cells.

Neuropathic pain – Initiated or caused by a primary lesion or dysfunction in the nervous system that cannot be explained by a single disease process or a single specific location of damage.

Recruitment – A phenomenon of abnormal loudness (or evoked potential amplitude) growth in ears with outer hair cell loss; despite a hearing loss the perceived loudness (or the evoked potential amplitude) is comparable to (or even larger than) those in normal-hearing people at high intensity levels. The result is a reduced dynamic range for processing sound.

More common is subjective tinnitus: a sound that is heard in the absence of any external or internal physical sound source. A benign form of subjective tinnitus is the short (<30 s) experience of a (usually) tonal ringing in the ear, sometimes accompanied by fullness in the ear and a slight transient hearing loss. Its cause is largely unknown, but it is likely not related to the death of a cochlear hair cell as sometimes suggested.

About 10–15% of adults experience tinnitus, and most commonly describe it as ringing, buzzing, cricket-like, hissing, whistling, and humming, and less frequently as a roaring sound. It is largely unknown why about 80% of the people with chronic tinnitus suffer little or do not seek treatment for their tinnitus, whereas about 20% manifest a clinically significant condition. When patients visit a doctor because of annoying tinnitus, a majority of them think that they have a serious problem and might become deaf. This is not the case in the vast majority of cases. It is usually the other way around: a mild-to-moderate high-frequency hearing loss that people do not find too bothersome in most cases is usually the cause of tinnitus. Typically, about 20% of people report that the tinnitus sounds were equal in both ears, about 35% report having tinnitus only in one ear, and most of the others report tinnitus to be stronger in one ear.

Where is Tinnitus?

Is tinnitus in the ear or in the brain? Tinnitus sensations associated with hearing loss are nearly always localized toward the affected ear(s). Does this mean that tinnitus is generated in the ear? Early on, in cases of truly debilitating tinnitus, a common surgical procedure was to cut the auditory nerve from the tinnitus ear in order to abolish tinnitus. However, in the majority of cases, the tinnitus sensation persisted after resection of the auditory nerve. This suggests that localizing the source of tinnitus is not so simple. In most cases tinnitus is indeed initiated by processes in the ear and, in some, its source may be in the ear as in the case for the very short transient forms of tinnitus and also potentially in some temporary forms that last less than a few weeks. However, most chronic tinnitus is of central origin and its source has shifted to the brain.

The localization of tinnitus to one or both ears is most likely attributable to a phantom sensation and is not unlike that related to sensations or pain experienced

What is Tinnitus?

In common English, tinnitus stands for ‘ringing in the ears,’ but hissing and roaring sounds also fall under the rubric of tinnitus. A more comprehensive definition is: “tinnitus is the conscious perception of a sound that is not generated by any source outside the body.” This definition comprises two forms of tinnitus: objective and subjective.

Objective tinnitus can be traced to defective or malfunctioning parts in the body, and results from internal sound sources such as abnormally strong pulsating blood vessels and spasms of the middle ear muscles. Most of these defects can be treated surgically and often result in the disappearance of tinnitus.

after losing a digit or, more severely, a limb. Itch or pain in a nonexistent part of the body is truly annoying and so is tinnitus. The pitch of tinnitus corresponds, when there is a hearing loss, to the frequency of that hearing loss. In case of low-frequency hearing loss (as in Ménière's disease) the tinnitus is low pitched ('roaring'), but in noise-induced high-frequency hearing loss the pitch of the tinnitus corresponds to a high-pitched ringing or hissing sound. The brain 'hears' the sound of the missing frequencies in the ear: a phantom sensation (**Figure 1**).

Not all persons with hearing problems resulting from hair cell loss have tinnitus or complain about tinnitus. In other words, cochlear damage does not always result in tinnitus. It is thus likely that differences in central processing are also important in the generation of tinnitus. Conversely, not all persons with tinnitus have a hearing loss. This suggests that the idea of a phantom sound does not universally work and that tinnitus is not a unitary concept.

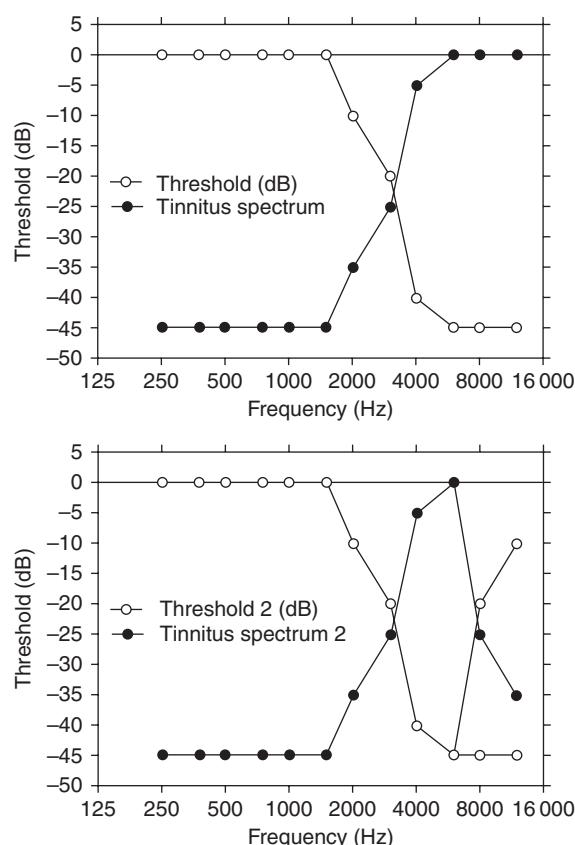

Figure 1 The tinnitus spectrum, that is, the range of frequencies making up the tinnitus, is closely related to the inverse of the hearing loss. This is shown here schematically. The top example with a relatively broad frequency loss likely would represent a hissing tinnitus, whereas the bottom example with a limited frequency range of loss could represent a more tonal tinnitus. A strict one-to-one correspondence of hearing loss and tinnitus pitch does not hold however.

Tinnitus without audiometric hearing loss can still be attributed to damage in the inner ear. Dead regions in the cochlea that are too small to be detected with standard octave spaced audiograms or hearing loss at frequencies above the 8-kHz upper limit of standard clinical measurement can be a contributor.

Somatic Tinnitus

Tinnitus can also result from head and neck injury and typically localizes to the ipsilateral ear, but generally there is no resulting hearing loss in that ear. There are at least two entrance points for somatosensory information in the auditory system: the dorsal cochlear nucleus (DCN) in the brainstem and the inferior colliculus (IC) in the midbrain. The input to the DCN granule cells originates among others from the trigeminal nuclei and the dorsal column nuclei. These represent both facial and upper spinal cord information, reflecting the position of the head and pinnae that are relevant for localization of sound. The output of the granule cells via the horizontal fibers is typically excitatory to the fusiform cells (the principal output cells of the DCN) that also receive excitatory input from auditory nerve fibers. However, the horizontal fibers also excite cartwheel cells that in turn inhibit the fusiform cells. Thus the increase or decrease in the output of the somatic nuclei as a result of injury could disrupt the balance between excitation and inhibition in the DCN and affect the spontaneous input to the IC. This could account for sources of tinnitus as diverse as whiplash, temporo-mandibular joint problems, orofacial movements, and the like.

Listening to Tinnitus

Listening to one's own tinnitus and matching it to externally generated sounds aim to objectively quantify tinnitus. This area of research uses psychoacoustic methods that can assess pitch and loudness, and measure the effects of masking sounds on tinnitus.

Pitch

Pitch matches often occur in the frequency region of maximum hearing loss or occasionally at the edge frequency of the hearing loss. Pitch-matching reliability varies widely across patients. Pitch matches can also vary from day to day or within a day. This may represent subtle shifts in the dominant frequencies in the tinnitus spectrum. The tinnitus percept can often be synthesized by combining pure tones into a tinnitus spectrum (**Figure 1**).

Loudness

Loudness is usually measured by a rating procedure or by matching it to the level of external sounds. The loudness of tinnitus is typically matched to sound levels that are only a few decibels above the hearing threshold. However, because of the recruitment type of hearing loss that underlies tinnitus this could still represent a fairly loud sound. The loudness level of tinnitus fluctuates, and this could be due to test-retest variability, actual fluctuation of the tinnitus loudness, and changes in tinnitus pitch or loudness produced by the measurement stimulus if presented to the tinnitus ear. Presenting a matching stimulus to the contralateral ear might reduce potential interference with tinnitus loudness, but because of central interactions it might not completely eliminate them. One way to avoid this sound-tinnitus interaction is to use cross-modal loudness matching.

Masking

Masking is based on two mechanisms: (1) a so-called ‘line-busy’ effect where the masking sound activates the neurons and prevents them from firing to a probe sound (e.g., tinnitus) and (2) a suppression effect where the masker interferes with the mechanical activity pattern of the probe sound in the cochlea. Although pure tones can mask tinnitus completely in the majority of patients, it does not follow the standard effects that a masker has on an external probe sound. It appears that the cochlear suppression mechanism is impaired in tinnitus patients likely because of the hearing loss (based on the measurements of psychoacoustic tuning curves). This finding again points to central effects that are different compared to controls. If the changes induced by the masker, and the generation site of tinnitus, were at the cochlear level, the masking of an external pure tone would be similar to the masking of tinnitus.

Residual Inhibition

This is a postmasking effect that, because of its long duration (usually seconds, but can last for minutes to hours), is again a central effect: in controls, such forward masking on external tones always lasts less than half a second. The residual inhibition is generally the largest when using masking sounds in the range of hearing loss and that resemble the tinnitus spectrum. The results suggest that cortical map reorganization induced by noise-induced hearing loss, which results in an overrepresentation of the edge frequency in the audiogram, is not the principal source of the tinnitus sensation. Because, in that case, one would expect the tinnitus pitch to match the edge frequency and that edge-frequency sounds would result in the largest residual inhibition.

Measuring Tinnitus Annoyance

Results of psychoacoustic-loudness estimates of tinnitus have been repeatedly shown to have little, if any, correlation with the degree of tinnitus severity or annoyance. The latter is generally assessed using tinnitus questionnaires. There are at least a dozen published outcome instruments that are used to obtain tinnitus-severity ratings; however, there is no consensus regarding their use across tinnitus treatment centers. In some ways, tinnitus resembles certain forms of pain, specifically neuropathic pain. Pain and tinnitus both may cause emotional and psychological distress that is out of proportion to the magnitude of the injury. Moreover, both pain and tinnitus are often associated with dysfunctional, inappropriate coping strategies. So treatments applicable to pain may be relevant to consider in the case of tinnitus.

Objective Measures in the Brains of People with Tinnitus

Objective methods to assess ongoing and spontaneous brain function in humans include recording the electroencephalogram (EEG) or the magneto-encephalogram (MEG). Stimulus-evoked changes therein are known as auditory evoked potentials (AEPs) or evoked magnetic fields (EMFs). The AEPs ([Figure 2](#)) are typically recorded from the scalp and reflect compound action potential activity in the auditory nerve and certain brain-stem centers (the auditory brainstem response), or compound postsynaptic potentials in the auditory cortex (the middle- and long-latency cortical potentials). In order to be detectable at the scalp, the neural activity needs to be tightly synchronized in time and the neural sources need to be oriented parallel in space.

Positron Emission Tomography and Functional Magnetic Resonance Imaging

Neural activity requires energy, which has to be provided by the blood flow in the brain regions that need it. Changes in the blood flow can be much localized and can be indirectly measured using positron emission tomography (PET) and functional magnetic resonance imaging (fMRI). The advantage of PET is that it is a silent technique whereas fMRI suffers from a high level of background noise related to the scanning cycle that could mask the tinnitus effects one wants to measure. The disadvantage of PET is that it has a poor spatial resolution compared to fMRI and that it requires injection of a radioactive tracer. High-resolution frequency-place (tonotopic) maps in auditory cortex have been obtained from fMRI by using high-strength magnetic fields (7 T).

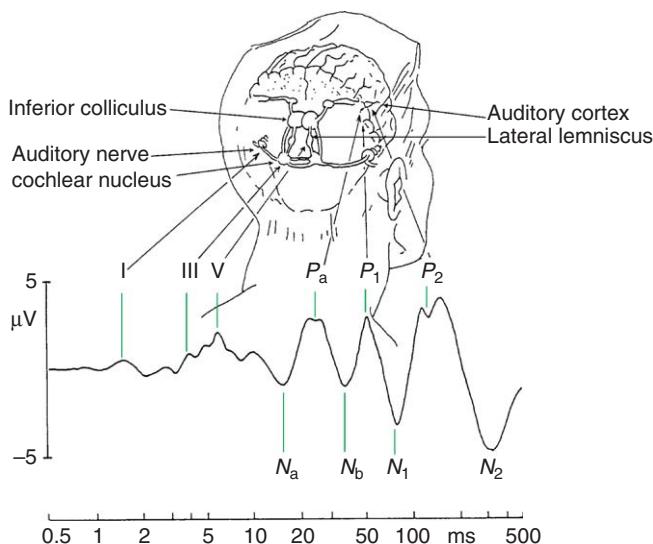

Figure 2 Schematic of auditory evoked potentials and putative generation sites. The waves labeled I, III, and V represent components of the auditory brainstem response (arrows indicate origin of these waves and the names of the structures). The components N_a , P_a , and N_b form the middle-latency response, and the P_1 , N_1 , P_2 , and N_2 represent the late cortical potentials. Note the logarithmic time axis. Reproduced from Picton TW, Hillyard SA, Krausz HI, and Galambos R (1974) Human auditory evoked potentials. I. Evaluation of components. *Electroencephalography and Clinical Neurophysiology* 36: 179–190 with permission from Elsevier.

Imaging tinnitus in humans needs to demonstrate increased neural activity during silence (generally seen as the crucial substrate linked to tinnitus). This latter problem cannot be readily solved at the group-comparison level between tinnitus patients and normal controls because of high variability in, and poor control of, resting-activity levels among people. Imaging tinnitus has been addressed indirectly by focusing on a group of persons, who can modulate the strength of their tinnitus by either changing eye-gaze direction or by making orofacial movements. An alternative is to temporarily abolish the tinnitus by intravenous lidocaine injection. For these groups, it has been demonstrated with PET scans that increased tinnitus loudness corresponds to increased neural activity in several auditory and nonauditory areas. The group data typically showed significant tinnitus-related hyperactivation in auditory cortex, but not in the primary areas (**Figure 3**).

In most cases, the presence of tinnitus can be linked to hearing loss. Various sources of evidence indicate that reduction of primary sensory input to the brain leads to an enhanced power in the delta frequency range (<4 Hz). The spontaneous cortical neuronal activity was characterized by a marked reduction in alpha (8–12 Hz) power together with an enhancement in delta (1.5–4 Hz) as compared to a normal-hearing control group. This pattern was especially pronounced for temporal regions of the brain. Moreover, tinnitus-related distress showed strong associations with this abnormal spontaneous activity pattern. There is also evidence that in persons with tinnitus spontaneous gamma-band activity correlates both with the annoyance of tinnitus and the ear to which it was localized.

By comparing human tinnitus subjects with normal controls and using tonal edge-frequency stimuli and tonal stimuli with a one-octave-lower frequency to elicit EMFs, it was found that the source location for the edge-frequency N_1 dipole (**Figure 2**) was abnormal. However, the map abnormalities that this study indicated did not relate to the strength of the tinnitus percept. This suggests that tonotopic map changes might be an epiphenomenon. In the auditory brainstem response, no differences in amplitude compared to controls were found but exceptionally large middle-latency response waveforms in the problem tinnitus group were found compared to normal-hearing controls, and a hearing-loss group without tinnitus. This could point to increased neural synchrony in auditory structures from the midbrain up.

All in all, these findings suggest that changes in the spontaneous EEG or MEG spectrum, increased evoked-potential or evoked-magnetic-field amplitude suggesting increased neural synchrony, tonotopic map changes in auditory cortex, and increased spontaneous firing rates in the auditory cortex are potential neural correlates of tinnitus in humans.

Objective Measures in the Auditory System of Animals

Do Animals Have Tinnitus?

The neural substrate of tinnitus can only be adequately studied in animal models that show behavioral evidence of tinnitus induced by agents similar to those causing

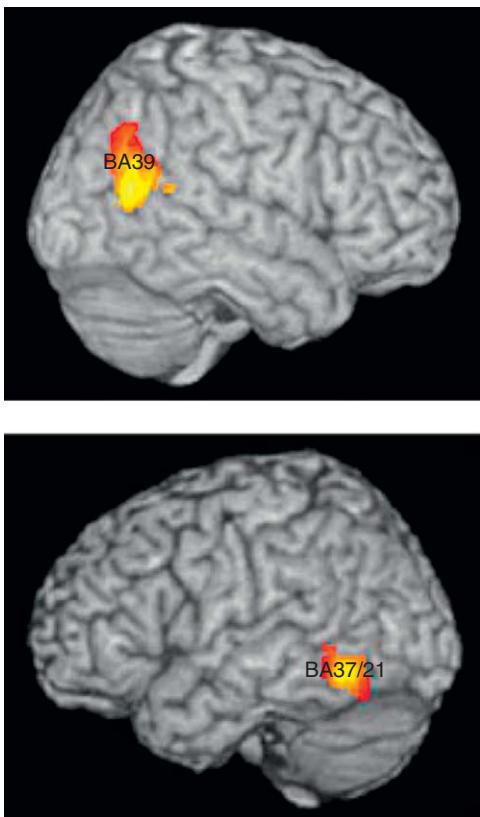

Figure 3 The PET-recorded activity related to tinnitus is seen in the right angular gyrus (BA39) and the left lower temporal cortex (BA37/21). Yellow colors indicate the highest activity levels. Here the significant differences between activity during tinnitus and that following intravenous injection of lidocaine, which temporarily abolishes tinnitus, has been plotted. This is an indirect way of quantifying the activity related to tinnitus. Reprinted from Plewnia C, Reimold M, Najib A, et al. (2007) Dose-dependent attenuation of auditory phantom perception (tinnitus) by PET-guided repetitive transcranial magnetic stimulation. *Human Brain Mapping* 28: 238–246 with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.

tinnitus in humans. Behavioral test models have been devised for several species. The findings are evidence that the conditions causing tinnitus in humans are also the same for common experimental animals.

Tinnitus and Changes in Spontaneous Firing Rate

A generally accepted neural correlate of tinnitus is increased spontaneous firing rate (SFR), and this is supported by objective measurements in humans as reviewed above. The fact that tinnitus is audible and ‘normal’ spontaneous activity in the auditory system is not (or only under extreme conditions such as being for some time in a completely soundproof room) indicates that (1) either the SFR is higher than a certain threshold set by evolution and lifetime experience (a

type of memory) or (2) the spontaneous firing activity in persons with tinnitus is different from that in people without tinnitus. These differences could be in temporal properties, such as burst firing (demonstrated to occur in the IC) or other changes in the serial correlation between the firings. It could be changes in the interspike interval distribution or, conversely, changes in the spectrum of spontaneous activity. It is also possible that changes occur in higher-order statistics of the population firing activity. However, most commonly, the changes observed in animal models are in the SFR as shown in the next two paragraphs.

Noise trauma. After noise trauma, the SFR in auditory nerve fibers (ANFs) was generally significantly reduced, but was significantly enhanced *in vitro* in chinchilla DCN. The *in vivo* recordings in hamster DCN indicated massive increases in SFR of superficial layer cells 5–180 days after noise exposure but not 2 days after. Complete or nearly complete section of ascending or descending inputs did not significantly affect the magnitude of DCN hyperactivity. The SFR increase correlated significantly with the strength of the behavioral index of tinnitus in the same animals. In the IC of mice, noise trauma significantly increased the SFR. In cat auditory cortex (AC), significant increases in SFR occurred after 2 h following the trauma, but not immediately (<15 min) following it. At least 3 weeks after the trauma, the SFR was significantly larger than in controls at all recording sites tested and not in the region of the hearing loss alone, although that region showed more pronounced changes.

Salicylate. Chronic salicylate application in doses that did not produce hearing loss did increase the spontaneous activity of the auditory nerve. Such low doses of salicylate in humans can result in tinnitus. Larger, acute doses (200 mg kg^{-1}) of salicylate failed to increase SFR in cat and gerbil ANF, whereas a still higher dose of 400 mg kg^{-1} did. In rats, moderate doses ($>200 \text{ mg kg}^{-1}$) of salicylate resulted in decreased mean interspike intervals (suggestive for increased SFR or burst firing) in IC neurons. In the IC of guinea pigs, 200 mg kg^{-1} of sodium salicylate increased the mean SFR threefold at 100 min after application. In mice, however, a dose of $200\text{--}300 \text{ mg kg}^{-1}$ decreased SFR significantly in IC. In anesthetized cats, salicylate at a dose of 200 mg kg^{-1} did produce increased SFRs for high characteristic frequencies (CFs) in secondary auditory cortex, but did not have an effect in primary auditory cortex. In awake rats, salicylate levels of 150 mg kg^{-1} that induced behavioral signs of tinnitus decreased SFRs in primary auditory cortex significantly. Therefore, salicylate results appear to be variable and more species dependent than those found for noise trauma.

Changes in Neural Synchrony

The degree to which the action potentials from two different neurons are time locked or, in other words, fire in synchrony may be important for tinnitus, as also suggested by the increased AEPs in people with tinnitus. Neural synchrony under spontaneous firing conditions was studied in the same single-neuron pairs before and after a 1-h exposure to a 5- or 6-kHz tone presented at a level of 115–120 dB SPL. The average hearing loss 6 h after the trauma was about 40 dB in the range of 6–32 kHz. Recordings from the primary auditory cortex were done using two multi-electrode arrays of eight electrodes each in each cat before and up to 6 h after exposure to the trauma tone while leaving the electrodes in place. The increase in peak synchrony was significant within 15 min after the trauma, and increased to an average of 54% increase over the pre-exposure values at 2 h after the trauma. Thus, increased neural synchrony may be a more direct contributor to tinnitus than increased SFR, because the latter takes 2 h to significantly increase, and tinnitus is generally experienced immediately after noise trauma. Chronic effects of noise trauma showed that the peak synchrony for neuron pairs in reorganized cortical areas were significantly higher than for pairs in nonreorganized areas and also significantly higher than for controls. Thus, cortical tonotopic map reorganization (see below) and increase in peak cross-correlation coefficients are closely linked.

Changes in Cortical Tonotopic Maps

Local mechanical damage to the cochlea, ototoxic-drug damage to the cochlea, and noise-induced hearing loss, all cause tonotopic map changes in primary

auditory cortex (**Figure 4**). The map changes are not causally related to the hearing loss but are always accompanied by increased SFR and increased neural synchrony. Map changes do not occur, if immediately after noise trauma, a compensatory complex sound that mimics the expected hearing loss in bandwidth and level is presented for several weeks. When this happens, the downregulation of inhibition that usually follows noise-induced hearing loss likely does not occur and the unmasking of new excitatory inputs does not happen or is reversed. When this ‘unmasking’ trigger for tonotopic map reorganization is absent, map changes do not occur despite a remaining hearing loss. If the enhanced acoustic environment does not match the hearing-loss frequencies, the effect thereof is lost.

Population Neural Activity

Despite a reduction in the compound action potential amplitude of the auditory nerve and the local field potential (LFP, an intracranially measured AEP) in the cochlear nucleus following noise trauma, the LFP amplitude in the auditory midbrain was typically enhanced at high intensity levels. After salicylate application, single-unit firing rates in the AC of awake rats were reduced, but the LFP was enhanced at 5, 8, and 16 kHz, suggesting increased neural synchrony or reduced lateral inhibition, resulting in unmasking of new excitatory units. These changes are thus comparable to the absence of changes in the auditory brainstem response and the increased cortical evoked potentials as measured in humans (see above).

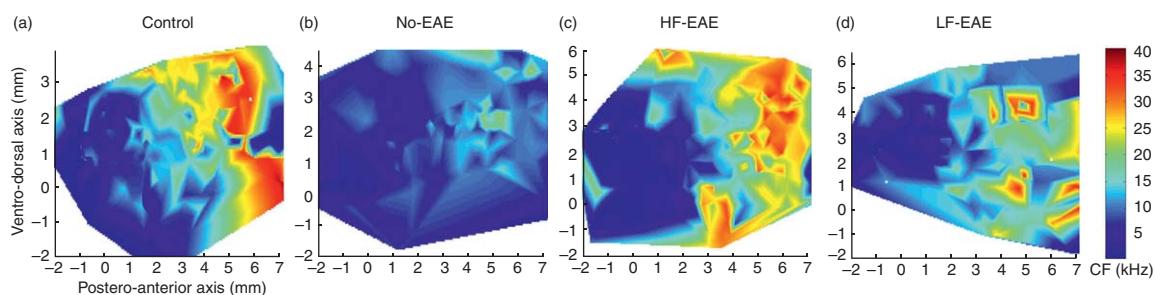

Figure 4 (a) Cortical tonotopic maps in control cats; (b) in cats following noise trauma and rearing in a quiet environment; (c) in cats following noise trauma and rearing in an enhanced acoustic environment that produced increased activation in the hearing loss range; and (d) in an enhanced acoustic environment that emphasized the normal hearing range. Along the horizontal axis (parallel to the midline) distance from the tip of the posterior ectosylvian sulcus (PES) is plotted, and along the vertical axis the distance in the ventral-medial axis again from the tip of the PES. The color bar indicates the characteristic frequency of each recording site with blue colors indicating low frequencies and red colors high frequencies. One notices the absence of high frequencies in the tonotopic map, and thus reorganization of the map, following noise trauma and rearing in quiet. These changes do not occur if an enhanced acoustic stimulation of the hearing loss frequencies occurs (c), but do occur when the enhanced acoustic stimulation does not match the hearing loss frequencies.

Homeostatic Mechanisms as a Cause for Tinnitus?

Homeostatic mechanisms are assumed to stabilize the mean activity of a neuron around a certain target level. The changes occur over timescales on the order of days and typically are effected by scaling the efficacy of all synapses of a neuron. Homeostatic plasticity can be modeled by a change in a gain factor that is proportional to the deviation of the mean activity from a certain target rate. In such a model, homeostatic plasticity restores the mean firing rate of a neuron after hearing loss. This mean firing rate includes both stimulus-driven and spontaneous parts, and both will be scaled upward to the target level. This applies to all neurons along the auditory pathway. Restoring the mean rate, therefore, likely increases the spontaneous rate throughout the auditory system. Interestingly, such a model also allows the evaluation of how the pathologic changes could be reversed through additional sensory stimulation. It is obvious that hyperactivity could be reversed in the model by restoring the regular spatial distribution of firing rates of auditory nerve fibers. As reviewed above, the effectiveness of stimulation that restores this spatial distribution of firing rates in the auditory nerve fibers has been demonstrated (**Figure 4**).

Conclusion

In the search for bottom-up (i.e., sense-organ driven) mechanisms of tinnitus, increased SFR and neural synchrony have attracted most of the attention. It is not clear whether increased SFRs in subcortical structures alone will lead to increased SFR in cortex, despite the action of homeostatic mechanisms. It is far more likely that increased neural synchrony in subcortical structures will propagate effectively along the auditory pathway and ultimately result in increased synchrony and/or increased SFRs in cortex. Increased neural synchrony combined with increased SFR would be very powerful indeed. Human studies using fMRI that find increased activation in certain brain regions potentially implicate an increased SFR in those regions. Enlarged evoked potential or magnetic fields in addition imply increased neural synchrony as its underlying mechanism. The fMRI data point to increased SFR in midbrain, thalamus, and cortex, whereas evoked potential data point to increased synchrony in these same structures. It is likely that both conditions co-occur as both may result from downregulated

inhibition levels. The laterality of the strongest activity in the EEG gamma band corresponded clearly with the laterality of the tinnitus percept. Gamma activity being a consequence of enhanced spontaneous neural synchrony was more prominent in tinnitus subjects than in controls. In that sense, gamma activity may play a similar role as it has been posited to do in normal auditory perception.

Glossary

Binocular rivalry – In this paradigm, two different images are presented separately to the two eyes. Under some conditions, the two images are fused to a combined perception, but this occurs only rarely. Most of the time one of the two images is perceived and the other image is suppressed. Which of the two images is perceived alternates, similarly as in bistable stimuli such as the Necker cube, for instance.

Functional magnetic resonance imaging (fMRI) – Using the different magnetic properties of oxygenated and deoxygenated hemoglobin, this imaging technique measures the blood-oxygen-level-dependent (BOLD) signal. A high BOLD signal is caused by a high oxygen level, which is in turn caused by a high cerebral blood flow. Cerebral blood flow increases if the consumption of oxygen is high. Neurophysiological studies showed that the BOLD signal is related to the input and the internal processing of a given area rather than its output.

Motion detector or Reichardt detector – A neural circuit for the detection of visual motion proposed by German biologists Werner Reichardt and Bernhard Hassenstein. It is based on the simple idea that represented movement as a position change from location A to location B, occurring within a certain time period t . A neuron N_c receives input from two neurons N_a and N_b whose receptive fields are at locations A and B. The connection from N_b to N_c is delayed by time t , and the neuron N_c only fires if the signal from N_a and N_b reaches N_c at the same time: it multiplies, so to speak, the incoming signals. In other words, the neuron N_c only fires if N_a is stimulated at time t later than N_b . Thus, neuron N_c is a detector of motion from location B to A. To disentangle flickering stimuli from true motion, two Reichardt detectors with opposite directions have to be combined.

Primary visual cortex (V1) – V1 is located in the occipital cortex and is crossed by a white stripe of axons; therefore, it is also called striate cortex. It is the first cortical area that processes visual information transmitted by the optic radiation. A lesion of V1 leads to blindness in the affected visual field and to a loss of conscious visual perception. However, V1 is not sufficient for conscious visual experience because lesions in other parts of the brain can lead to blindness for selective visual attributes such as motion or faces.

Random-dot kinematogram – Such displays are often used to study motion perception. Dots are distributed randomly in the display. In each new frame, a few randomly selected dots (i.e., the signal dots) are replaced by dots in the same direction and with the same step size, while the remaining dots (i.e., the noise dots) are replaced randomly. The advantage of this kind of stimuli is that they allow to vary the strength of the motion signal by varying the proportion of signal dots. Most importantly, motion cannot be recovered by following a single dot. Instead, information has to be integrated across the visual field.

Stereogram – In a stereogram, two nearly identical pictures are presented to the two eyes. By introducing spatial offsets to objects between the two pictures, a perception of depth is introduced. In vision research, stereograms are often made up of random arrangements of black and white dots, with some spatial offset between the pictures for the two eyes. In a special version, the anticorrelated random-dot stereogram, one random-dot pattern is the contrast-inverted version of the other pattern.

The significance of visual perception for the daily life of humans and other primates can be seen by the number and size of cortical brain areas associated with visual processing and the preparation of vision-related behavior. Next to the primary visual cortex (V1) and the adjacent area V2, which occupy around 13% and 10% of the cortex, respectively, more than 40 anatomically and/or functionally distinct subdivisions of visual responsive cortex were identified. In total, around 60% of the primate cerebral cortex is involved in the perception, interpretation, and the reaction to visual stimuli.

Overview

Information processing in the visual system begins with the photoreceptors in the eye. In the retina, there is a large degree of convergence from photoreceptors to ganglion cells. In the primary visual pathway, the different ganglion cells send their axons to the cells in the different layers of lateral geniculus in the thalamus, which project mainly to the primary visual cortex. In the cortex, there is

an enormous amount of divergence. Every part of the visual field has to be examined along several properties such as color, orientation, texture, movement, and depth. After this initial stage of processing in V1, processing of visual information splits into two distinct pathways, a dorsal processing stream toward the parietal cortex and a ventral processing stream toward the lower temporal cortex.

Despite our knowledge about where different aspects of visual stimuli are processed, our understanding of how they are processed is rather limited. The initial stages of cortical processing seem to deal with the extraction of single stimulus features. In V1, neurons are capable of signaling the orientation and color of stimuli. Enormous progress has been made in identifying the selectivity of higher levels of processing for specific visual stimuli (e.g., hands, faces, or movements), but the computations underlying this selectivity are largely unknown. The processing stages from simple edge primitives to whole objects are still a big mystery for scientists, and the fact that the visual system can solve this in less than 100 ms does not make its solution any easier!

Retinal Processing

The human retina is densely packed with photoreceptors that transform light into electrical signals. Humans possess four different types of retinal photoreceptors: rods and three types of cones. Whereas rods have a high sensitivity and are important for perception under low illumination, cones are the basis of perception during daylight. The three different types of cones differ in their spectral absorption curves and thus enable the perception of color. Information from the cones is conveyed to retinal ganglion cells through a complicated network of horizontal and vertical connections that achieve a highly efficient coding process.

Retinal ganglion cell are always stimulated from the same photoreceptors, which react to stimuli in a certain part of the visual field. This area in the visual field, where visual stimulation causes a physiological response, can be accurately mapped, and is called the receptive field. Ganglion cells that are positioned adjacent to one another have overlapping receptive fields, and they also project to the neighboring neurons in the next, higher processing stage. This spatial order is maintained from the receptor level in the retina to higher levels of processing in the cortex. At each stage, the size of the receptive fields increases.

Almost all (90%) retinal ganglion cells send their signals through their axons (the optic nerve) to the lateral geniculate nucleus (LGN), which is located in the thalamus. The LGN is the most important subcortical relay station between eye and cortex. It is made up of six layers:

the two inner layers (1 and 2), which contain relatively large (magno-)neurons (about 10% of the LGN population) with large receptive fields and fast, transient responses. The four outer layers contain smaller (parvo-)neurons (about 80% of the LGN population) with small receptive fields and slow, sustained responses. The distinction between a magno- and a parvocellular pathway starts at the first synapse in the retina with diffuse bipolar cells and parasol ganglion cells for the magno- and midget bipolar and midget ganglion cells for the parvocellular pathway. Although there are differences in the functional properties of these neurons, our visual system could work with only one of these pathways. The biggest difference is that magnocellular cells of the LGN are almost completely colorblind. They process information only about the brightness of the visual stimuli, have a higher contrast gain at all luminance levels, and are involved in the processing of rapid picture sequences and flickering stimuli. The parvocellular layers of the LGN process information about the brightness and red–green differences. Damage to parvocellular layers of the LGN leads to a loss of color vision, and also results in a reduction of visual acuity. The information regarding blue–yellow differences is passed on to the koniocellular layers of the LGN. These are thin in-between layers and were discovered more recently.

Through the preservation of spatial order of the retinal ganglion cells, also the LGN is retinotopically organized. In the optic chiasm, axons of nasal–retinal ganglion cells cross the side, so that each LGN receives only input from the contralateral visual field. However, the separation of the signals of the two eyes is still preserved as the layers 1, 4, and 6 receive input from the contralateral eye and the layers 2, 3, and 5 from the ipsilateral eye. The visual maps of the six layers sit above one another, and the receptive field of vertically aligned neurons are located at the same retinal position. The LGN is not only a relay station for incoming signals from the eye to the V1, but it also receives input from the cortex and the brainstem, which modulates the retinal information stream into the LGN.

Retinal ganglion cells have small circular receptive fields, which show an antagonistic center-surround organization. In the fovea, the location of greatest acuity, the receptive field centers are only a few minutes in diameter, whereas in the periphery they reach 3°–5° of visual angle. Approximately half of the ganglion cells are the so-called on-center cells: they are excited by light projected into their center and inhibited by light illuminating their surround. The remaining are off-center cells, and they are inhibited by central light and excited by surround light. If the entire receptive field of either ganglion cell-type is stimulated with light, they respond only weakly. Because of this antagonistic center-surround mechanism, ganglion cells are very sensitive to spatial contrast. If ganglion cells are stimulated by, for example, black

and white patterns, the simultaneous inhibition and excitation of center and surround causes a response behavior, which can lead to increased differences in brightness perception (Mach bands; Figure 1).

Lateral inhibition intensifies the signals at the edges and blurs the regions of slower-intensity transition. A statistical analysis of natural scenes shows that a large amount of our visual environment consists of stimuli of slow-intensity transition. If ganglion cells did not encode the relative intensities of an image, many neighboring ganglion cells would forward the same signal, which would be very inefficient for the analysis of image information. Instead, because of the lateral inhibition, the bandwidth is reserved for accentuating edges.

A similar problem of redundancy, which is inefficient encoding, arises from color vision. Color vision results from the three different types of cones in the retina. They

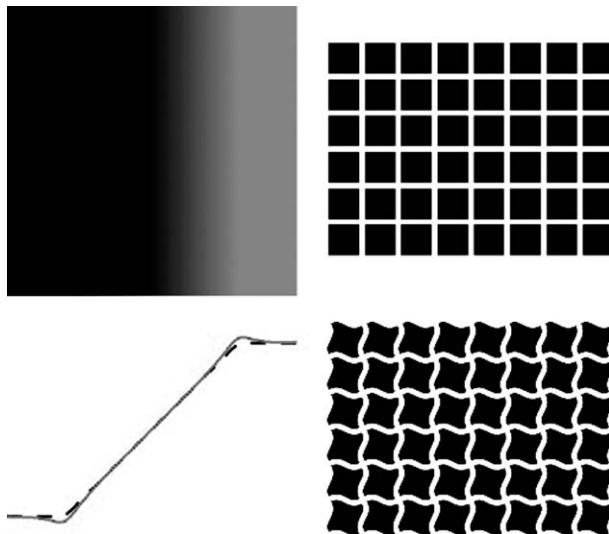

Figure 1 Lateral inhibition. (Top, left) Mach bands. In the middle of the nineteenth century, the physician Ernst Mach discovered that in the perception of a stimulus with a luminance profile, dark and light bands appear at the points where the contrast begins to change physically. (Bottom, left) Stimulus intensity (black) and the resulting neuronal activity of an on-center ganglion cell (red). (Top, right) Hermann grid. When looking at the Hermann grid, illusory small gray disks appear at the white alley crossings situated away from the fixated crossing. These illusory spots may be explained by the centre-surround antagonism or lateral inhibition within the concentric receptive fields of retinal and/or geniculate ganglion cells. The illusion is strongest when the bar width matches the size of receptive-field centers. The smaller diameters in the fovea explain why the illusion tends to be absent in foveal vision. (Bottom, right) Grid modification. When the grid edges are curved, the illusion is reduced, suggesting that also orientation-sensitive cells in the LGN and visual cortex contribute to this illusion. The straight and the curved Hermann grid were taken with permission from Geier J, László B, Hudák M and Séra L (2008) Straightness as the main factor of the Hermann grid illusion. *Perception* 37(5): 651–665 published by Pion Limited, London.

differ from one another in terms of their spectral absorption of light, as shown in Figure 2.

One cone-type, the s-cone, receptor absorbs light mostly in a short-wavelength area between 350 and 450 nm with a peak of 420 nm. The absorption spectrums of the other two cone types peak in the middle- and long-wavelength part of the spectrum and have largely overlapping sensitivities. The reason for this similarity in absorption is that these cones evolved from the same ancestor rather than recent (approximately 35 million years ago). This means that for the eye, the signals of long- (L-) and middle-wavelength-sensitive (M-) cones are highly correlated. The redundancy can be cleaned up by encoding the signals differently. The calculated sum total of the L- and M-cones corresponds to luminance. At the same time, the difference between the signals from the L- and M-cones is calculated, and the difference between the signals from the S-cones and the sum of the L- and M-cones. These difference mechanisms are called color-opponent mechanisms, and their signals are passed on to the parvocellular and the koniocellular layers of the LGN. The color-sensitive neurons in the parvocellular LGN layers show a preference in the red–green cardinal color direction and those in the koniocellular layers, in blue–yellow. Neurons that react strongest to mixed colors, for example, orange, first appear in area V1.

Cortical Visual Processing

Retinotopy and Maps

When we fixate a small object, its image is projected onto a small position in the center of the retina, the fovea centralis, which occupies around 2° of the vision field. Foveal vision has the greatest acuity because here the density of photoreceptors is highest, and also that of the retinal ganglion cells; and the proportionally largest area of visual cortex is devoted to it. It is only in the fovea that we have a high resolution of detailed vision, which is essential for activities such as reading this text. The fovea contains approximately 50 000 ganglion cells per square millimeter compared with 1000 in the periphery. In addition, in contrast to other retinal areas, photoreceptors in the fovea have a 1:1 connection with ganglion cells. Because only a few ganglion cells project to a single neuron in the LGN, the fovea, which only takes up 0.01% of the whole retina, and its immediate surrounding, is represented by approximately half of the neurons in the LGN. The V1 maintains these proportions. Half of the neurons in V1 represent the fovea and its directly connected regions (Figure 3).

Recent investigations suggest that the increased representation of the fovea in the cortex is not only due the density of foveal ganglion cells, but it is also the result of assigning additional area for foveal input. A ganglion cell

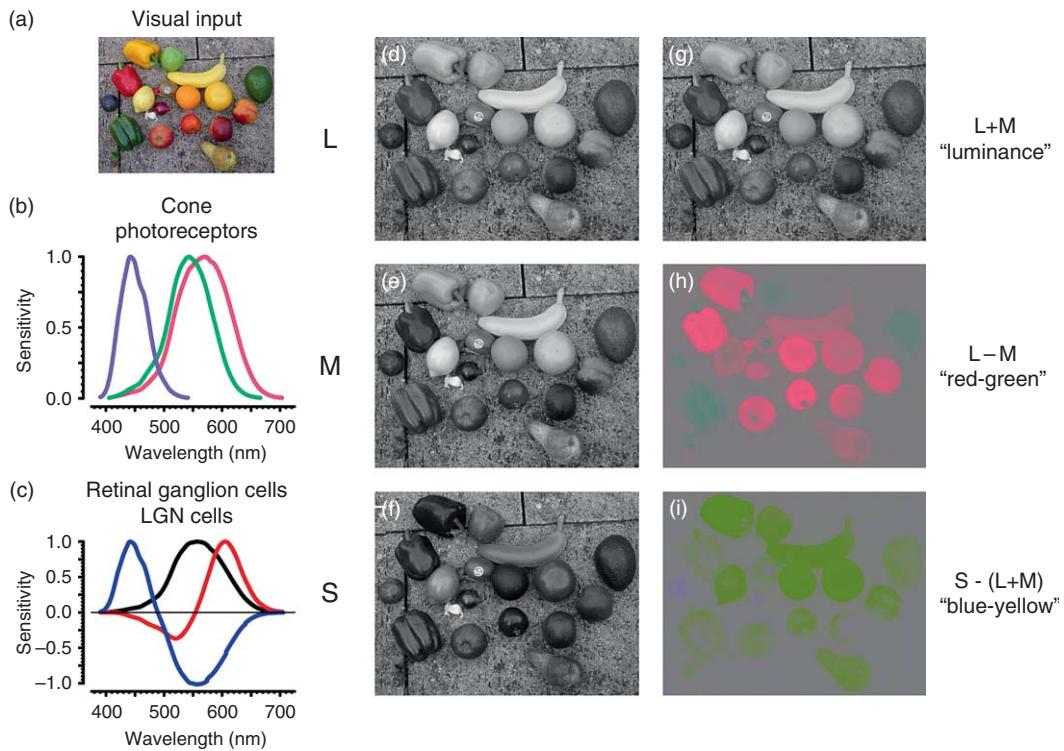

Figure 2 Opponent colors. The transformation of cone signals in color-opponent coordinates. Color vision (e.g., of the picture shown in (a)) starts with the absorption of light by three types of cone photoreceptor (L, M, and S) in the retina (b). The three black and white pictures ((d)–(f)) show how the three cone types are excited by the image in (a). Please note that the L- and M-cone images are similar. The electrical signals generated by these photoreceptors go through complicated circuitry (c) that transforms the signals into three channels: one carrying luminance and the other two being color opponent, red-green and blue-yellow ((g)–(i)). These color-opponent signals are sent to the visual cortex through the thalamic lateral geniculate nucleus (LGN).

close to the fovea is connected to 3–6 times as many cortical cells than a ganglion cell in the retinal periphery. The maximum available processing capacity is concentrated on a relatively small foveal region at the center of our visual field. Because the eyes are movable and any object of interest can thus be brought to project onto the fovea, a large field of vision (180° horizontally) and a precise recognition of details can be achieved at the same time with rather limited resources.

It is known since long that the LGN and V1 are organized in visual field maps, which means that the receptive fields of neighboring neurons cover adjacent areas in the retinal image. Recent advances in functional magnetic resonance imaging (fMRI) have made it possible to investigate these visual maps in higher cortical visual areas as well. Visual maps have been found in various visual areas in the occipital, temporal, and parietal cortices, and these visual maps are arranged in clusters of several maps with a confluent representation of the fovea. As most of these different visual areas are sensitive to specific aspects of the stimuli, the visual scene is sampled several times in the human brain in a spatial orderly fashion. Such topographically organized maps might be especially useful to combine information from different

modalities. For instance, neurons in the parietal cortex have overlapping receptive fields for visual and auditory stimuli and might contribute to the integration of visual and auditory signals.

The Primary Visual Cortex (V1)

David Hubel and Torsten Wiesel examined the response behavior of neurons in V1 to visual stimuli, and they received the Nobel prize in 1981 for this work. In contrast to neurons in the retina or the LGN, V1 neurons respond only slightly or not at all to point-light stimuli, but respond very strongly to short light stripes or lines. Depending on the type of visual stimuli, several types of neurons can be distinguished.

Simple cells respond to stripes or lines of a certain orientation. The elongated receptive fields of simple cells are also distinguished by an excitatory and inhibitory region lying next to one another and oriented in a certain direction (Figure 4). Following the work of Hubel and Wiesel, these long excitatory and inhibitory regions in simple cells are created through the convergence of a few concentric organized cells. Lateral connections between oriented cells lead to a further sharpening of the orientation tuning.

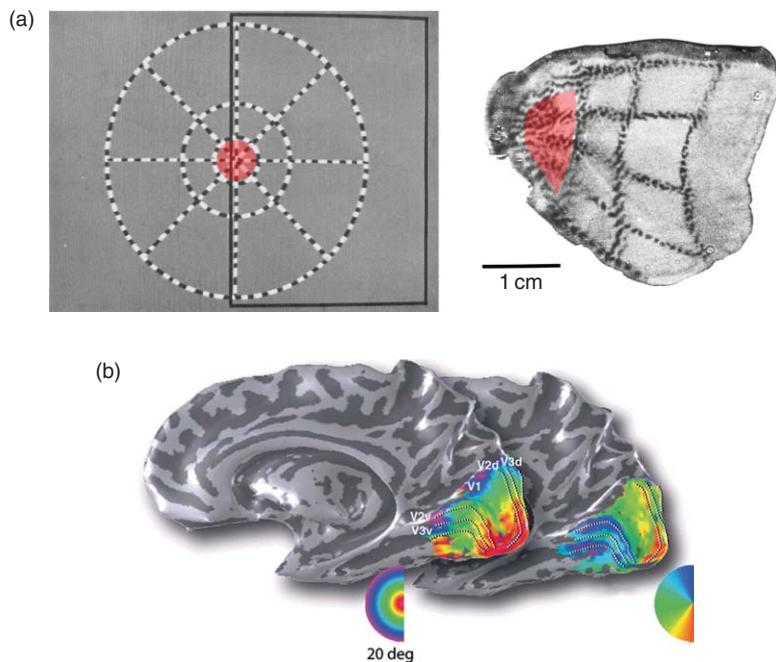

Figure 3 Representation of the fovea in the visual cortex. Although the fovea only takes up an area of 2° in the visual field, it uses a large proportion of the neurons in the primary visual cortex (V1) and the extrastriate visual areas (V2) and (V3). (a) Staining. The stimulus for the mapping of the receptive fields is shown left and the resulting mapping on the right. The foveal region in the stimulus and the cortical tissue is shaded in red. (b) Retinotopic organization of visual areas V1, V2, and V3 measured by fMRI in the human brain with a series of expanding concentric annuli (left) or rotating sectors (right) (a) (modified from Tootell RB, Silverman MS, Hamilton SL, Switkes E, and De Valois RL (1988) Functional anatomy of macaque striate cortex. V. Spatial frequency. *Journal of Neuroscience* 8: 1610–1624. (b) From Wandell BA, Dumoulin SO, and Brewer AA (2007) Visual field maps in human cortex. *Neuron* 56(2): 366–383.

Accordingly, the strongest response results from an elongated stimulus presented in the same orientation and width as the excitatory region of the cell. The selective sensitivity for a particular orientation is measured by comparing the cell's response to stimuli of different orientations (orientation-tuning curve).

Complex cells do not show a clear spatial division between excitatory and inhibitory regions in their receptive fields. However, they do answer selectively to the orientation of elongated stimuli, but independent of the exact position of the stimuli within the receptive field. The properties of the receptive fields of complex cells can also be explained in terms of convergent excitatory input from simple cells with similar receptive fields.

Hypercomplex (end-stopped) cells respond to edges or lines of a specific length. If the stimulus exceeds what has been termed the ‘classical receptive field’ or ‘minimum response field,’ activation of the nonclassical surround region modulates the firing of the cells.

By placing microelectrodes into the cortex, it was discovered that the center of the receptive fields from overlapping neurons are at the same location in the visual field and that these neurons also prefer the same stimulus orientation. By examining the orientation preference of neurons tangentially along a certain cortical layer, we find that the optimal stimulus orientation shifts in continuous

steps through all angles, as we measure from consecutive, adjacent, column-shaped regions. These were conveniently named orientation columns, and each column has a width of approximately $30\text{--}100\ \mu\text{m}$. With the help of a radioactive substance, the activity of neurons can be directly imaged on the cortical surface. Using this method, it was possible to prove the organized structure of these columns in V1. We find the organized orientation columns along one dimension and the so-called ocular-dominance columns along the other dimension, which show a preference for the left or right eye, consecutively alternating as we measure from one column to the next.

To summarize, V1 seems to be made out of a column system, which is characterized by three features with respect to (1) the position of the receptive fields (all neurons within approximately 1 mm^2 receive their input from the same location on the retina); (2) the ocular-dominance dimension (along this dimension, the columns of the left and right eyes alternate systematically; so within a 1-mm^2 section, there are essentially two ocular-dominance columns, one for each eye); and (3) the orientation dimension (every ocular-dominance column contains a complete set of orientation columns from 0° to 360°). Hence a 1-mm^2 section contains the two eye-dominance columns and a series of orientation columns and is called a

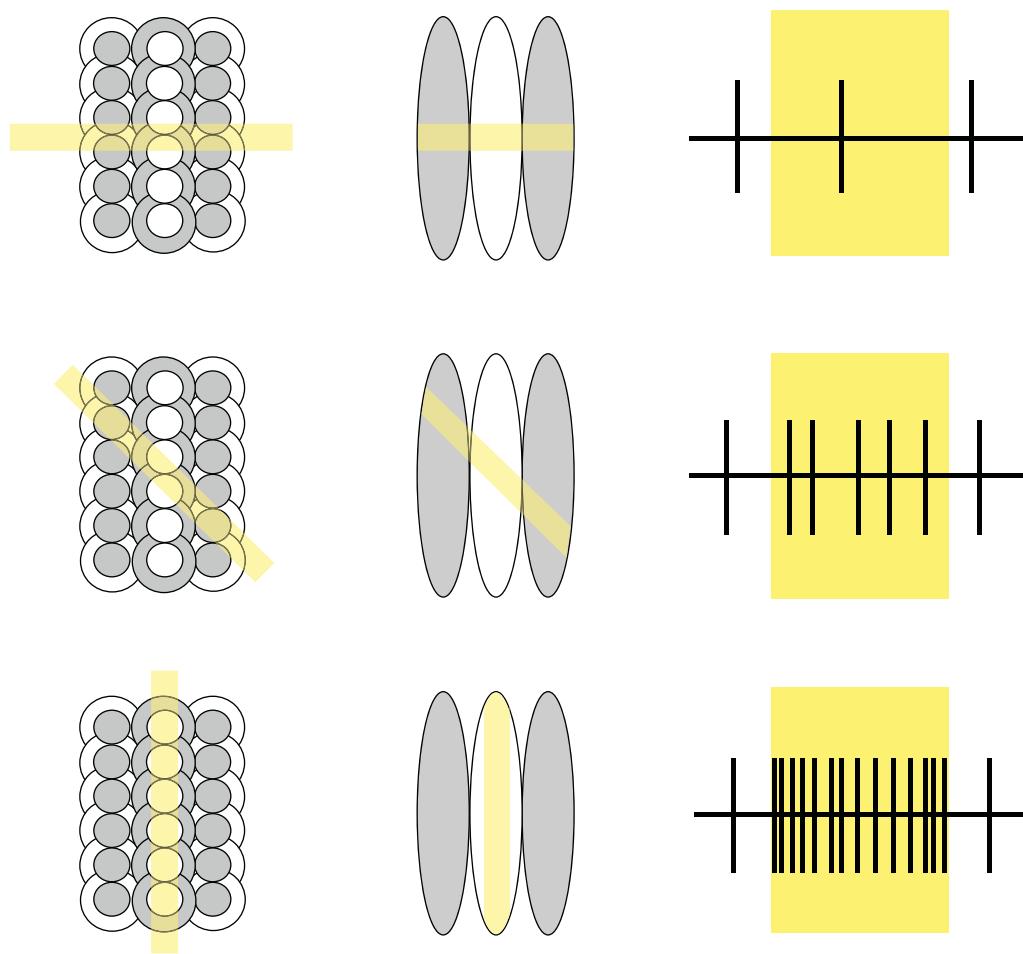

Figure 4 Orientation sensitivity and response behavior of neurons in V1. The left side shows how oriented receptive fields can be combined from concentric receptive fields in the input layer. Excitatory and inhibitory areas are shown in white and gray, respectively. In the middle is the larger orientation sensitive receptive field of simple cells. The right side demonstrates the simple cell's response to light bars (shown in yellow) of various orientations. Every vertical line corresponds to one action potential. This neuron reacts best to vertical light bars.

hypercolumn. The surface of the primary visual cortex is made out of regular ordered hypercolumns, which represent the necessary requirements for the detailed analysis of visual stimuli.

Parallel Processing Pathways

In the 1980s, the first parallel-processing computers appeared and some scientific theories of brain processing have been modelled on this technology. The functional column system in V1 shows that different aspects of visual stimuli are processed distinct from each other. Every image point is analyzed in terms of its orientation, color, movement, and depth. It has been proposed that the brain computes all these local analyses at the same time in parallel. There is some empirical support for this hypothesis. At the level of anatomy, V1 and V2 show the largest number of distinct connections. The enzyme cytochrome oxidase (CO) makes those areas rich in this substance

visible when stained. Within layers 2 and 3 of area V1, there are CO-rich blob regions in the centers of the hypercolumns, which result in a characteristic spotted appearance. In area V2, we also see a distinct pattern when stained with CO, in which thick and thin stripes alternate with pale stripes. It has been hypothesized that these anatomical differences also have functional significance. The idea is that color is processed in the blob regions of V1 and the thin stripes in that of V2. A similar pattern was postulated for the analyses of movement (in the thick stripes of V2) and of forms (in the pale stripes of V2). However, several in-depth studies found only a slight tendency for the postulated division. In general, most neurons from for example V2 simultaneously react to several visual attributes. A strict division of visual information in parallel-processing pathways could not be confirmed. In addition, psychophysically, it has been shown that form and movement can also be perceived by stimuli exclusively defined by color. For further

evaluation of visual signals, simultaneous, multidimensional analyses have an important advantage. The information of different properties of an object (e.g., color, form, and movement) does not have to be combined again at an uncertain higher-processing level.

Cortical Computations

Several investigations have been carried out to identify the areas in the visual cortex containing those neurons capable of coding for a particular stimulus property. However, knowing where a calculation might be performed is not nearly as interesting as knowing which computation is performed. Over the years, there has been progress with respect to the computations made by visual cortex. A few of these features are considered separately.

Motion

Motion perception plays a central role in visual perception. Not only is it used to compute the speed and direction of moving objects, but it is also quite important for the control of one's own body and eye movements. Research in this area has succeeded in determining a cortical neuronal circuit whose properties are also consistent with several behavioral experiments. Around 1970, the small middle temporal area (MT, see Figure 5) was discovered in monkeys, which seems to be a very important area for local motion processing. It primarily contains neurons sensitive to the direction of motion stimuli, and acts similar to the Reichardt's model. The specific motion disorders of patient L.M., who suffered from bilateral strokes in the temporoparietooccipital cortex, confirmed that area MT is very important for motion perception in humans. In monkeys, bilateral lesions of area MT led to deficits in motion perception; however, if these lesions are small, monkeys recover within a week.

The combination of single-cell recordings, microstimulation experiments, and psychophysical studies in alert behaving monkeys provided direct evidence that neurons in area MT are involved in the process of determining the direction of motion of a stimulus. In these experiments, random-dot kinematograms were used and alert monkeys were trained to signal the direction of motion. At the same time, the activity of single cells in MT was measured. This way, the activity of single cells predicted quite precisely the direction of motion seen by the monkey observer. On average, neurons showed the same motion sensitivity as the monkey, with some neurons being slightly better and others slightly worse. To determine the behavioral response, the activity of a large number of neurons is averaged. Further work used microstimulation and found that stimulating a single-direction column in

area MT systematically affected the behavioral judgments of the monkey, as if a visual stimulus moving in the direction corresponding to the stimulated column had been presented. This result impressively demonstrates the significance of neurons in area MT for the perception of the direction of motion.

However, area MT is not the sole physiological basis for all kinds of perceived motion. For many different types of motion, such as biological motion, certain types of second-order motion or optic flow, cortical activity in several other areas has been observed in neuroimaging studies. Neurons in area MT signal the local motion of stimuli, even when human observers perceive a global motion in the opposite direction, indicating additional neural substrates for the perception of motion.

Color

Initial studies of the functional architecture of primate visual cortex found only a small percentage of about 10% of all neurons devoted to the analysis of color signals. In these studies, the quest was for neurons that would respond to stimuli defined by color only, and not to luminance. According to a view promoting a functional segregation, it was thought that these neurons would analyze the color of objects, while other specialized neurons would deal with form, motion, and depth. In contrast to these results, later neuroimaging studies observed a strong and vigorous response to color in V1 and many extrastriate visual areas that exceeded the response to luminance stimuli. The solution to this seeming contradiction was found when the color properties of single neurons in V1 were investigated in more detail. There is a large proportion of neurons that responds well both to color and to luminance. This is in line with anatomical findings that the three streams (Figure 2) that arrive in the visual cortex from the retina do not remain segregated but do get mixed to a large degree. Along these lines, many recent studies failed to find a strong segregation of functional properties in V1 and V2. Rather, it seems that the tuning of each cell for different visual stimulus attributes is more or less statistically independent. For example, knowing that a cell is selective for color does not allow a prediction about the orientation selectivity of that cell.

Although it was initially thought that the chromatic properties of cortical cells in V1 are quite similar to those of the retinal cells, more details have been discovered in recent years. In the retina, responses of a neuron to all colors can be predicted just by the knowledge of the cells' preferred color, since these neurons sum their cone inputs in linearly. Furthermore, the preferred colors fall into two clusters of L-M and S-(L+M). While a majority of the cells in V1 still follow the linear model, the color preferences are more widely distributed. These cells still show quite a broad tuning to color, responding to many

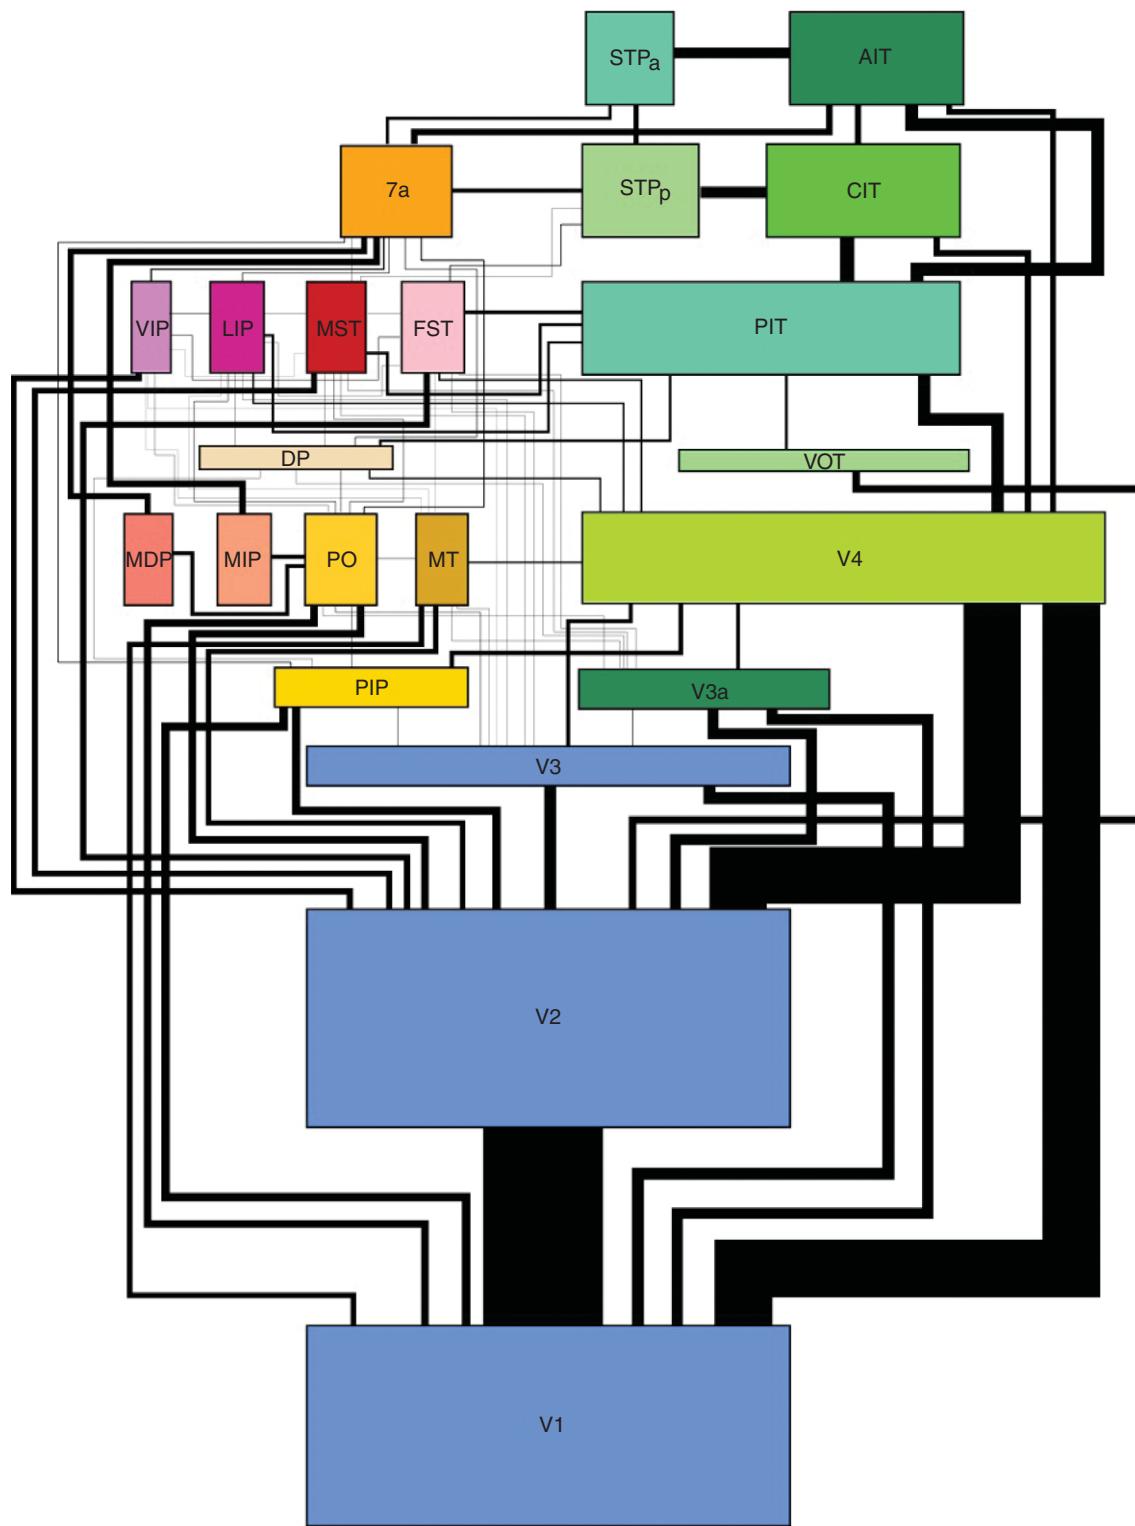

Figure 5 Cortical visual pathways. Schematic representation of the main anatomical connections between different cortical areas of the human vision system. The size of the boxes corresponds roughly to the relative size of the regions, and the thickness of the connections to the strengths of the anatomical connections between them. different hues. In V2, a subpopulation of neurons that has more restrictive responses limited to a rather narrow range of hues was found, mimicking the behavior of the so-called higher-order color mechanisms observed psychophysically. Similar effects have been reported in V4, and there seems to be a progression from V1 through V2 to V4 and inferotemporal (IT) cortex in terms of the specificity of the chromatic response.

Another important characteristic of color cells that emerges in V1 is double opponency. As mentioned above, the single-opponent cells in the retina and LGN cannot signal spatial and chromatic properties at the same time. They respond best to the color of large unstructured stimuli. Double-opponent cells are both spatially and chromatically opponent and are therefore able to signal chromatic boundaries, for example, a red fruit next to a green leaf. Since they effectively compute color contrast – the difference between two neighboring colors – their response would be independent of the average color in the scene, which is mostly determined by the illumination color. Therefore, this would be an ideal mechanism to achieve color constancy, which is the ability of the primate visual system to assign a stable color to an object, independently of how it is illuminated. These double-opponent cells have been recently found in the primate visual cortex. These are members of the class of cells that respond equally well to luminance and color.

Depth

The perception of depth is a critical ability to act accurately in a three-dimensional (3D) environment. The reconstruction of depth is also a quite fundamental ability of the visual system, since information about depth is lost in the 2D projection on the retina and has to be inferred indirectly by a multitude of monocular and binocular depth cues.

After the invention of random-dot stereograms (RDSs) by Bela Julesz, it became possible to study binocular disparity without possible intrusions of monocular depth cues. Disparity is the horizontal offset between the retinal images in the two eyes. This offset allows to calculate the depth of objects relative to the fixated object. Corresponding image features in the two retinal images have to be identified to make use of this disparity. Therefore, one needs disparity-sensitive neurons, which receive input from both eyes at some spatial offset. Although disparity-sensitive neurons have been found a long time ago in several cortical visual areas, including V1, it was recently shown that the corresponding problem is not solved at the level of V1. Bruce Cumming and Andrew Parker measured neuronal responses to anticorrelated RDSs. In such a display, a random-dot pattern is shown to one eye and the contrast-inverse pattern with some spatial

offset to the other eye. Although these anticorrelated stereograms do not lead to depth perception, they activate the disparity neurons in V1. Therefore, neurons in V1 are not the neural substrate of depth perception. It is also known that neurons in V1 respond to absolute disparity, that is, to the amount of disparity between the two retinal images. More useful for the calculation of depth, however, is the relative disparity between two objects at different distances. There is evidence that neurons in V2 can encode relative disparity.

Through the widespread research on RDS, the effect of monocular depth cues such as linear perspective, texture gradients, relative size, and occlusion had been neglected quite dramatically. In contrast to binocular depth cues, monocular depth cues are perceivable with one eye and are completely contained in the visual scene. More recent work has shown the importance of monocular depth cues and how these different cues are combined with each other and with disparity for a single, optimally reliable depth estimate. It has been shown recently that monocular depth cues have a major effect on the retinotopic mapping in early visual areas. Scott Murray and colleagues presented pictures of 3D scenes that contained a sphere either at a near or a far perceived distance. Using fMRI, they were able to show that the size of activation in the retinotopic map of V1 depends on the perceived size of the sphere and not on the angular size of its retinal projection. This indicates that some monocular depth cues are incorporated in early visual processing. For instance, to use occlusion information for depth perception, it has to be determined to which surface a border that separates two surfaces belongs. This computation of border ownership is present as early as in V2.

Object Recognition

In the temporal cortex, areas respond specifically to certain object categories. For example, some cells in the infero-temporal cortex of primates respond selectively to hands or faces. Within the subset of face-specific cells, there are some that respond best to a frontal view of a face, whereas the removal of certain features, or changing the viewpoint (e.g., a profile view), results in a significant response decrease. Other neurons have been shown to respond best to profiles or to certain facial expressions or single facial parts or features. Sometimes, basic features, such as a line and two points, are enough to cause a response. It appears that there is a division in neuron populations for recognizing common features of faces versus whole faces. There are clusters of neurons with various response properties in the recognition of faces. The identification of an individual face probably occurs because of specific activation patterns of such a neuronal cluster. So there is no single

grandmother-neuron, which is special for recognizing the face of your grandmother. Nonetheless, it seems that there are other such specific areas for representing and recognizing various object categories in the temporal cortex of the human.

Given the high relevance of faces for human perception, it is not surprising to find a visual area that responds most vigorously to faces. However, there are also specialized areas for other types of stimuli: the parahippocampal place area (PPA), which responds best to pictures of scenes and landscapes and the extrastriate body area (EBA), which is activated especially well by pictures of bodies. The PPA seems to be specifically responsive to the spatial layout, which is contained in pictures of visual scenes, and seems also to play a role in navigation.

It is puzzling how neurons in the temporal lobes can have such complex response properties. This process becomes even more puzzling when we consider that these neurons are located only 5–10 processing stages away from V1. Neurons in V1 show high sensitivity to the orientation and length of edge-segments, hence for parts of objects. These neurons must be connected in such a way that whole objects can be recognized, in fact, with only a few processing stages. This was impressively demonstrated in experiments by Simon Thorpe and colleagues where observers had to detect the presence of an animal in a natural scene. The task of the subject was to hold a response key down and to release it only when an animal appeared in the image. It took on average 300 ms for subjects to release to button. This includes the processing time of the stimulus and the motor response. An analysis of evoked visual potentials showed that after only 150 ms, there were differences in the brain activity for the two kinds of pictures (animals vs. no animals). It takes about 50–80 ms for visual stimuli to reach V1, so this leaves only 70–100 ms for cortical processing of this complex task. This short time period allows only 5–10 additional cortical-processing stages.

Conclusion

Major advances in visual neuroscience were achieved in the past 40 years since the breakthrough work of Hubel and Wiesel, although it is clear that the most important processes are still unknown. Until now we have some rough ideas how humans recognize objects and perceive motion, but the visual system and the complexity of neural connections and interactions are still a mystery. The biggest advances are likely to come from the combination of single-cell measures and psychophysics.

Glossary

Body mass index (BMI) – A measure obtained by dividing an individual's body weight by the square of their height. BMI provides an index to assess the normal range of an individual's body weight.

Basal metabolic rate (BMR) – The energy utilized by a person in calories, at rest, in a thermo-neutral environment and while being in a postabsorptive state (fasting for at least 12 h). BMR is a measure of the energy expended by the body for the normal functioning of vital internal organs.

Electroencephalogram (EEG) – The electrical activity of the brain measured by placing highly sensitive electrodes on the scalp.

Maximal oxygen consumption ($\text{VO}_2 \text{ max}$) – Also known as aerobic capacity, a measure of maximal oxygen consumption by an individual during maximal exertion. Increasing ability to transport and metabolize oxygen during high levels of exertion corresponds to the cardiorespiratory and physical fitness of an individual.

Metabolic equivalent (MET) – The amount of oxygen consumed while sitting at rest and is equal to 3.5 mL kg⁻¹ body weight per minute. The intensity of any aerobic physical activity may be gauged by the increase in oxygen consumption measured in multiples of MET units.

Non-rapid-eye-movement sleep (NREM) – It comprises stages 1 through 4 of normal sleep. NREM, unlike REM sleep, is characterized by little or absent eye movements and minimal muscle atonia and autonomic disruption. NREM sleep accounts for 75–80% of total sleep time in normal adult humans. Transition from wakefulness to stage 1 NREM sleep is characterized by the absence of alpha waves (8–13 Hz) usually seen in awake individuals. EEG of stages 1 and 2 of NREM sleep is characterized by theta waves (4–8 Hz), sleep spindles (burst of 12–16 Hz waves occurring for 0.5–1.5 s), and K complexes (single short high-voltage (greater than 100 µV) wave lasting longer than 0.5 s). Stages 3 and 4 of NREM sleep (SWS) produce predominantly low-frequency delta waves (2–4 Hz).

Rapid-eye-movement sleep (REM) – It comprises a stage of normal sleep characterized by rapid movements of the eye, muscle atonia, and autonomic disruption. Adult humans spend about 20–25% of their

total normal sleep duration in REM sleep. EEG during REM sleep is characterized by high-frequency, low-voltage waves distinct from other stages of sleep. A distinct cycling of the different sleep stages including REM sleep occurs in adult humans with each cycle lasting between 90 and 110 min.

Slow-wave sleep (SWS) – Also known as deep sleep, restful sleep, SWS comprises the deeper stages of NREM sleep (stages 3 and 4). The EEG during SWS is characterized by large-voltage (75 µV), low-frequency waves (2–4 Hz) also known as delta waves.

Energy Consumption during Sleep

Humans spend roughly about one-third of their lives in sleep, yet the many functions of sleep remain incompletely understood (Figure 1). In 1983, Horne suggested that sleep serves a restorative function in the brain. In 1995, Benington and Heller proposed a model postulating that the restorative function of sleep involves replenishing brain glycogen. Cerebral glycogen stores are depleted progressively during waking and thereby decreases the availability of a key energy source that supplements brain glucose. The transient reduction in cellular metabolism due to depleting energy sources results in the increased synthesis of adenosine in the brain. The stimulation of adenosine receptors on neurons in the cortex and thalamus results in electroencephalogram (EEG) manifestations similar to those seen during sleep deprivation. This model of sleep regulation as a restorative phenomenon assumes that the restoration takes place primarily during the slow-wave sleep (SWS) segments of non-rapid-eye-movement (NREM) sleep rather than rapid-eye-movement (REM) sleep. Interspecies and interstrain differences may be accounted for by the differences in the sleep-deprivation-induced increase in glucocorticoids. Regional differences in metabolic rate and glycogen metabolism may explain the diverse responses observed in different brain structures during sleep deprivation. Maintaining the brain glycogen energy store does not seem to be functionally related to sleep on a whole brain basis (Figure 2).

Temperature Regulation during Sleep

Evolutionary perspectives reveal that temperature regulation and sleep are interrelated and developed in response to similar physiological needs. Most species sleep during the circadian trough of their core body temperature rhythm. In humans, there is a close temporal relationship between sleep onset and the body temperature rhythm. Sleep is initiated on the declining portion of the temperature curve at a time when its rate of change, and body heat loss, is maximal (Figure 3). In the morning when heat production is dominant over heat loss, body temperature increases, as does the propensity to wake up. These findings indicate that the drive to sleep and the duration of sleep are tightly coupled with the thermoregulatory system.

The hypothalamus initiates thermoregulatory responses upon activation by inputs from thermoreceptors in the skin and internal thermoreceptors in the brain and blood vessels. The preoptic area of the hypothalamus, which contains a high density of thermoreceptors, regulates body temperature by altering the activity of the autonomic nervous system and by modulating sleep mechanisms. Temperature regulation in the human body varies according to the different stages of sleep, and sleep is altered in response to changes in temperature of the environment. The thermoregulatory efficiency during REM and SWS sleep in human adults is less prominent than in other mammals. In addition, the thermoregulatory process during REM sleep is less efficient than during SWS. Thermoregulation during REM sleep in neonates, in contrast to adults, is well maintained or

even enhanced. Transition between different stages of sleep has been proposed to change the hierarchical and functional control of the central nervous system (CNS) structures involved in thermoregulation.

A thermoneutral environment is defined as the range of air temperatures in the environment within which the metabolic rate is minimal and regulation of body temperature can be achieved by non evaporative physical processes alone. Changes from a thermoneutral environment disturb both the efficiency and structure of sleep. Sleeping in a nonthermoneutral environment results in a conflict between maintenance of homeothermia and sleep pressure. Thus, animals sleeping in cold or warm environments show alterations in sleep patterns. Different thermoregulatory responses are at play depending on the sleep stage and alterations in sleep observed outside of the thermoneutral environment.

Hibernation and Torpor

Sleep, shallow torpor, and hibernation appear to be homologous processes that evolved in response to the need for energy conservation. These three states comprise a continuum of decreasing metabolism and body temperature. In 1984, Berger observed that hibernation and torpor are regulated based on periodic environmental factors that affect food intake and energy balance. Mammals and birds are endotherms and homeotherms generating body heat from metabolism, thus maintaining a relatively constant body temperature across a wide range of environmental temperatures. Shallow torpor

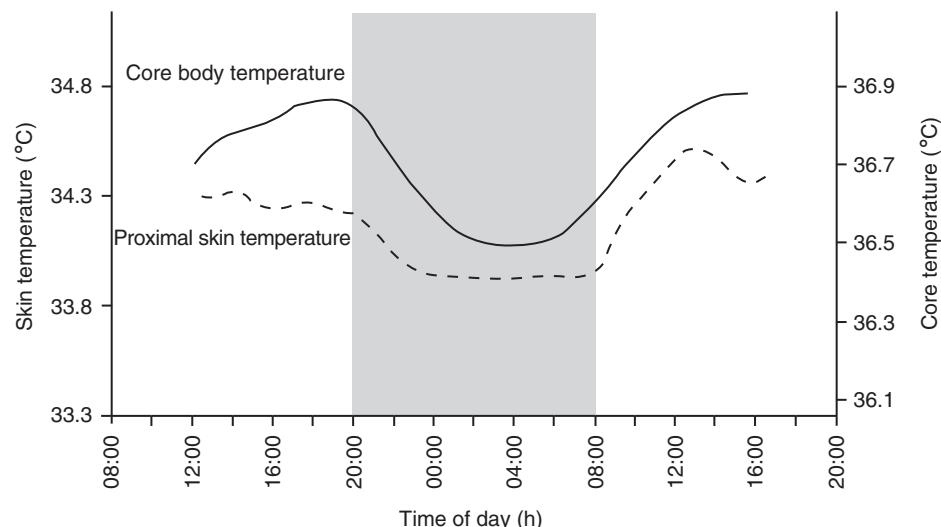

Figure 3 Smoothed average human core body and skin temperature curves under constant routine conditions showing declining body temperature during periods of increased propensity for sleep (gray shaded area depicts normal sleep period). Modified with permission from Van Someren EJ (2006) Mechanisms and functions of coupling between sleep and temperature rhythms. *Progress in Brain Research* 153: 309–324. Original source: Krauchi K and Wirz-Justice A (1994) Circadian rhythm of heat production, heart rate, and skin and core temperature under unmasking conditions in men. *American Journal of Physiology* 267: R819–R829.

and hibernation developed in order to maintain the high rates of metabolism and body heat during seasonal environmental changes and limitations in energy supplies. Decreases in body temperature and metabolism are seen uniformly in all species during sleep, although these changes are subtle and less profound than decreases observed during shallow torpor and hibernation. Endotherms adjust metabolic rates during inactivity so as to balance predation pressures against energy shortages. Shallow torpor is characterized by a decrease in body temperature, diminished responsiveness to environmental stimuli, and a quiescent posture. Shallow torpor may occur as part of the daily circadian rhythm during the normal sleep period or may extend over multiple days. Shallow torpor occurring during the drier and hotter seasons is termed ‘estivation.’ Hibernation is not as commonly seen as shallow torpor, and only a few species exhibit this behavioral state.

Similarities in the EEG patterns of sleep and hibernation suggest that hibernation may be an extension of sleep. Most mammals exhibiting hibernation enter this state of deep inactivity through sleep. The initial decrease in body temperature and metabolism that occurs during sleep is further enhanced as animals enter hibernation. An EEG characteristic of SWS is the predominant EEG pattern seen during hibernation. The decrease in REM sleep during hibernation is also linearly correlated with the decrease in body temperature. Body temperature is regulated continuously, although there is a decreased body temperature during hibernation.

Brain Energy Metabolism

The CNS is characterized by high metabolic demand. Although CNS tissue comprises about 2% of the body mass, CNS function uses about 20% of the total oxygen consumed. Glucose is the most important substrate utilized by the brain to maintain its function. Since glycogen, the storage form of glucose is found in very limited quantities in the brain, a continuous supply of glucose is essential for normal brain function. Oxidative metabolism of other sources of energy such as fats and ketone bodies in the brain is minimal. High plasma glucose levels and efficient transporters that shuttle glucose across the blood-brain barrier are important factors that have made glucose the preferred substrate for the brain. Under resting conditions, the ratio between the cerebral oxygen consumption (CMR_{O_2}) and cerebral glucose utilization (CMR_{glc}) is about 5.5, suggesting an oxidative efficiency of more than 90% for the consumed glucose. This implies that there is a direct relationship between oxidative metabolism and brain activity.

Energy metabolism in neurons is linked with glial cells. Astrocytes modulate blood flow in microvessels and

shuttle nutrients to the neuron. Metabolism in astrocytes accounts for a large proportion of glucose consumption during activated states of the brain. The energy derived from this process is utilized for accumulating the transmitter glutamate and its amidation to glutamine. Lactate produced during this process is transferred to neurons where it is then oxidatively metabolized. Astrocytes also utilize glucose for synthesis of glycogen (glycogenesis) (Figure 4). Neurons do not have the enzymes required for glycogenesis and therefore cannot store glucose as glycogen. Glycogenolysis occurring in the astrocytes in response to different stimuli provides an additional source of energy that may be utilized by neurons. Brain glucose plays an important role in regulating cerebral glycogenolysis. Brain glucose levels remain remarkably constant during sleep and vary to a much lesser extent than glycogen even in sleep deprivation.

Approximately 85–90% of glucose consumed in the brain is metabolized via the glycolytic pathway and oxidative tricarboxylic acid (TCA) cycle for the synthesis of ATP. Smaller amounts of glucose are utilized for other synthetic purposes such as glycogen (0–2%), nucleotides and lipids (5–10%), and proteins (0.5–2%). A large portion of the ATP produced from glucose is used for signaling and synaptic activity in the brain (75%). About 80% of brain energy is used for action potentials and postsynaptic potentials. Neuronal and glial resting potential maintenance take up about 13% and postsynaptic calcium entry and neurotransmitter cycling consume about 3% of the signaling-related expenditure of energy in the brain. Therefore, in resting conditions, approximately 10–15% of cerebral glucose is utilized for structural metabolism and 85–90% for functional needs.

Maximal glucose uptake occurs in regions rich in synapses, dendrites, and axons, while areas with cell bodies of neurons have low glucose utilization. Oxidative metabolism takes place in the mitochondria within cells where one of the important enzymes catalyzing the production of ATP is cytochrome oxidase. Large numbers of mitochondria and high concentrations of cytochrome oxidase in both the presynaptic and postsynaptic regions of neurons suggest that neuronal synapses require intense oxidative metabolism.

Regional Cerebral Glucose Metabolism during Sleep

Energy metabolism in the brain progressively declines during SWS and reaches its minimum level during the deepest stages of NREM. Cerebral glucose metabolism has been shown to decline by 30% during SWS from those during wakefulness. Although cerebral glucose metabolism does not differ significantly from waking levels during stage 2 NREM sleep, it decreases by 40%

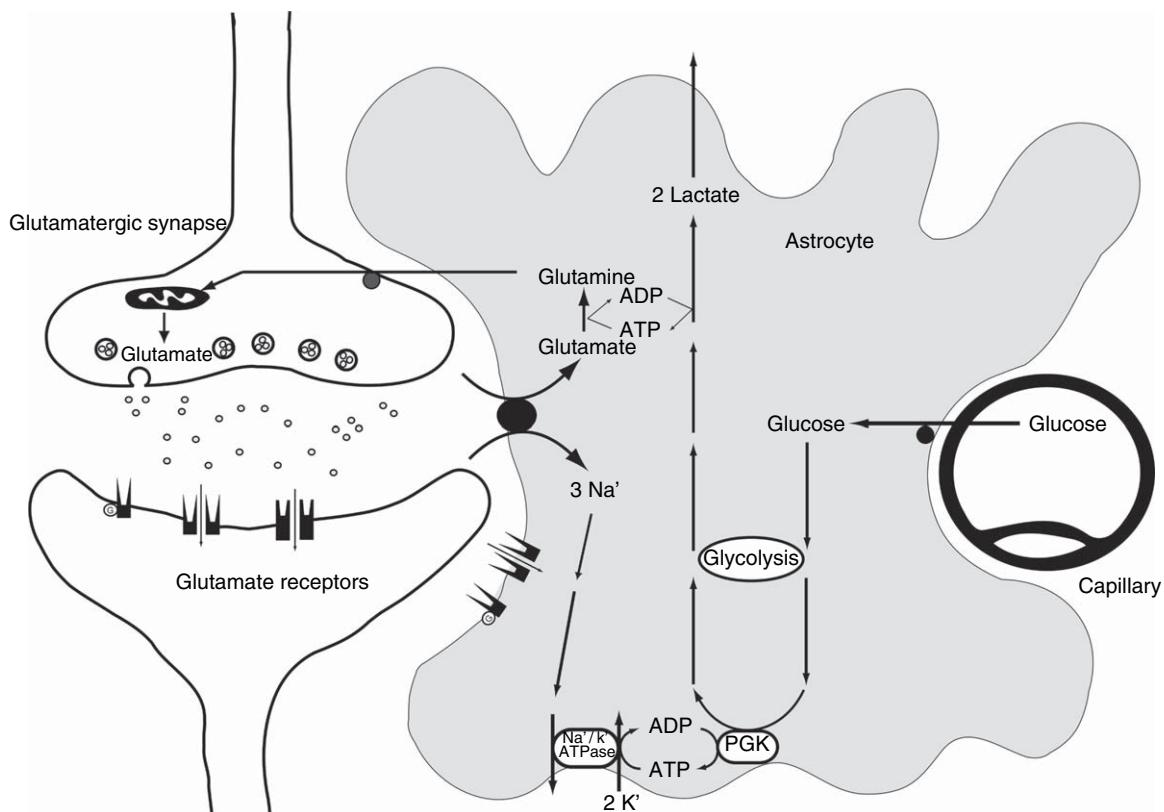

Figure 4 Glutamine–glutamate cycling between neurons and astrocytes is an important metabolic process seen during the activated states of the brain. Lactate production by astrocytes and its uptake and oxidative metabolism by neurons is also seen when the brain is active. ADP, adenosine diphosphate; ATP, adenosine triphosphate; PGK, phosphoglycerokinase. during stages 3 and 4 of NREM sleep (SWS) in humans. REM sleep is characterized by intense brain activity similar to that seen during waking. Direct measurements of metabolic parameters during REM sleep are difficult due to the short durations of REM sleep episodes in animals. Autoradiographic studies by Lydic *et al.* in 1991 revealed significant increases in glucose metabolism in regions comprising the thalamus, limbic system, and pontine reticular formation during REM sleep in cats. These regions have either cholinergic neurons or have significant cholinergic input from other areas, consistent with a key role for cholinergic and cholinoreceptive mechanisms in REM sleep regulation. Human studies during REM sleep have demonstrated similar levels of increase in cerebral metabolism. Increased cerebral blood flow is seen in the anterior cingulate, frontal, and extrastriate cortical areas besides the brainstem regions suggestive of activated cortical regions of the brain during REM sleep (**Figure 5**).

Inferences of metabolic activity from neuroimaging techniques measuring cerebral blood flow assume that cerebral blood flow correlates with neuronal activity

which in turn correlates with metabolic activity. There is a global decrease in cerebral blood flow during NREM sleep. Decreased blood flow during NREM sleep is seen in the dorsal pons, mesencephalon, thalamus, basal ganglia, basal forebrain, anterior hypothalamus, prefrontal cortex, anterior cingulate cortex, and precuneus. The regional decreases in blood flow may be grouped into three main cerebral areas – subcortical structures, cortical structures, and other areas.

Intense neuronal activity, high-energy metabolism, and increased blood flow to the brain characterize REM sleep. When compared to wakefulness, increased blood flow is seen in the cingulate cortex, temporo-occipital areas, basal forebrain, cerebellum, and caudate nucleus during REM sleep. Decreased regional blood flow is seen in the dorsolateral prefrontal cortex (DLPF), posterior cingulate gyrus, precuneus, and the inferior parietal cortex. The pedunculopontine tegmental (PPT) and the laterodorsal tegmental (LDT) nuclei project cholinergic neurons dorsally to the thalamus and ventrally to the basal forebrain where they mediate cortical activation.

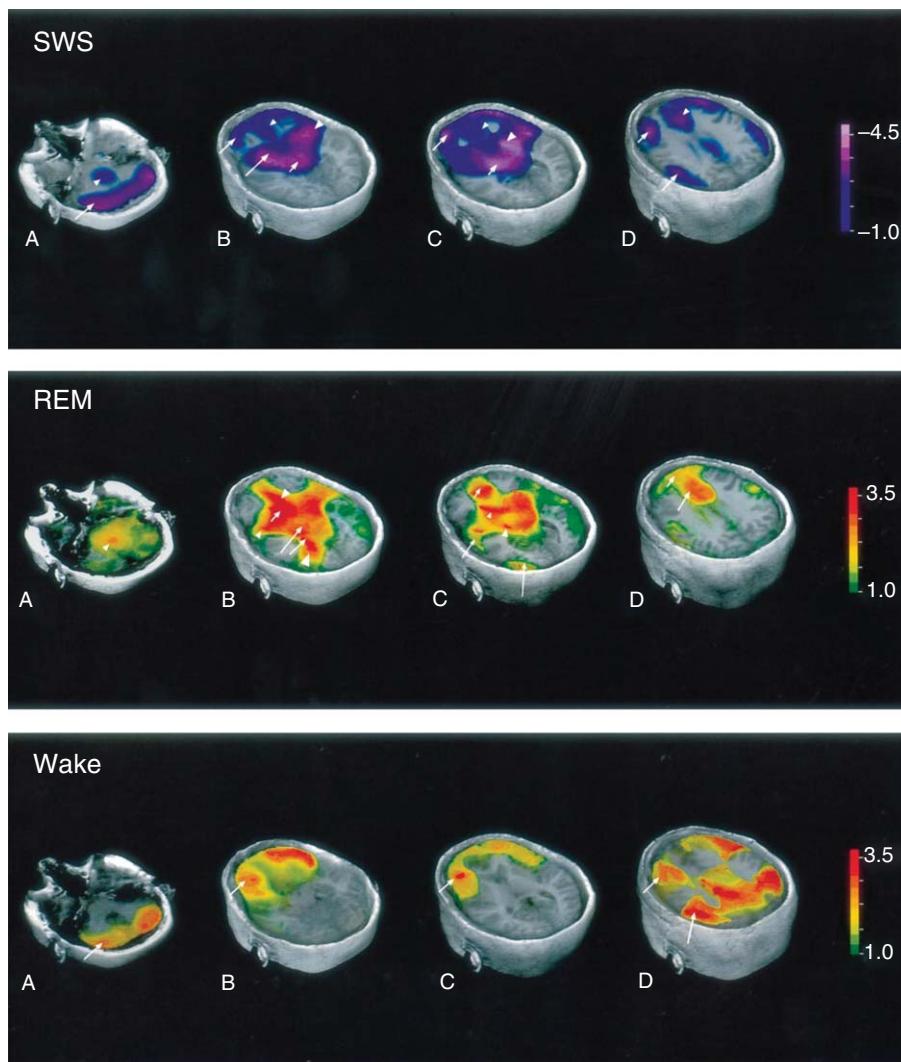

Figure 5 Brain maps illustrating changes in regional cerebral blood flow (rCBF) during different stages of sleep and wakefulness. Modified with permission from Braun AR, Balkin TJ, Wesensten NJ, et al. (1997) Regional cerebral blood flow throughout the sleep-wake cycle. An H₂(15)O PET study. *Brain* 120 (Pt 7): 1173–1197.

Hormones Regulating Sleep and Metabolism

Hormones that regulate feeding and sleep strengthen the coupling between sleep and energy metabolism. Both the normal sleep-wake cycle and altered sleep patterns show sizeable effects on the hormones of the hypothalamic-pituitary axis and other hormones which control carbohydrate metabolism, water, and electrolyte balance.

Growth hormone (GH) is a single-chain polypeptide hormone synthesized, stored, and secreted by the somatotroph cells of the anterior pituitary gland. The major secretory control of GH is exerted by two hypothalamic peptides, GH-releasing hormone (GHRH), which stimulates GH secretion, and somatostatin, which inhibits GH. Ghrelin, secreted from the stomach and pancreas, also

stimulates the release of GH from the anterior pituitary. Physiological factors affecting this balance at the level of the hypothalamus include stimulators of GH secretion such as exercise, hypoglycemia, protein intake, and sleep and inhibitors such as free fatty acids, hyperglycemia, and glucocorticoids. GH has profound anabolic effects on the tissues of the body. By acting on specific receptors, GH directly stimulates cell multiplication and growth involving a number of cell types especially cartilage, bone, and muscle. GH promotes lipolysis, increases protein synthesis, decreases the uptake of glucose by the liver, and stimulates gluconeogenesis. Although the secretion of GH occurs in several large pulses, the largest and the most predictable peak in secretion occurs shortly after the onset of sleep. GH release is stimulated by SWS and is proportional to the delta power of sleep.

Ghrelin is a peptide produced in response to fasting by the cells lining the fundus of the stomach and epsilon cells of the pancreas. Plasma ghrelin levels fall rapidly after food intake and rebound during hunger. Nocturnal ghrelin levels rise during the first half of the night and decline during the second half. Ghrelin by its action in the hypothalamic arcuate nucleus acts as a powerful GH secretagogue. Ghrelin also promotes the secretion of orexigenic neuropeptides, neuropeptide Y (NPY), and agouti-related peptide (AgRP) in the hypothalamic arcuate nucleus, resulting in increased feeding. It has been shown to cause a positive energy balance, increase adiposity, and reduce oxidation of fat. It has been suggested that ghrelin acts as an endogenous sleep-promoting factor. Exogenous ghrelin increases SWS and enhances delta activity during sleep while REM sleep is reduced during the later parts of the night. Exogenous ghrelin increases GH release as can be expected. Ghrelin administration increases cortisol levels during the early part of sleep in contrast to the late increase in cortisol seen during normal sleep. This effect differs from that of GHRH, which decreases cortisol secretion during sleep.

The thyroid hormones thyroxine and triiodothyronine regulate the rate of cellular growth and metabolism by regulating DNA transcription. They increase protein synthesis and oxygen consumption by increasing metabolism. Thyroid hormones also have modulatory effects on immune function, cognition, and emotions. In the fetus, thyroid hormones are crucial for the development of the brain. Thyrotropin-releasing hormone (TRH), secreted by the hypothalamus, stimulates the release of thyroid-stimulating hormone (TSH) from the anterior pituitary, which in turn stimulates the release of thyroid hormones from the thyroid gland. TSH secretion is related to the circadian rhythm; daytime levels are minimal and rise during the night to reach a maximum by the middle of the night before declining toward the morning. Thyroid hormone levels are high during the day and low at night. Alterations in sleep are common in thyroid disorders.

Corticotropin-releasing hormone (CRH), corticotropin (ACTH), and cortisol of the hypothalamic–pituitary–adrenocortical (HPA) system mediate body reactions to acute physical and psychological stress. A typical reaction to stress initiates a cascade of activity beginning with the release of CRH from the hypothalamus, which stimulates the release of ACTH from the pituitary. ACTH in turn facilitates the release of cortisol from the adrenal cortex. Sleep and the HPA system interact with each other in both directions. All cells in the body have receptors for cortisol, and therefore cortisol can be expected to have wide-ranging effects on the body. The overall effect of cortisol on metabolism is to ensure an adequate supply of glucose to vital organs including the brain at times of stress. Cortisol increases the synthesis of glucose in the liver from noncarbohydrate sources (gluconeogenesis) by mobilizing

substrates such as amino acids. Glucose uptake in the muscles and adipose tissue is inhibited and channeled into the blood for utilization by the brain. Cortisol stimulates the breakdown of fat in adipose tissue, providing an additional source of energy. Besides its enormous effects on glucose metabolism, cortisol also exerts important effects on development, cognitive, and immune functions (**Figure 6**).

A major proportion of ACTH and cortisol secretion occurs during sleep. The first pulse of ACTH and cortisol occurs a few hours after the onset of sleep, followed by further pulses of secretion until awakening. Cortisol is secreted during the second half of nightly sleep when the time spent in REM sleep is maximal. It is during the first few hours of sleep that the majority of SWS and the peak of GH secretion occur, at which time there is relatively no cortisol secretion. Predictably, in sleep deprivation, cortisol secretion is accentuated. In contrast to CRH, ACTH and cortisol increases SWS and reduces REM sleep.

Hypocretin (also known as orexin) is a neuropeptide secreted by the posterolateral hypothalamus that promotes increased feeding behavior and arousal. This dual function of hypocretin illustrates the close connection between the regulation of hunger and satiety and the regulation of sleep. The orexinergic neurons interact with arousal centers in the brainstem and basal forebrain, and important feeding centers in the hypothalamus. Activity of arousal-related monoaminergic neurons in the brainstem parallel that of the hypocretin neurons in the hypothalamus, suggesting a regulatory role of hypocretins on these neurons. Cholinergic neurons in the LDT/PPT which are active during wakefulness are stimulated by hypocretin. Hypocretin neurons strongly activate cholinergic neurons in the basal forebrain, which play an important role in behavior and cortical arousal. Activation of histaminergic neurons in the tubulo-mammillary nucleus (TMN) by hypocretin plays an important role in the regulation of arousal. Cerebrospinal fluid (CSF) levels of hypocretin are the highest during the active periods of the day. The hypocretinergic system communicates with the suprachiasmatic nucleus integrating the circadian rhythm with feeding behavior and sleep.

Leptin, a peptide synthesized and secreted by adipocytes, suppresses food intake and stimulates energy expenditure by its action on the hypothalamus. Although obese individuals have high circulating levels of leptin, they may be resistant to its effects (leptin resistance). Under normal conditions, there is a marked nocturnal rise in plasma leptin levels, which is partly dependent on food intake. Systemic administration of leptin in rats increases SWS and decreases REM sleep, an effect that is abolished by food deprivation. Leptin inhibits the activity of neuropeptide Y and hypocretin, both of which are peptides that increase appetite and wakefulness.

NPY is a peptide hormone/neurotransmitter secreted by the hypothalamus and associated with energy balance,

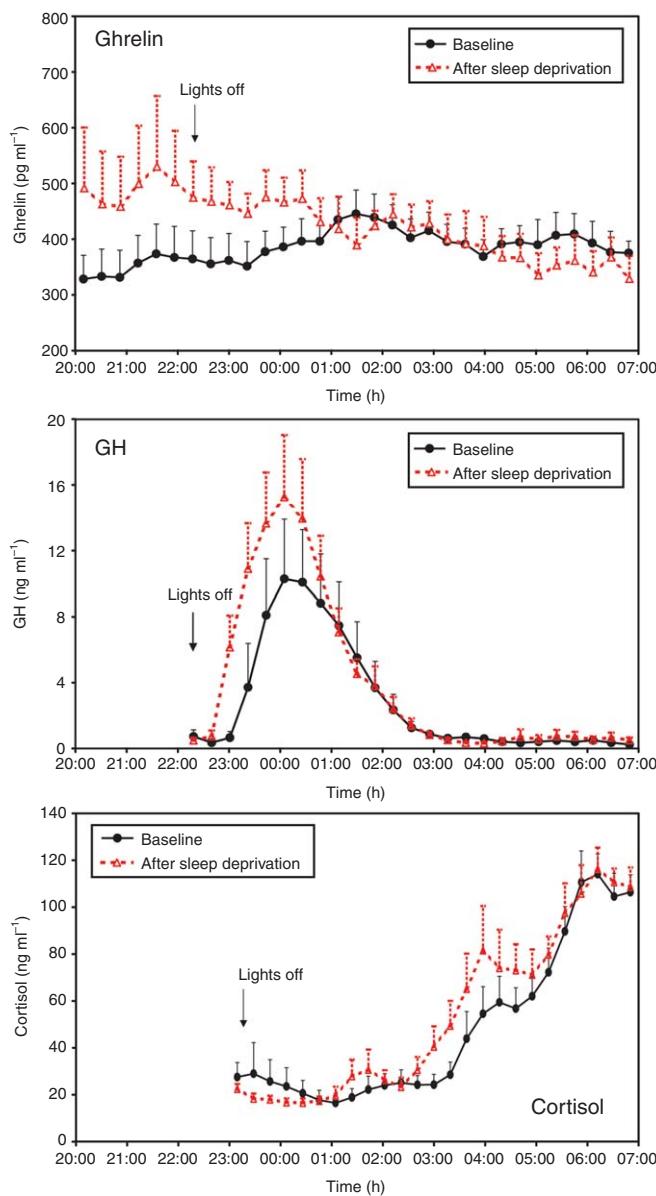

Figure 6 Nocturnal secretion of ghrelin, growth hormone (GH), and cortisol during normal sleep (black solid line) and after one night of total sleep deprivation (red dashed line) in eight human subjects. Modified with permission from Schüssler P, Uhr M, Ising M, et al. (2006) Nocturnal ghrelin, ACTH, GH and cortisol secretion after sleep deprivation in humans. *Psychoneuroendocrinology* 31: 915–923.

learning, and memory. It is a potent stimulator of food intake and facilitates the storage of energy, especially as fat. The effects of hypocretin on appetite may in part be modulated by NPY. Leptin can antagonize the effects of NPY.

Sleep Deprivation, Sleep Restriction, and Metabolic Disturbances

In 2004, it was estimated that more than 30% of adults and more than 17% of children and adolescents in the United States were obese. The prevalence of obesity in

adults doubled between 1980 and 2002, exponentially increasing the healthcare costs associated with obesity. Interestingly, over the same period, chronic voluntary sleep curtailment developed as a societal by-product of rapid economic and industrial expansion. More than 30% of adults in the United States reported sleeping less than 6 h per night in 2004. Recognizing the metabolic and neurohumoral links between obesity and altered sleep may provide opportunities for novel treatment modalities for both groups of disorders.

Sleep deprivation causes profound disturbances in glucose metabolism, the understanding of which may

provide insights into the pathogenesis of diabetes, one of the major risk factors of cardiovascular disease. Chronic sleep restriction, through its effects on a variety of neurohumoral factors, increases appetite and decreases energy expenditure, resulting in weight gain. Voluntary sleep restriction also modifies exogenous factors that affect metabolism such as choices of food and increased time to eat.

Pioneering studies of chronic partial sleep deprivation in humans have demonstrated significant alterations in the parameters of glucose metabolism. Sleep-deprived individuals show lower glucose tolerance (glucose clearance after exogenous glucose administration) and glucose effectiveness (a measure of non-insulin-dependent glucose clearance) (Figure 7). The mechanisms by which chronic sleep deprivation disrupts glucose metabolism may include increased sympathetic autonomic activity, altered secretion of counterregulatory hormones such as GH and cortisol, and increased activity of inflammatory cytokines.

Appetite regulation involves complex interactions between metabolic and hormonal signals and neural mechanisms. It is widely accepted that the appetite-control center in the brain is the arcuate nucleus of the hypothalamus, which integrates the peripheral signals. Appetite-regulating mechanisms have been shown to have strong links with neuronal systems regulating sleep. Chronic sleep deprivation causes an overall decrease in the levels of leptin, the satiety-promoting hormone secreted by the adipose tissue. Chronic sleep deficit advances the time of maximal secretion of leptin which occurs earlier in the night when compared to normal secretory activity while decreasing the amplitude of daily variation. Acute total sleep deprivation has the opposite effect of leptin levels. Ghrelin, the appetite-promoting peptide secreted by the stomach, has been shown to increase in sleep-deprived states. An increased ghrelin:leptin ratio during sleep restriction enhances the subjective feeling of hunger.

Energy expenditure is an important component of normal metabolic balance and plays a significant role in the control of body weight (Figure 8). Decreasing locomotor activity and a sedentary lifestyle result in lower energy expenditure. In endothermic animals, energy is required for basal cellular activity (BMR) at rest, food-related activity for the absorption, digestion, metabolism, and storage of nutrients, and physical-activity-related expenditures. Activity-related utilization of stored energy is the most variable component of the total energy expenditure. Increased activity corresponding to increased food intake can play a role in the control of body weight. Chronically sleep-deprived individuals report reduced physical activity, and therefore it may be assumed that energy expenditure is reduced. Leptin may increase energy expenditure by its thermogenic activity in brown adipose tissues. Ghrelin has been shown to decrease locomotor activity in rodents. Increased ghrelin and reduced leptin seen during chronic sleep deprivation may therefore negatively affect energy expenditure.

Maximal Oxygen Consumption, Bioenergetics, and Health

Sleep forms an important part of the restorative process in animals and adequate sleep is essential for optimal cognitive functioning. Understanding the relationship between sleep quality and exercise capacity may provide unique insights into how sleep affects metabolism and improves well-being. Vigorous exercise increases the need for oxygen in the body in order to maintain the high rates of metabolism. Maximal oxygen uptake ($\text{VO}_2 \text{ max}$) is a measure of the maximum oxygen consumption during maximal exertion. It is a good measure of exercise capacity and reflects the ability of an individual's body to transport and metabolize oxygen during incremental exercise. $\text{VO}_2 \text{ max}$ has been used as a measure of cardiopulmonary and physical fitness in athletes participating in

	Fully rested	After 5 days of sleep restriction	P level

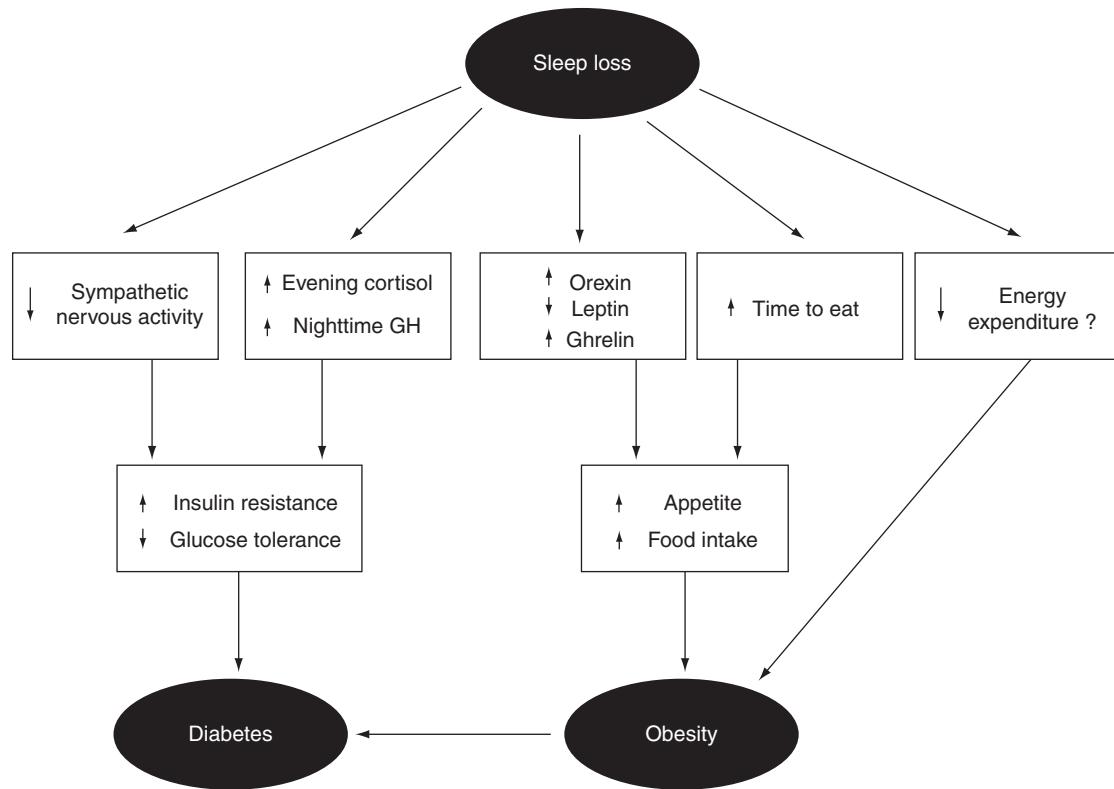

Figure 8 Possible pathways by which sleep loss leads to diabetes and obesity. Modified with permission from Knutson KL and Van Cauter E (2008) Associations between sleep loss and increased risk of obesity and diabetes. *Annals of the New York Academy of Sciences* 1129: 287–304.

high-endurance sports. Another measure of aerobic exercise capacity that is used more commonly is the metabolic equivalent (MET). One MET is defined as the amount of oxygen consumed while sitting at rest and is equal to 3.5 mL kg^{-1} body weight per minute. MET provides a useful tool to describe intensity of exercise activity in simple units.

A recent study by Kokkinos *et al.* in 2008 demonstrated a graded reduction in all causes of mortality with increasing exercise capacity. The risk for mortality was found to be 13% lower for every 1 MET increase in exercise capacity. Individuals with moderate exercise capacity (5–7 MET) had a 50–70% lowered risk of mortality compared to individuals with low exercise capacity (<5 MET). The enormous impact of maintaining even a moderate exercise capacity underlines the importance of aerobic fitness. Similar studies by Myers *et al.* have shown identical results; every 1 MET increase in exercise capacity resulted in a 12% improvement in survival. This study compared a number of other risk factors, including smoking, hypertension, diabetes, hyperlipidemia, and cardiac arrhythmias, with exercise capacity in predicting mortality. Compared to other risk factors, exercise capacity was identified as the measure with one of the best prognostic values for predicting mortality.

Sleep, Obesity, and Metabolic Syndrome

Metabolic derangements have a large impact on sleep. Individuals with obesity and metabolic syndrome are known to have disordered sleep. Decreased total sleep time, fragmentation of sleep, and altered sleep architecture have been described in such individuals. Obese individuals report significantly less total sleep time than individuals with normal body weight. Sleep apnea and excessive daytime sleepiness in obese patients may be manifestations of metabolic syndrome. Large abdominal circumference, hypertension, and diabetes, which are components of metabolic syndrome, have all been implicated in the heightened risk of sleep-disordered breathing.

Patients with obstructive sleep apnea syndrome (OSAS) have repetitive collapse of pharyngeal airways during sleep, leading to oxygen desaturation, sleep fragmentation, and increased daytime somnolence. There is a significant correlation between the severity of OSAS and increasing BMI. Recurrent apneic episodes in individuals with OSAS lead to intermittent hypoxia and sleep fragmentation, which in turn trigger sympathetic activation, cellular oxidative stress, and systemic inflammation. Inflammatory cytokines, tumor necrosis factor-alpha

(TNF- α), interleukin-1 beta (IL-1 β), and IL6, are involved in physiological sleep regulation. High levels of these cytokines have been demonstrated in obese patients with OSAS.

Chronic sympathetic activation along with oxidative stress and systemic inflammation in individuals with OSAS may cause insulin resistance and glucose intolerance. Epidemiological and cross-sectional studies have demonstrated a strong link between hypertension and OSAS, independent of other risk factors. Similar factors that link insulin resistance with OSAS are also thought to play a role in the pathogenesis of OSAS in hypertension. Abnormal lipid metabolism manifested as low high-density lipoprotein (HDL) levels and high triglycerides have also been reported in patients with OSAS. Reducing body weight and controlling other metabolic parameters may significantly improve apnea and oxygen desaturation in patients with OSAS. Sleep restriction causes a number of hormonal and metabolic peripheral effects that may cause obesity, and in turn leads to further sleep disruption.

Glossary

Chronotherapeutics – The treatment protocol for cancer whereby the time of day when chemotherapy is administered is chosen in order to be maximally effective in treating the tumor, but have minimal effects on the patient.

Circadian – Biological rhythms approximately 24 h in duration.

Clock – A device used to measure time.

Entrainment – The process by which an environmental stimulus regulates the period and phase of an oscillator.

Infradian – Rhythms with a period of days, weeks, or years.

NREM – Nonrapid eye movement sleep, consisting of several sleep stages that are defined based on the frequency of brain electrical activity.

Oscillator – A series of components with a combined action that varies between extreme values over a precise period of time.

Period – The duration of a single oscillation measured from peak to peak or from one reference point to the next, e.g., from midnight to midnight on a 24-h clock.

Phase – The momentary state of an oscillation.

REM – Rapid eye movement sleep.

Ultradian – Rhythms with a period of less than 1 day.

weeks, months, or even years. Examples include the human menstrual cycle, hibernation, and the 17-year cycle of certain North American cicadas, respectively (see [Figure 1](#)).

The coordination of parallel and serial processes necessitates rhythmicity at all levels of biological organization. Ultradian rhythms likely arose in order to separate in time those mutually incompatible chemical reactions that could not be physically separated within the space of a single cell. In more complex systems, ultradian rhythmicity provides a metabolically inexpensive mechanism for efficient signal transmission. For example, it may be energetically expensive or even toxic for an organism to have constantly high levels of a hormone in circulation, when the same signal can be transmitted by pulsatile hormone release. Temporal separation of incompatible chemical reactions is also observed at a circadian timescale, such as the daily rhythm of photosynthesis. Circadian rhythmicity is also critical for the synchronization of multiple biological processes with the external environment and allows the organism to anticipate the environmental demands of the solar cycle.

Properties of Biological Clocks

In their most basic form, biological rhythms consist of a negative-feedback loop with a time delay. For example, there are numerous proteins that repress transcription of their own genes, such as the period (PER) and cryptochromes (CRY) proteins, essential components of the mammalian circadian clock (described in more detail below; see [Figure 2](#)). At least one negative-feedback loop is necessary for an oscillation. Most biological clocks are made up of a series of weakly coupled oscillators, which make them more robust with respect to perturbations by outside stimuli. Greater complexity also tends to allow for timing of longer intervals.

The most important characteristic, and hallmark of a true biological clock, is temperature compensation: the period of the oscillation must be very similar over a wide range of biological temperatures. This has been studied extensively in circadian rhythms, but is also a characteristic of ultradian clocks. Intrinsic rhythmicity and a free-running period under constant conditions are also necessary properties for biological clocks.

Introduction

The term ‘biological rhythm’ can be used to describe any molecular, physiological, or behavioral event or process that is recurring, and is a defining characteristic of all living organisms. Rhythmicity can be observed over the entire range of timescales from fractions of a second to years, but can be broadly grouped into three categories: ultradian, circadian, and infradian. Ultradian rhythms, such as cell division or the human rapid eye movement (REM)–non-REM (NREM) sleep cycle, can have a period of seconds, minutes, or hours, and occur multiple times per day. Circadian rhythms, including photosynthesis, the rest–activity cycle, and the plasma concentration of numerous circulating hormones, repeat approximately every 24 h. Infradian rhythms have periods of longer than 24 h, ranging from days to

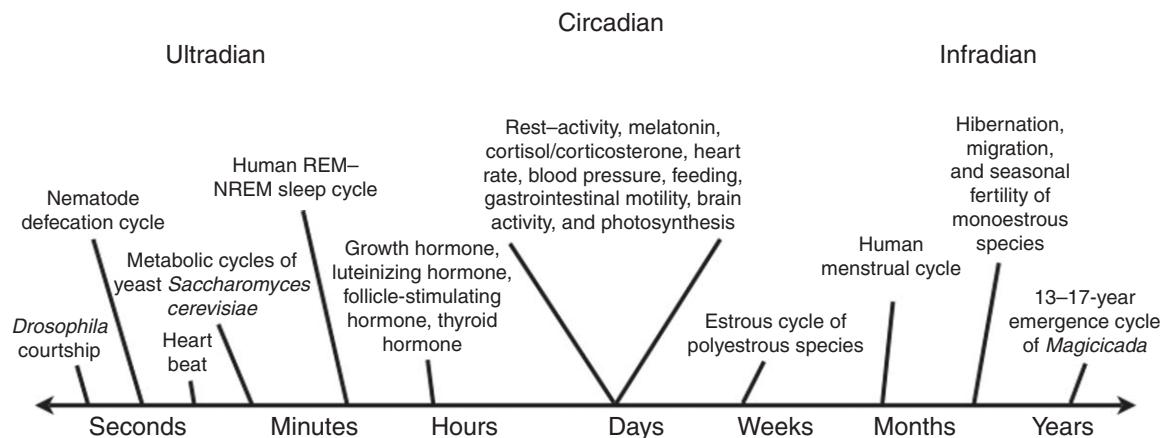

Figure 1 Timescale of biological rhythmicity with examples.

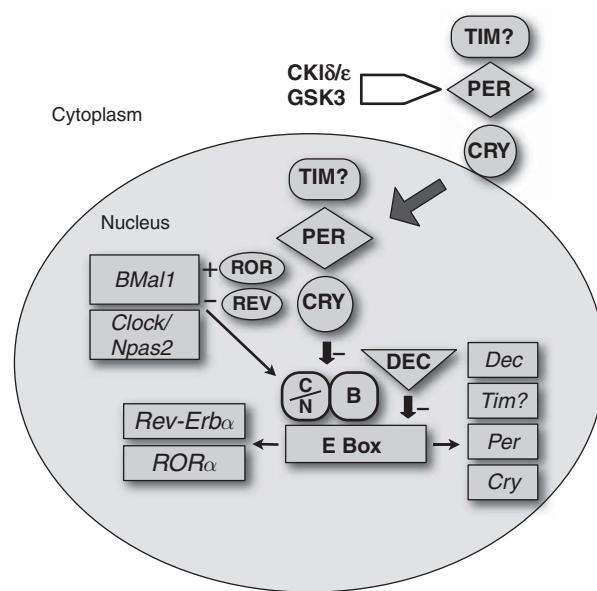

Figure 2 Molecular mechanisms of the mammalian circadian clock. Clock gene mRNAs are indicated by italics and proteins are in bold font. Fine arrows indicate transcription, block arrows indicate binding or interaction, the gray arrow indicates translocation, and the open arrow indicates posttranscriptional modification. Excitation and inhibition are indicated by plus (+) and minus (-) signs, respectively. C: CLOCK protein, N: NPAS2 protein, and B: BMAL1 protein.

Ultradian Rhythms

As the timescale of ultradian rhythms is so broad, from fractions of a second to hours, a large number of biological clocks fall into this category and a comprehensive discussion is not possible in this article. However, an example of a well-studied ultradian rhythm is the approximately 40-min cycle of cellular respiration observed under continuous aerobic culture conditions in the yeast *Saccharomyces cerevisiae*. Interestingly, the majority of the individuals

within a culture will become synchronized with one another, such that the O₂ concentration and intracellular pH of billions of cells become perfectly coordinated. This ultradian oscillator meets all of the requirements of a true clock. It is intrinsically rhythmic, temperature-compensated, and maintains a 40-min oscillation for months under constant culture conditions. The signaling mechanism responsible for the mass intercellular synchronization has not yet been established, but two diffusible chemicals, H₂S and acetaldehyde, are possible candidates, as they show rhythmic changes in concentration and can shift the phase of the ultradian metabolic clock. The molecular mechanisms of this clock are under investigation, and putative clock genes include *GTS1*.

One of the first ultradian rhythms to be studied in humans was the REM–NREM sleep cycle, which has a period of about 90 min and occurs 3–5 times in the average sleep episode. This rhythm is composed of the synchronous activity of a number of different processes including oculomotor activity, muscle tone, dominance of the autonomic nervous system, brain electrical activity, and energy utilization. Similar to many other biological processes, sleep shows rhythmicity at multiple timescales. In addition to a 90-min ultradian rhythm, a circadian rhythm is also evident.

Circadian Rhythms

With the exception of organisms living in extreme environments, such as the deep ocean floor, all others are exposed to the daily solar cycle and have an internal clock that cycles about once a day. For example, the unicellular marine algae *Gonyaulax polyedra* moves up to the higher levels of the ocean to absorb sunlight and CO₂ for photosynthesis during the day, but descends to the nutrient-rich lower layers during the night to absorb nitrogen and phosphorous.

In multicellular organisms, the molecular machinery for circadian rhythms is present in nearly every cell. These clocks perform functions specific to each individual tissue and are synchronized with the external environment by a master circadian pacemaker. In mammals, this master circadian clock is located deep in the brain in the suprachiasmatic nucleus (SCN) of the hypothalamus. The SCN has all of the defining attributes of a biological oscillator: intrinsic rhythmicity, a free-running period under constant conditions, and temperature compensation. Substantial evidence indicates that the SCN is the master circadian clock as SCN lesions abolish circadian rhythmicity of locomotor activity, feeding, drinking, and hormone release. Furthermore, surgical transplantation of SCN cells can restore circadian rhythms of locomotor activity to recipient animals with SCN ablation. Hamsters with the tau mutation have an endogenous circadian rhythm with a period shorter than 24 h. Animals homozygous or heterozygous for the mutation have periods of 20 and 22 h, respectively, whereas wild-type animals have an endogenous period of about 24 h. SCN grafts taken from a homozygous tau mutant donor and placed in a wild-type recipient will restore locomotor activity rhythms with the same period as the donor animal, demonstrating that the circadian period is conferred by the donor SCN.

The SCN receives photic information directly from the eye via the retinohypothalamic tract. The synchronization of the master clock occurs by a process known as photic entrainment. The primary circadian photoreceptor melanopsin is found in the soma region of most retinal ganglion cells that innervate the SCN. Melanopsin-containing retinal ganglion cells are relatively insensitive to brief light exposure, but gradually become more activated in response to constant illumination of an intensity similar to that of the dawn sky.

Nonphotic cues have relatively little impact on the SCN master clock, but nevertheless, profoundly influence circadian behavior by altering individual peripheral clocks. The nonphotic stimuli known to affect circadian rhythms are numerous and include olfactory cues, food, pathogens, social interactions, emotional state, and conditioned stimuli. Perhaps the most important of these is feeding.

Feeding is a potent synchronizer of behavior. Nocturnal rodents will consume the majority of their daily caloric requirement during the dark portion of the light-dark cycle. If they are placed on a 24-h feeding schedule that limits food access to a short period during the daytime, nocturnal rodents will show a reliable increase in activity several hours prior to food availability. This food-anticipatory activity only occurs when the feeding schedule is in the circadian range, as rodents are unable to anticipate feeding schedules that are much shorter or longer than 24 h.

The semihierarchical organization of circadian oscillators in mammals allows peripheral oscillators to respond to relevant stimuli, but remain synchronized with each other and the external environment via the light-specific master clock. The SCN can synchronize peripheral oscillators either by direct neural projections or by a diffusible or blood-borne signal. Although entrainment is generally top down, there is also some evidence that peripheral clocks can influence the master circadian clock. For example, under conditions of constant bright light, the rodent SCN becomes arrhythmic, but can be entrained by scheduled meals delivered once every 24 h.

Molecular Mechanisms of Circadian Rhythms

Circadian rhythmicity at the molecular level is the result of both positive- and negative-feedback loops and includes mRNA transcription, protein translation, protein–protein interactions, and posttranscriptional protein regulation (see **Figure 2**). Three eukaryotic organisms have been fairly well characterized: *Neurospora*, *Drosophila*, and rodents. Only the latter will be described here; however, there is a high degree of similarity among all three. In mammals, genes *Clock* and *Bmal1* encode two basic helix-loop-helix (bHLH)-PER-ARNT-SIM (PAS) domain-containing transcription factors called CLOCK and BMAL1 (brain and muscle ARNT-like protein 1; also known as MOP3). CLOCK and BMAL1 dimerize and bind to E-box enhancers, activating transcription of genes *Period 1*, *2*, and *3* (*Per1*, *Per2*, *Per3*); *Cryptochrome 1* and *2* (*Cry1* and *Cry2*); *Rora*; and *Rev-Erbα*. ROR α activates *BMAL1* transcription, while REV-ERB α inhibits it, providing positive and negative feedback on the clock, respectively. The main negative-feedback loop is formed by clock proteins PER and CRY, which associate and are translocated back into the nucleus, where they inhibit their own transcription by interacting with the CLOCK/BMAL1 heterodimer. The rate of accumulation, association, and translocation of PER and CRY, critical for the period and phase of the molecular clock, is controlled by enzymes casein kinase I epsilon (CKI ϵ) and casein kinase I delta (CKI δ), the *Drosophila* shaggy homolog glycogen synthase kinase 3 (GSK3), and several other recently identified substances. Interestingly, it is a mutation of CKI that leads to the short-period tau mutation in hamsters described above. A number of other clock components have been studied. NPAS2, an alternate dimerization partner for BMAL1, seems to be important for clock function in cells outside the master circadian clock, but is virtually absent from the SCN. Other proteins, such as DEC1 and DEC2, can act as transcriptional repressors by interacting with E-box-binding sites. The mammalian homolog of timeless, a

core component of the *Drosophila* clock, also appears to have a role in the negative limb of the mammalian circadian clock. However, the roles of these and numerous other genes, proteins, and enzymes in clock function are still being delineated.

Relationship of Circadian Rhythms to Physical and Mental Health

The essential circadian clock genes are ultimately responsible for circadian rhythms of physiology and behavior, and disruptions of circadian rhythms may play a role in pathology. For example, shift workers, who habitually work during the late-evening and night hours, have a higher risk of developing long-term diseases, are more likely to be hospitalized, and consult more frequently with health care providers than individuals working a more typical day-oriented nine-to-five schedule. Shift work is associated with an increased risk of a number of serious health conditions, including cardiovascular disease, non-insulin-dependent diabetes, gastrointestinal illness, cancer, spontaneous abortion, premature birth, infertility, and psychological distress. Also at risk are transcontinental flight personnel, who experience a chronic asynchrony between their internal circadian rhythms and the external environment.

The link between circadian rhythms and cancer may be due to the direct role of the molecular clock in the regulation of the cell cycle. Experiments causing disruptions of the circadian system in animals, such as alterations of the light–dark cycle, SCN lesions, or clock gene mutations, result in an increased risk of cancer and faster growth of preexisting tumors. Mice lacking the *Per2* gene are more likely to develop tumors than wild-type mice, and do not show the typical induction of essential clock genes by gamma radiation, suggesting that in wild-type mice, circadian clocks respond to cellular damage in order to activate apoptosis (programmed cell death) and suppress tumors. A practical application of this research is the advent of chronotherapeutics, which aims to take advantage of the observed asynchrony in cell division and metabolic rhythms between healthy tissues and the tumor. Thus, treatment can be prescribed for a time of day where chemotherapy will be maximally toxic for the tumor, but have minimal effects on the patient.

The human molecular clock also has been implicated in certain sleep disorders. Mutations of the *PER2* and *CK1 δ* genes were found to be the cause of two familial cases of advance sleep phase disorder (bedtime = 6–9 p.m. and wake time = 1–3 a.m.), while the opposite condition, delayed sleep phase disorder (bedtime = 3–6 a.m. and wake time = 1–3 p.m.), was found to be associated with a polymorphism of human *PER3*.

Circadian clock genes have also been implicated in mental health. For example, the genes *CLOCK*, *PER3*, and *TIMELESS* have been associated with schizophrenia/schizoaffective disorder and bipolar disorder. Support for a role of *CLOCK* mutations in bipolar disorder has recently come from animal literature, with evidence that the *Clock* mutant mouse might constitute an animal model of mania. There is also evidence that the therapeutic action of the mood-stabilizing agent lithium may be related to direct effects on the circadian clock component GSK3. Even more interesting are findings that the inhibition of GSK3 may be common to other mood-stabilizing and antidepressant therapies, including drugs which target the serotonergic and dopaminergic systems as well as electroconvulsive therapy.

Relationship between Ultradian and Circadian Clocks

There is strong evidence that ultradian and circadian clocks are interrelated. In complex organisms, the master circadian clock synchronizes ultradian clocks with the external light–dark cycle and many processes have both ultradian and circadian rhythmic components. For example, the cell cycle has an ultradian rhythm that varies by the organism and type of cell, but cell populations tend to enter into the cell cycle at the same time each day. Another example is the secretion of numerous hormones that have both pulsatile and circadian secretion patterns.

Commonalities also are found at the molecular level. For example, lithium, commonly used as a mood-stabilizing agent, as described above, has been shown to lengthen the period of both ultradian and circadian clocks. Lithium lengthens the period of circadian rhythms in rodents and can lengthen the period of neuronal firing of cultured SCN neurons in a dose-dependent manner, via the inhibition of the core circadian clock component GSK3. The period of the ultradian metabolic clock of the yeast *Saccharomyces cerevisiae* is also lengthened by lithium. This suggests that there are common molecular mechanisms that underlie both of these clocks.

Some ultradian rhythms may actually share molecular components with the circadian clock. Like mammals, a core component of the *Drosophila* molecular clock is the gene *period*. A null mutation of *per* abolishes the circadian clock, while other mutations can lengthen or shorten its period. These mutations have the same effect on the ultradian mating song cycle. The short form of *per*, called *per^f*, not only shortens the period of the circadian clock, but also that of the ultradian mating song cycle. Similarly, *per^{L1}* lengthens both circadian rhythms and the song cycle, while the null mutation abolishes both rhythms completely. As the molecular mechanisms of other ultradian rhythms become known, other points of commonality between circadian and ultradian rhythms will likely emerge.

Conclusion

Rhythms are a ubiquitous property of all living organisms and not merely an anomalous phenomenon occurring in a few isolated systems. They are observable at all timescales from fractions of a second to years and are necessary for the coordination of the multitude of biological systems that characterize healthy cells, tissues, systems, and organisms.

Glossary

Ascending reticular activating system (ARAS) – A diverse system of varying neuron types and neurochemical identities occupying the core of the brainstem and projecting to the diencephalon and cortex, where it produces activation reflected behaviorally by waking and dreaming and electrophysiologically by increased frequency and decreased amplitude of brain waves. The ARAS includes nuclei of the major neuromodulatory systems known to increase forebrain activity using acetylcholine, norepinephrine, and serotonin.

Coherence – The relative degree to which oscillatory activity, measured by electroencephalography (EEG) or magnetoencephalography (MEG), at a particular frequency tends to be in phase (synchronized) between different specified regions of brain.

Functional Magnetic Resonance Imaging (fMRI) – Functional neuroimaging of the brain measuring blood flow responses to regional changes in oxygen demand (hemodynamic response) that, in turn, change the blood-oxygen-level-dependent (BOLD) magnetic response to magnetic stimulation, which varies with the relative proportion of oxygenated and deoxygenated hemoglobin in the blood.

Magnetoencephalography – Regional activity of the brain measured at the scalp by detecting minute fluctuations in electromagnetic fields produced by underlying neuronal electrical activity.

Phasic activity – Brain activity occurring over a brief interval (milliseconds to seconds) measured by EEG or MEG such as the spindle and K-complex of nonrapid eye movement (NREM) sleep or the rapid eye movements of rapid eye movement (REM) sleep.

Positron emission tomography (PET) – Functional neuroimaging of the brain that measures regional brain activity in terms of regional blood flow or metabolism that is determined by measuring radiation emitted from injected isotopes.

Tonic activity – Brain activity that continues over sustained time periods of seconds to minutes such as the EEG- and MEG-rhythmic oscillations (brain waves).

The Neuropsychological Study of Sleep

The study of neuropsychological processes occurring during or dependent upon sleep presents unique challenges. Because persons asleep cannot respond to queries or enact volitional behavior, neuropsychological assessment of mental processes occurring during sleep must be done during waking, a limitation shared when studying the neuropsychology of dreaming. Investigators studying neurobehavioral processes and phenomena associated with sleep have employed five main techniques to overcome sleep's barriers to direct observation.

First, the amount of sleep can be varied and subsequent performance can be compared to that of the same individuals prior to this manipulation or to population norms. Such manipulations include acute deprivation of sleep for varying durations, chronic sleep restriction, sleep fragmentation by repeated awakenings, selective reduction or enhancement of specific sleep stages, and sleep extension. The many important discoveries resulting from such experimental techniques have included characterization of the attentional deficits resulting from total sleep loss as well as cumulative attentional impairment resulting from chronic sleep restriction ("sleep debt") – work pioneered by Robert Wilkinson in the 1950s and 1960s and recently by David Dinges and his colleagues. Indeed, in addition to attention, contemporary sleep researchers have demonstrated experimentally that most cognitive functions including several memory systems, executive functions, as well as social and emotional skills are negatively impacted to a greater or lesser extent by sleep loss. An important addition to performance studies of sleep deprivation has been the use of functional neuroimaging to examine brain physiological changes that accompany behavioral changes. Prominent among these studies have been those using functional magnetic resonance imaging (fMRI). From such data, Sean Drummond and colleagues have proposed a cerebral compensatory response to cognitive demands in the sleep-deprived state.

The second technique, a variant of the first, has been to utilize normal sleep and normal waking as contrasting 'interventions' to study their differential effects on memory consolidation. This approach, pioneered by Robert

Stickgold, Jan Born, Matthew Walker, and others has been used to demonstrate sleep facilitation of procedural learning in perceptual and motor domains as well as of declarative and emotional forms of memory. The specific sleep physiological correlates of different forms of memory consolidation have been examined by correlating performance changes with polysomnography (PSG) measures such as sleep stage percentages or by comparing performance change over the slow wave sleep (SWS)-rich first half of the night with the random eye movement (REM)-rich latter half. In addition to memory performance, these paradigms have shown sleep-related adaptive modifications of the relationships among different items stored in memory including increasing resistance to interference and integrative processes that facilitate categorical learning.

In a third technique, a sleeping individual is awakened from different sleep stages and performance is tested upon awakening. This procedure relies on a putative physiological carry over from sleep to the temporally proximal waking and has been used by Robert Stickgold and Matthew Walker to demonstrate differential effects of REM and NREM sleep on associative memory and cognitive flexibility.

The fourth and fifth techniques both probe neuropsychological functions occurring during sleep itself. Recent findings resulting from such research are the topic of this article. First, using the new technologies of functional neuroimaging, it has become possible to directly visualize activity in the sleeping brain. During the last decade, pioneering positron emission tomography (PET) studies have been done in the laboratories of Pierre Maquet, Allen Braun, and Eric Nofzinger. More recently, fMRI has been employed in the laboratories of Michael Czisch and others. From sleep-stage dependent regional activation data, cognitive processes taking place during as well as before and after sleep can be hypothesized. The relationship between regional brain activity and known performance and experiential phenomena during waking is, of course, the body of knowledge from which such inferences must begin.

The subjective correlate of neural processes occurring during sleep is dreaming and, hence, some of the neural processes underlying the phenomenology of dreaming can also be inferred from neuroimaging sleep. The last approach – observing changes in the phenomenology of dreaming resulting from brain injury – provides additional information to hypotheses derived from imaging the sleeping brain. Neuroimaging of waking performance can tell us which brain structures are recruited by particular functions or cognitive domains but do not establish the necessity of such active areas for enacting the behavior in question. Behavioral data following lesions resulting from stroke and other forms of brain injury can begin to address the actual requirement of a particular brain structure for a specific behavioral function and such

information forms the basis of traditional neuropsychology. The necessity of certain areas for particular dream elements or for dreaming itself can be similarly inferred by querying brain injured patients about their dreams. However, the same mediation of any such accounts by waking processes involved in recollection and recounting must be recognized.

Global Changes in Brain Metabolism and Blood Flow between Sleep/Wake Stages

With sleep onset and entry into NREM sleep, global cerebral energy metabolism and oxygen utilization decrease from waking levels. As sleep deepens through the stages 1 to 4 of NREM as characterized by slowing of the scalp electroencephalograph (EEG), further decrease in global energy metabolism and oxygen utilization in the range of 10% in light NREM to as much as 40% during slow wave sleep occurs. The cellular correlate of these changes is decreased firing rate of neurons in the wake-promoting regions of the ascending reticular activating system (ARAS). The behavioral correlate of these global physiological changes is the loss of consciousness at sleep onset with further decreases in arousability, alertness upon arousal and intensity of reported sleep mentation as NREM deepens. In contrast, during REM, global cerebral energy and oxygen metabolism return to levels equal to or exceeding those of waking. The EEG correlate of these changes is increased frequency and decreased amplitude, while the cellular correlate is an increased firing rate of specific components of the ARAS. The behavioral correlate of this REM reactivation is increased arousability, alertness upon arousal and intensity of reported sleep mentation.

Regional Changes in Brain Metabolism and Blood Flow

Deactivation of frontal cortices is one of the first physiological signs of human sleep. Early deactivation of frontal areas has been reported using the full spectrum of physiological recording techniques including EEG, magnetoencephalography (MEG), PET, and fMRI. Frontal deactivation early in sleep may be related to frontal regions' greater need for homeostatic recovery from waking activity. For example, Alexander Borbely and his colleagues have shown that a useful marker of homeostatic sleep pressure, slow wave activity (SWA), is greater in frontal than in parietal and occipital regions during the first NREM episode of the night. PET studies have then described further decreasing activation, as measured by regional cerebral blood flow (rCBF) or by glucose metabolism. PET studies in the laboratory of

Pierre Maquet have shown that decreased rCBF to the thalamus may be an early event following sleep onset that is then succeeded by deactivation of medial cortical, limbic, and striatal areas. These researchers have also shown that decreasing blood flow to the ventromedial prefrontal cortex (vmPFC) correlates with increasing SWA. The vmPFC is part of a network of primarily medial cortical areas that has been termed the brain's 'default network.' Correlated activity throughout this network occurs in waking when the brain is not engaged in any effortful task and such correlated activity may persist into the lighter stages of NREM.

Recent fMRI work by in the laboratory of Michael Czisch and colleagues provides greater detail on the widespread deactivations that occur from waking to NREM and as NREM deepens. Following sleep onset, blood flow decreases to frontal areas including inferior, middle, and superior frontal gyri, as well as medial frontal and primary motor cortices. As NREM sleep deepens, deactivation is also seen in midline subcortical (e.g., hypothalamus, caudate), thalamic (e.g., anterior nucleus), limbic (e.g., insula, hippocampal complex), parietal (e.g., inferior parietal), and occipital (e.g., precuneus, cuneus) structures. Such deactivations are greater in the right hemisphere.

Much of the lateral frontal and parietal cortices remain less active than in waking after the transition from NREM to REM. However, PET studies have shown that blood flow and glucose metabolism increase during REM in subcortical brain regions such as the pons, midbrain, thalamus, amygdala, hypothalamus, and basal ganglia as well as limbic-related cortices such as parahippocampal cortex, temporal pole, anterior insula, caudal orbitofrontal cortex, subcallosal anterior cingulate, and medial prefrontal cortex. Maquet and colleagues have shown that regions most consistently remaining hypoactive in REM sleep compared to waking are in lateral cortical association areas, specifically those in middle and inferior frontal gyri, inferior parietal and temporo-parietal cortices.

In contrast, there are areas where the increase in regional glucose metabolism during REM exceeds even that of waking. Eric Nofzinger and colleagues have termed these areas the 'anterior paralimbic REM activation area,' a midline region comprised of structures including hypothalamus, ventral striatum and pallidum, hippocampus and uncus, as well as supplementary motor, pre- and subgenual anterior cingulate and insular cortices.

Thomas Balkin and colleagues have shown that frontal reactivation lags behind that of the rest of the brain following awakening. Such a lag in frontal reactivation may be the basis of reduced alertness and performance measured immediately following awakening, especially after sleep that follows sleep loss, a phenomenon termed 'sleep inertia.'

The Effects of Brain Lesions on Dreaming

Traditional neuropsychology infers regional brain function from the effects of stroke and other brain injury on behavior. Mark Solms has applied this approach to the study of dreaming by surveying hundreds of his patients and reviewing older neurological and neuropsychological reports asking the question what happens to dreaming when different parts of the brain are damaged. Solms has identified brain-injury-related syndromes of dreaming. In global anonera, total cessation of dreaming results either from bilateral or unilateral inferior parietal lesions or deep bilateral lesions of the ventromedial prefrontal white matter as was produced by lobotomy. In visual anonera, complete or partial loss of dream visual imagery results from bilateral lesions of visual association cortices in medial occipito-temporal areas. Solms found that patients with visual anonera were also unable to produce mental imagery in waking, a syndrome termed visual irreminiscence. Visual anonera need not be total, and there exist partial syndromes in which the dreaming counterpart to the waking function of an extrastriate area is lost when that area is damaged (e.g., 'kinematic anonera' or 'facial anonera'). Solms also identified disorders in which seizure activity increased the frequency and intensity of dreaming or anterior subcortical damage appeared to disinhibit dreams.

Damage to areas that remain relatively deactivated during REM sleep, the primary visual and dorsolateral prefrontal cortices, has little effect on dreaming. In contrast, several of the areas where lesions do affect dreaming are notable in that they do show increased blood flow during REM. Such areas include visual association cortices of the inferior temporal lobe, and particularly those associated with the ventral stream of visual processing – the portion of the visual system that identifies objects, faces, and places. Another such area is the anterior limbic cortex and subcortex corresponding to Nofzinger's "anterior paralimbic REM activation area."

Both Solms and earlier investigators found that isolated damage to the inferior parietal cortex, especially on the right side, can eliminate dreaming. The right inferior parietal lobe (rIPL) is an area essential to spatial attention and its damage, or even temporary inactivation using transcranial magnetic stimulation (TMS), can result in a neglect of left hemispace. The rIPL has also been linked to a number of high-level cognitive skills, including visual working memory, preparation of serial actions, allowing an egocentric frame of reference, and visual self-other discrimination. However, paradoxically, Maquet and colleagues have shown that, in most PET studies, the inferior parietal lobes have remained deactivated in REM. Notably, however, in an early PET study, the Maquet group found that an anterior portion of the right

supramarginal gyrus was activated in REM. Explanation why this multifunctional high-level association cortex should be essential to dreaming remains an intriguing question.

The Electroencephalographic Correlates of Dreaming

After REM sleep was discovered by Aserinsky and Kleitman in 1953, investigators noted a high probability of obtaining a dream report when a sleep laboratory subject was awakened from REM. Such observations led early dream researchers to speculate that REM sleep was the exclusive time when dreaming occurred. However, soon thereafter, additional sleep laboratory studies also demonstrated substantial recall of dreams following NREM awakenings. Nonetheless, subsequent laboratory studies have clearly shown that a larger percentage of REM than NREM awakenings are associated with dream recall. Moreover, it has been consistently shown that, compared to NREM dreams, REM dreams are longer as well as more bizarre, motorically active and emotional. In a review of 29 studies, Tore Nielsen has estimated a NREM recall rate of 42.5% contrasted with a REM recall rate of 81.8 %. Nielsen hypothesizes that NREM dreams may result from REM-like physiological conditions that fail to generate the particular suite of biosignals used to score REM by standard criteria – a phenomenon he terms “covert REM.”

Fast neuronal oscillations at gamma frequencies (30–80 Hz) appear in waking in association with attention to stimuli, working memory, and other forms of effortful, directed cognition. Oscillations at this frequency are greatly diminished during NREM; however, EEG and MEG studies have shown that these fast oscillations return in REM sleep. It has been hypothesized that, in waking, the functional correlates of these gamma oscillations are long-range binding of the multimodal components of complex percepts. David Kahn and colleagues have suggested that the gamma frequency oscillations of REM sleep may play a similar role with regard to the construction and cohesion of dream elements.

Contrasting with REM, in human NREM sleep and especially stage 2 and SWS, gamma frequency activity is greatly attenuated and, instead, the slow oscillatory rhythms generated by thalamocortical networks, including spindles, delta waves the cortical slow (<1 Hz) oscillation predominate. The lesser frequency and intensity of dreaming in NREM may, therefore, be due to interference with ongoing mental activity by such intrinsic oscillations.

Spectral analysis uses fast Fourier transformation of EEG data to compute the percentages of total EEG power

that occur in the different sleep-relevant frequency bands of the EEG spectrum. This technique has been used to investigate whether greater power in particular frequency bands before awakening is associated with dream recall. Greater percentages of EEG power in faster frequencies (e.g., beta) or lower percentages in slower frequencies (e.g., delta) have been associated with greater frequency, length, or dream-like character of reports in some but not all studies. Since faster EEG frequencies are associated with greater cortical arousal, their association with sleep mentation is predicted and the weight of evidence across majority of studies generally supports this prediction. However, there have been a number of studies that found no such dream correlations, dream correlations that were only seen at certain scalp locations (EEG derivations), were opposite to the predicted direction, or occurred with post- versus pre-awakening EEG spectral composition. In addition, correlations of spectral power distribution with dream recall were not identical between studies of REM and NREM awakenings. Moreover, most studies did not associate dream variables with spectral power in the fastest (gamma) or slowest (<1 Hz cortical slow oscillation) EEG frequencies.

A great deal of attention has been paid to cognitive correlates of phasic (brief, intermittent) events during sleep in relation to dreaming. For example, in stage 2 NREM, Russell Conduit and colleagues have shown that auditory stimuli below the threshold for awakening increase the frequency of reports of visual imagery in subsequent awakenings. These investigators also showed that NREM awakenings preceded by eyelid movements (ELMs) yielded a higher frequency of visual imagery reports than awakenings not preceded by ELMs. They attribute their observations to imagery being stimulated by transiently increased brain arousal that either follows sensory stimulation or occurs spontaneously producing both the ELM and associated imagery.

Most attention, however, has been paid to dream correlates of the phasic events occurring during REM, especially the REMs themselves. Investigators have traditionally subdivided REM sleep into phasic periods during which clusters of REMs occur and tonic periods lacking or with only occasional, isolated REMs. Intense interest in phasic REM has resulted from the close temporal association of REMs with ponto-geniculo-occipital (PGO) waves discovered in the cat. These ascending potentials, originating in the brainstem, suggested to Allan Hobson and Robert McCarley, in their activation-synthesis hypothesis, a means by which, during REM, a phasic signal, arriving via the visual pathway, might be interpreted as sensory input by the visual cortex thereby leading to dream hallucination.

Since the publication of Hobson and McCarley's hypothesis in 1977, tantalizing suggestions of human PGO waves have been reported from EEG and

neuroimaging studies. Three very recent findings, however, have provided the most powerful evidence of the human PGO and of cortical correlates of phasic REM respectively. First, Lim and colleagues described phasic signals with wave form and temporal characteristics very similar to the feline PGO, originating, during REM, from the pons of a Parkinson's Disease patient with depth electrodes placed in the pedunculopontine nucleus (PPT). Second, using MEG tomography, Ioannides and colleagues have shown that preceding and correlated with rapid eye movements (REMs), there is phasic brain activity in the pons that is accompanied by simultaneous activity in frontal eye fields (FEF). Notably, just prior to REMs, activation was also seen in the amygdala and limbic cortices. Third, using fMRI, Renate Wherle, in Michael Czisch's laboratory, has shown that characteristic changes in forebrain activity accompany phasic REM episodes arising from a tonic REM background. Changes included disappearance of the residual responses of the auditory cortex to sound stimulation seen in tonic REM as well as enhanced synchronization with thalamic activity of a broad cortical-limbic-striatal network. These investigators posit that this represents activation, during phasic REM, of networks important to memory and emotional processing that are simultaneously shielded from interference by an increased cortical threshold to external sensory input.

Cortical Connectivity in Sleep

Profound changes in addition to those used to stage sleep can be seen in the EEG of the sleeper when techniques of quantitative EEG are applied. Such techniques suggest both increased synchrony of slow oscillations and loss of coherence among fast EEG rhythms in NREM and REM sleep, respectively.

The slowing and synchronization of the NREM EEG is accompanied by the emergence of waveforms that reflect underlying thalamocortical oscillations such as spindle- and delta-frequency rhythms and the slow cortical oscillation discovered by the late Mircea Steriade. A widely replicated finding has been that slow wave activity is greater in frontal cortex following sleep onset and then spreads posteriorly as NREM deepens. For example, using mathematical estimates of functional coupling and direction of information flow, Luigi DeGennaro and colleagues have demonstrated an anterior-to-posterior directionality in the progressive EEG synchronization following sleep onset.

While such slow oscillations suppress cognitive activity in NREM, loss of long-range coherence in rapid gamma frequency oscillations may contribute to disorganization of cognition in REM dreaming. Unlike the wide-range coherence of gamma frequency oscillations seen in

waking, in REM, such oscillations become desynchronized and lose coherence between frontal and posterior cortex or between cortex and hippocampus. Researchers, such as Maria Corsi-Cabrera, suggest that such gamma desynchrony may reflect functional disconnections between different brain regions that could contribute to the hypofrontal features and weirdness of REM sleep dreaming. In the last several years, transcranial magnetic stimulation (TMS) studies have been employed to experimentally demonstrate such functional disconnections between different brain regions during sleep.

A Descriptive Neurobiological Model of Dreaming

Empirical demonstration of regional brain activity preceding specific dream reports awaits experiments combining EEG and neuroimaging techniques. Nonetheless, neuroimaging studies of sleep, phenomenological and brain-lesion studies of dreaming, and, especially, the ever-increasing understanding of the brain basis of waking skills and subjective experience allow us to construct a speculative, descriptive neurobiological model of the brain basis of dreaming. This model is summarized here and is detailed in two book chapters by this author and a review by Hobson *et al.* cited below.

First, since dreaming is a form of consciousness, albeit one lacking insight into one's mental state, portions of the forebrain must be activated to a level that will support such fictive experience. As described in preceding sections, during REM sleep, the ascending reticular activating system (ARAS) activates the thalamus and basal forebrain that, in turn, activate subcortical limbic structures as well as specific parts of the cortex described above. Importantly, however, during REM, this ascending activation is driven by the cholinergic nuclei of the mesopontine brainstem rather than by the full complement of wake-promoting aminergic (noradrenergic, serotonergic, and histaminergic) systems that accompany cholinergic activation in waking.

Relative to forebrain activation in waking, such aminergically deficient and cholinergically biased forebrain activation in REM undoubtedly contributes to the unique quality of dream awareness. For example, differences in waking and sleep neuromodulation of the forebrain might underlie the differing regional pattern of forebrain activation seen in these two states of consciousness. Alternatively, or additionally, since aminergic systems have been abundantly demonstrated to facilitate higher cognitive functions such as attention and working memory, the nadir of such systems' influence on the forebrain during REM may subtract certain key capacities of waking consciousness (e.g., insight) from that of dreaming.

The regional pattern of brain activity in REM includes Nofzinger's "anterior paralimbic REM activation area" as well as brainstem activity in the pons and midbrain. Included in this midline activation are the hypothalamus, basal forebrain, amygdala, ventral striatum and pallidum, as well as anterior cingulate (ACC) and other limbic cortices. Activity in these regions may generate the emotionally salient features of dreaming. For example, anger, sexuality, or panic states in dreaming may result from activity in specific regions of the hypothalamus that trigger such instinctive programs. Similarly, appetitive behaviors, Freud's dream 'wish fulfillment' that is emphasized in Mark Solms' dream theory, may result from activity in the brain's reward system that includes midbrain dopaminergic cells of the ventral tegmental area (VTA) as well as the ventral striatum and pallidum and the medial prefrontal cortex. Similarly, fear and anxiety, ubiquitous if not predominant dream emotions, may result from activity in the amygdalar, hippocampal, basal forebrain (e.g., bed nucleus of the stria terminalis), and medial prefrontal (e.g., subgenual ACC) areas that support the encoding of fear and extinction memories. Ross Levin and Tore Nielsen's recent theory on the emotion regulatory function of normal dreams as well as dysfunction of this system in nightmare disorders focuses on REM-related activity in these fear circuits of the limbic forebrain.

In addition to a role in reward processing and fear regulation, regions of the medial prefrontal cortex are essential to social cognition and social judgment, prefrontal functions emphasized in Antonio Damasio's somatic marker hypothesis. Notably, dreaming is a highly social experience in which the dreamer interacts with a panoply of fictive characters of a variety sometimes wider than in waking, such as when characters from the distant past reappear. Moreover, many of the sophisticated social skills deployed in waking such as the ability to 'mind-read' – i.e., infer and proactively or reactively respond to what a dream character may be thinking or feeling – are preserved in dreams. Additionally, high-level social emotions such as guilt and empathy are not uncommon in dreams.

While episodic memory in the form of reenactment of events experienced in waking is notably deficient in dreams as reported by Roar Fosse and colleagues, recognition memory is intact and sometimes bizarrely enhanced. For example, in a study by David Kahn and colleagues, almost half of dream characters were identified on the basis of 'just knowing' who they were. Moreover, it is also not uncommon for a dream character to substantially differ (e.g., in appearance, age, sex, or mortal status) from its waking counterpart but nonetheless be confidently identified as that individual.

Altered distribution of activity in among different components of the hippocampal complex in REM

compared to waking may underlie this altered distribution of mnemonic activity and accuracy in dreaming. Neuroimaging studies of waking are increasingly assigning roles to frontal cortices in memory function. Lateral and polar frontal areas are involved in effortful, strategic encoding and retrieval, whereas posterior medial areas are involved in feeling-based confirmatory aspects of memory. In this regard, poor working memory, loss of orientation and the illogical, non-volitional appearance of dream persons, places, and things may reflect the above-noted hypo-activity of the lateral prefrontal cortex. Conversely, the confabulatory nature of dream narratives may reflect the REM-related hyperactivity of posterior-medial frontal areas and adjacent basal forebrain – the very areas whose disruption in waking leads to amnesic confabulatory syndromes.

Fictive motor activity is being initiated, controlled and inhibited during dreaming just as its actual counterparts are enacted in waking. In REM, however, actual contraction of skeletal muscle for the enactment of motor commands is inhibited by the active atonia described in previous sections. Prominent activity in those areas involved in the initiation and control of motion, specifically the basal ganglia and cerebellum, have been noted in neuroimaging REM, such as in the PET studies of Allen Braun. Cerebellar activity may specifically result in the vestibular anomalies of dreaming such as sensations of flying, falling, or moving in a vehicle. Interestingly, primary motor cortex and lateral pre-motor areas are not reported to be re-activated in REM. It is possible, however, that motor functions of medial areas, such as the dorsal anterior cingulate or pre-supplementary motor area (pre-SMA), produce motor commands in dreaming. As in the case of most aspects of the functional neuro-anatomy of dreaming, such hypotheses suggest important studies yet to be performed.

Perhaps the most striking aspect of dreams is their remarkably life-like visual character. ARAS activation of the visual forebrain as well as phasic signals from brainstem to visual association cortices may account for dreams' visual content. For example, complex hallucinosis of animate and inanimate objects may be subserved by activity in visual association cortices of the ventral stream of visual processing. Braun's PET studies have identified REM-related activity in extrastriate areas of the ventral stream and, as noted above, Solms' studies have associated damage to these areas with nonvisual dreaming. This may be a process analogous to the visual hallucinosis of waking as is suggested both by neuroimaging of complex hallucinosis in waking (e.g., in Charles Bonnet syndrome), and by the co-occurrence of nonvisual dreaming and inability to visualize during waking reported by Solms. Notably, specific areas identified with waking perception of faces and scenes, the fusiform gyrus of the inferior temporal

cortex and the parahippocampal gyrus, respectively, have also been shown to increase their activity during REM.

Although dream hallucinosis is thus neurobiologically explicable, the integration of these hallucinations into identifiable scenes as well as into elaborate dream plots is a remarkable phenomenon that suggests a predisposition of the brain to generate narratives even absent the awareness of doing so. This is all the more remarkable given the deficits in executive and higher-order functions during dreams, deficits that can be explained by the relative inactivity of lateral frontal and parietal cortices during REM as compared with waking. Such executive deficits include the attenuated attention, working memory, logic, volition, and orientation that Allan Hobson and colleagues have described. The persistence of narrative capacity in the face of such deficits may involve activity of medial prefrontal structures shown by Braun and colleagues to be activated by narrative generation whether it is in spoken language or in sign language.

A second mystery, as discussed above, is the role assigned to the inferior parietal cortex, especially in the right hemisphere, that, although typically remaining deactivated in REM sleep, has been shown by lesion studies to be essential to dreams. It has been suggested that its role is to generate the fictive space in which dreaming occurs. However, there may be other functions dependent upon this high-level multimodal association cortex, such as the establishment of an egocentric spatial perspective, without which dreaming cannot occur.

Conclusion

Laboratory awakening studies on the polysomnographic correlates of dream recall frequency or intensity have generated important hypotheses and provided valuable, replicated findings. Similarly, neuroimaging of the sleeping brain has provided replicated observations of regional cerebral activity corresponding to polysomnographically defined sleep stages, albeit without accompanying subjective reports. Inevitably, awakenings from sleep and their dream reports will be accompanied by both spatially precise functional images of the dreaming brain and temporally precise EEG measures. When such techniques become widely employed, activity of the sleeping brain as it generates a dream may at last be directly observed. As has been the case throughout the history of dream research, however, such technical advances will undoubtedly generate yet more new and intriguing questions.

Introduction

To make a faithful copy of the world is one good act a brain can do. However, to correctly predict the world's features is even better. It is the general theme of this article as well as the articles related to sleep that the inherent capacity of the brain to change its state, as it does in sleeping, waking, and dreaming confers significant adaptive advantage upon those organisms that can do so regularly. One clear implication of the state changes from waking to rapid eye movement (REM) is to reveal the brain's built-in capacity to predict.

Timing by Neuronal Clocks

It is already clear that all cells, be they animal or vegetable, anticipate the light-dark cycle of the world by means of intrinsic rhythms of about 24-h circadian length. Even individual molecules of DNA are clock-like mechanisms that can self-regulate so as to operate in the most favorable light and temperature phases of each day.

On the other hand, higher animals with elaborate brains can do more than this. They can take advantage of their intrinsic circadian rhythms to program sleep during the rest phase of their circadian rhythm and within that sleep they can program an oscillation of sleep phases in one of which we humans dream. This article, attempts to show that animals take advantage of these extrinsic and intrinsic rhythms to conserve energy (and manage its expenditures) and to organize information (and apply its instructions) in an admirably supple way that varies markedly according the ecological realities to which each species must conform.

Why do we dream? The theory that we develop here is that we dream because our brains are performing genetically programmed virtual behaviors of use to us in the sensorimotor development of our learning about the world.

The Concept of State

Most simple organisms have two states, activity (on) and rest (off), which depend upon ambient temperature. Thus, at any given warm temperature, they have

only one state, waking. They may be more or less on as a function of temperature-mediated activation. At all other cool states, they become torpid. Notable exceptions to this rule have raised hopes that a genetically detailed but simple neuronal model could be developed for basic sleep research. The fruit fly (*Drosophila*) and the round worm (*Caenorhabditis*) have both been shown to reduce activity and responsiveness with changes in temperature.

Mammals and birds are the only creatures that maintain a high (+37 °C) body temperature over a wide range of ambient temperatures. We say that they are homeothermic (rather than poikilothermic like their less-sophisticated forebears). Some mammals adopt an intermediate strategy: hibernation. Hibernation is an active state in which core body temperature is reset at 0.5 °C in the late fall and held at that level until ambient temperature rises in the spring.

Homeothermy conveys an adaptative advantage. Behavior can be maintained despite relatively unfavorable environmental conditions. The behavior that is maintained by homeothermy is also more versatile than that of poikilothermic animals. This versatility not only extends to such motor skills as walking, swimming, or flying, but also to the succession of global states such as sleeping and waking. Most spectacular of all, and crying out for deeper understanding, is the brain-activated state, called REM, which regularly punctuates sleep and is associated in humans with vivid hallucinoid dreaming.

These sets of conditions are called 'states' because they are so global, so enduring, and so clearly distinguished from each other as to imply distinct regulatory mechanisms and differential functions. It is the burden of this article as well as related ones to communicate the insights that have been gained regarding these states over the past half century.

To anticipate a bit, we will show that mammals have modified these interrelated states in order to achieve an even more impressive set of capabilities that allow their brains (1) to anticipate the future and prepare for it through development; (2) to incorporate the past, and learn from it; and (3) to maintain homeostasis so as to guarantee optimal achievements in the planning, coping, and creative behaviors of the future.

Spontaneity and the Reflex Model

For most of the twentieth century, neurobiology and psychology were both dominated by Ivan Pavlov and BF Skinner who applied the reflex paradigm to psychology. This paradigm was also very fruitful in the hands of the father of neurophysiology, Charles Sherrington, and it came to define the first century of experimental neuroscience from 1900 to 2000 and beyond. In the reflex paradigm, a set of resting conditions is established. Then a stimulus (S) is applied and a response (R) is measured. The characteristics of the S–R complex are then analyzed and intervening brain processes are inferred. New hypotheses can be derived and tested by modifying the stimulation parameters.

Essentially, the same format was used in psychology throughout the twentieth century. Pavlov combined stimulus pairs to evoke conditioned responses from unconditional stimuli and Skinner altered response pattern to spontaneous stimuli arising from the behavior of animals, the operant which was to be conditioned. In Skinner's model, the response became a stimulus which structured an environmental reward placing the reflex loop outside the brain.

The brain was thus seen as either a black box (a la B.F. Skinner) or a black board (a la John Locke) upon which the outside world wrote its messages and dictated our behavior. Prior to 1950, there was little room in physiology or in psychology for much of value to arise from within the brain itself. By postulating the id, Freud began to help build the case for spontaneity, for oscillation, and for built-in order and purposeful design. However, with the discovery of the electroencephalogram (EEG) in 1928, the recognition of the sleep cycle in 1936, the conceptualization of the reticular activating system in 1949, and, especially, the discovery of REM sleep in 1953, it was possible to realize how much useful information came from within the brain itself.

Activation (A)

Until Hans Berger discovered the EEG in Jena in 1928, there was no objective instrumental means for studying sleep. Charles Sherrington, the father of neurobiology, opined in *Man on His Nature*, that the brain turned off in sleep, while the great experimental psychologist, Ivan Pavlov, ascribed sleep to cortical inhibition. Both men shared the hypothesis, promulgated by the Belgian physiologist, Frederic Bremer, that sleep was caused by the decline in sensory stimulation that occurred at nightfall and was triggered by turning out the light in our bedroom. Not until morning was external stimulus strength sustained enough to support waking.

The Overthrow of the Deafferentiation Hypothesis

By 1930, when Hans Berger had put the EEG into the hands of scientists like the Belgian physiologist, Frederic Bremer, the sensory deafferentation hypothesis was so deeply engrained that it took almost 20 years to dislodge it. Yet nothing in Hans Berger's work suggested that brain activity ceased at sleep onset. In fact, the characteristic spindles and slow waves of sleep helped to convince early skeptics such as Edgar Adrian in Cambridge that the EEG signals were really of brain origin and not muscle artifacts.

The brain of Berger's EEG subjects had not turned off at sleep onset; instead, it had changed state and we now know that the activation level (A) declines by 20–40% overall in sleep. This signifies that the brain, without external stimulation, is capable of maintaining a remarkably high level of activation, but one that is not high enough to support consciousness and to be fully compatible with significant information processing. Bremer tried to prove his deafferentation hypothesis by cutting across the midbrain creating the *cerveau isolé* whose EEG rostral to the cut was permanently that of sleep. Bremer assumed that this effect was caused by the loss of information arising from the lower body. However, when he found that the EEG of a cat with a C-1 spinal cord transection was constantly activated, he was obliged to posit that the activating force was entirely due to sensory stimulation arising in the trigeminal nerve which entered the brainstem between the levels of the two cuts!

Never once did Bremer, or any other scientist, take the hypothesis seriously that activation arises within the brain itself. This failure to consider an internal activating system is more surprising, given the impact of the somnolent effects of the 1918 flu epidemic which Von Economo tentatively but presciently ascribed to damage in the midbrain and hypothalamus.

In part because of this conceptual block and in part because of the complexity of the new technology, progress was slow through the 1930s and 1940s and stopped entirely with the outbreak of World War II. In 1936, Loomis and Harvey did describe periodic activation and deactivation of the EEG in human sleep with a period length of about 90–100 min; however, they failed to observe REM and hence to conclude that the cyclic activation of the brain in sleep was entirely intrinsic. This discovery, when it was finally made, was entirely accidental!

The Reticular Activating System (1949)

Giuseppe Moruzzi was a friend and colleague of Frederic Bremer. After World War II, Moruzzi went from Pisa, Italy, to the Northwestern University in Chicago to study

the motor system with the American neurophysiologist, Horace Magoun. They used sharpened insect pins to record the action potentials from pyramidal tract cells of the cat motor cortex. Subsequently, they stimulated pyramidal tract fibers in the medullary brainstem hoping to identify pyramidal motoneurons via antidromic invasion. To monitor level of anesthesia in the animals, Moruzzi and Magoun recorded the cortical EEG as well.

To their great surprise, Moruzzi and Magoun observed that whenever they stimulated the brainstem the cortical EEG generated low-voltage fast waves indicative of activation. Having excluded the possibility that the effects were due to the afferent sensory inputs emphasized by Bremer, they suggested, for the first time, that brain activation could be intrinsically mediated by the brainstem itself.

Although the brain-activating effects observed by Moruzzi and Magoun could be obtained at many points from the hypothalamus to the medullary reticular formation of the brainstem, the anterior midbrain was the most potent activating site. We now suspect that this is because of the concentration of both aminergic and cholinergic modulatory neurons at the site, which are known to participate differentially in the activation process of both waking and REM sleep. Because of its anatomical complexity, the brainstem reticular formation had been dubbed ‘a wearisome labyrinth’ by Santiago Ramon y Cajal. It is important to emphasize that even today we are only beginning to understand this small but critically important part of the brain.

The Discovery of REM Sleep (1953)

Similar to the 1949 discovery of the reticular activating system, which was an accidental by-product of a study of the motor system in cats, the discovery of REM sleep was an accidental by-product of the study of attention in children. Nathaniel Kleitman’s graduate student, Eugene Aserinsky, placed electrodes beside the eyes of his young subjects in order to monitor their alertness during the performance of an attentional task. When they became bored, these subjects dozed off. As they were young, they often had sleep-onset REM periods and, when awakened, reported vivid dreams. (One of the subjects was Aserinsky’s 9-year-old son, Armand.)

Following Aserinsky’s report on his findings in children to Kleitman, it was decided to record the nocturnal sleep of adults. When they observed the periodic EEG activation of sleep, together with the eye movements, Aserinsky and Kleitman performed instrumental awakenings in an attempt to elicit reports of mental activity. Awakenings from REM sleep yielded detailed reports of vivid, bizarre, and sustained dreams, a finding which has been confirmed and elaborated upon in the subsequent half century. Aserinsky and Kleitman also described the

heart and respiratory rate increases and irregularities during REM sleep. Their study ended forever the myth that dreams were mysterious imaginations coming from outside of the body or even from some obscure part of the mind. The naturalization of the human psyche can be said to have commenced, in earnest, in 1953!

By 1957, William Dement had established the existence of REM sleep in the cat. Dement’s discovery was confirmed by Michel Jouvet and Francois Michel in Lyon, France, in 1959. Wishing to monitor alertness in their cats, which were subjected to Pavlovian conditioning in order to study learning, the neck muscle electrodes that were implanted showed a complete cessation of electromyography (EMG) activity as the cats postural muscle tone was inhibited at REM sleep onset. This observation set the stage for the many fascinating findings that are described as the input–output gating functions of REM sleep. Before turning our attention to this topic, let us emphasize that up to this point, brain activation was thought to be a global and uniform process because its regional and chemical differentiation were still unknown.

The Non-REM–REM Sleep Cycle

The easiest way to think of variations in activation over the sleep cycle is by picturing a damped oscillator with its greatest amplitude and longest stays in non-REM (NREM) sleep early in the night and shallower depth with longer stays in REM later in the night. Period length is relatively constant, for adult humans, at 90–100 min.

The damping of the NREM–REM sleep oscillator is a function of the interaction of the circadian tendency to alternate rest and activity with the homeostatic tendency for NREM sleep drive to increase with increasing time awake. Alex Borbely has incorporated these data in his elegant two-factor model of sleep propensity over time.

Sleep is a highly conserved behavior indicating its priority among survival strategies. Most adult humans sleep 4–10 h a day and suffer with less than their baseline quota. Lost sleep is recovered scrupulously: about 50% is recovered as time asleep and more as the intensity of rebound sleep. Short sleepers tend to be energetic and productive; long sleepers are more likely to be lethargic and reflective. Deprivation of sleep leads to fatigue, sleepiness, irritability, difficulty in concentrating, feeling cold and, in extreme cases, to psychosis. There is no difference between the effects of REM and total sleep deprivation but the universally fatal effects of both suggest that REM may be a more efficient recovery process. Rats which are sleep deprived for 4–6 weeks lose weight in the presence of abundant food, fail to regulate their body temperature, and become susceptible to infections they normally resist (see the section titled ‘Functional implications’).

The Concept of the Brain–Mind

So closely do the psychological features of cognition and emotion parallel the physiological features of sleep and waking that we can now hypothesize that mental activity is a brain function and the brain–mind is an integrated system. It is obvious to most people, and certainly to most scientists, that mind and brain are inseparable even though we do not yet understand how they could be as unified as they appear to be. This is what philosopher David Chalmers calls ‘the hard problem.’ One possibility is that brain–mind is only one entity but an entity which possesses subjective as well as objective features. This formulation, which seems philosophically and scientifically inescapable, does not yet resolve the mind–brain problem (or even make it easy) but it does seem to make a unified theory inevitable.

A working hypothesis of those scientists who study brain–mind states is that a deeper understanding of how brain activity becomes mental can be gained by the strategic study of sleeping, waking, and dreaming. Such studies have already proved illuminating with respect to sensation, perception, orientation, emotion, and memory. These modular functions contribute to the kind of consciousness that we experience in the several states. For example, it is dramatically clear that while waking is dominated by external perceptions and by abundant thought, dreaming is dominated by intense perceptions of internal origin and by greatly impoverished thought.

Thus, the kind of consciousness that we experience is clearly a brain function and we can now specify how and why this is the case. We can also model both the internal percepts of dreaming and the deficient cognitive capacities of that state and suggest how they might derive from changes in perfectly normal neurophysiology. It remains to be deduced what advantage may arise from these modular differences between dreaming and waking. Our suggestion is that the capacity to form visual images in the absence of external inputs is an important skill for both normal exteroception and for imagination. The creature with a well-developed capacity for these skills will be at a competitive advantage.

The EEG in NREM Sleep

The alert brain–mind is characterized by a low-voltage fast EEG; a gamma rhythm of $40\text{--}60\text{ c s}^{-1}$ can be seen. This rhythm is generated by the activated and synchronized neuronal firing in widespread cortical circuits. Drowsiness is characterized by EEG slowing in the $4\text{--}8\text{ c s}^{-1}$ theta range. When thalamocortical circuits escape from brainstem control, stereotyped clusters of $12\text{--}15\text{ c s}^{-1}$ spindles dominate the cortical EEG and sleep proper (stage II) commences. As sleep lengthens and deepens, $1\text{--}3\text{ c s}^{-1}$ slow waves come to be associated with spindles

in stage III and then to dominate the record of stage IV NREM sleep (**Figure 1**). This progressive process reverses itself when REM sleep supervenes. All spindles and slow waves are suppressed as their neuronal oscillators are blocked and the EEG reverts to wake and drowsy-like patterns of low voltage, fast activity, including alpha, theta, and gamma rhythms (**Figure 2**).

REM sleep is at its peak prominence at 30 weeks *in utero* when the brain is rapidly developing. It falls steadily during the first year of postnatal life during which time it may decline as much as 400% while waking greatly increases. The correlation of REM sleep with brain immaturity suggests a developmental function consistent with the idea that the sleeping brain is capable of activating circuits that are crucial for waking behavior and for consciousness. Contrastingly, the capacity to generate robust NREM sleep increases with age and with brain development from early infancy to age 30 when it sharply declines only to disappear at age 40. With the disappearance of NREM sleep goes brain secretion of such anabolic chemicals as growth hormone (GH) and luteinizing hormone (LH).

Both NREM and REM sleep diminish in strength over the balance of a lifetime when cognitive and other functions show parallel declines.

Many other functions parallel the NREM–REM change with a night of sleep. Heart rate, respiratory rate, and blood pressure decline in NREM only to rise again to waking levels or beyond in REM. Erection (in males) and clitoral engorgement (in females) are common in REM whether or not the associated dreams are erotic. These and other changes in bodily function are often pathologically exaggerated. These clinical findings destroy forever the myth of sleep as inwardly peaceful. Under the cover of relative unconsciousness and immobility lurks a wide variety of physiological activities, not all of which are beneficial to health.

In animals, a highly rhythmic theta EEG rhythm can be recorded from the hippocampus. Such activity is also seen during intense exploratory activity in waking. In the cat, REM is associated not only with strong hippocampal theta but also with large biphasic sharp waves often occurring in clusters together with the eye movements. These waves are created in the pons (P), lateral geniculate body (G), and the occipital cortex (O). They are therefore called ‘PGO waves,’ named by their discoverer, Michel Jouvet of Lyon, France.

The many provocative similarities between waking and REM stimulate hypotheses about a functionally significant homology between the two brain states in which one (REM) is seen as the benefactor of the other (wake) and vice versa. This idea is at the heart of the unified theory developed here: REM sleep is an activation state of the brain–mind, which both anticipates and plans for waking. The brain–mind then uses data from waking state to shape its expectations of the future.

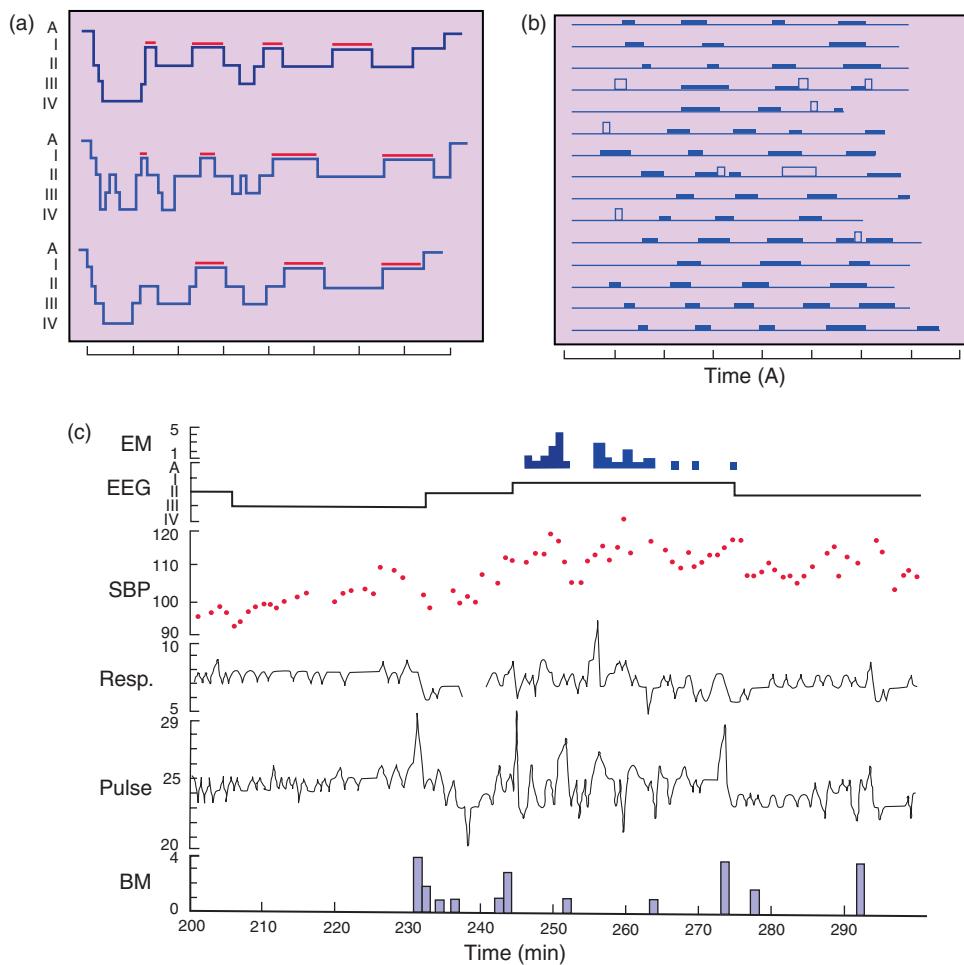

Figure 1 Stages of sleep: (a) standard polygraphic representation of three nights of human sleep; (b) ten nights of human sleep showing recurrent periods of brain activation; and (c) a single cycle of human sleep showing that clusters of eye movement in REM are associated with increases in systolic blood pressure and cardiorespiratory irregularity.

The dynamic interaction of sleep and wake states plays itself out at many levels of brain organization and benefits temperature control, cerebral homeostasis, and learning and memory. It is the unique task of the brain–mind to process information. This is the main assumption of the reflex paradigm in its focus upon external information. But what about internal information? Much internal information is in the service of the reflexive processors of the sensorimotor systems. This is particularly true of many autonomic pathways. However, just as the heart contracts rhythmically on its own, so does the brain manufacture its own data without any help from the outside world. An infant does not need to learn how to cry; it is born with that innate, powerful, and useful motor skill. In addition, there are many other such survival-enhancing skills, like sleep itself, which are innate and instinctual.

Information Source and Fate (I)

In this section, we summarize what sleep research has learned about how information processing is altered by sleep so as to help us understand both external (reflexive)

and internal (innate) information processing. Throughout this discussion, we will have reference to two aspects of this process: (1) those which regulate information flow to and from the world (via input–output gates) and (2) those which arise with the brain itself.

Sensory Input Gating

In order to preserve sleep in the face of strong central activation, it is necessary not only to suppress motor output but also to block sensory input. In the course of his work on the motor inhibition of REM, the Italian neurophysiologist, Ottavio Pompeiano, had shown that the sensory threshold was raised through the mechanism of presynaptic inhibition during REM sleep, especially when the eye movements were present. It is at such times that dreaming is most intense.

A second, important mechanism is the raised threshold to external sensory signals that occurs at secondary relay stations, especially in the thalamus, the sensory gateway to the cortex. As an intrinsic mechanism of sleep onset,

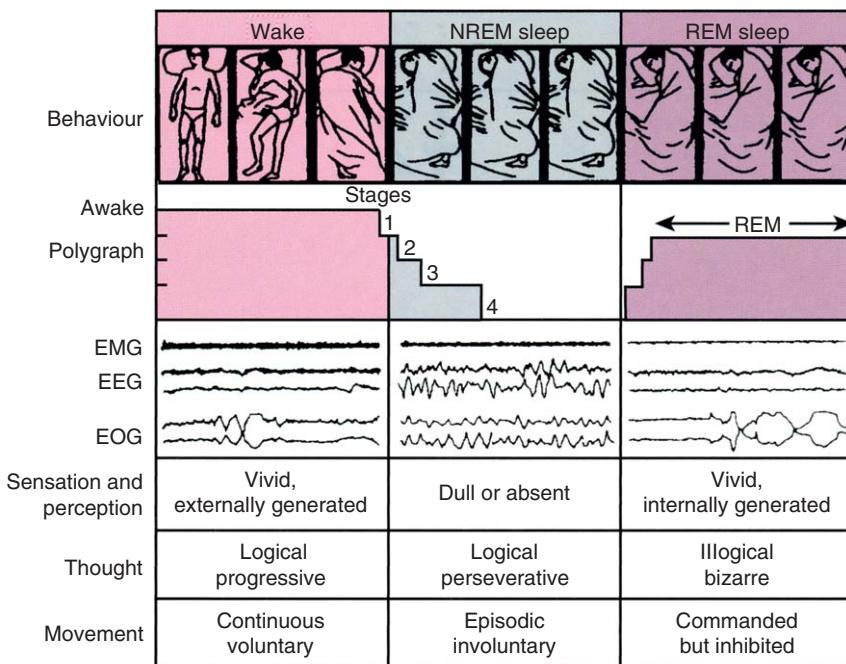

Figure 2 Behavioral states in humans. Posture shifts and changes in mental activity are associated with shifts in brain physiology.

the spindles of stage II NREM constitute spontaneous rhythmic discharge in thalamocortical and corticothalamic neurons. These paroxysmal discharges do not give rise to sensation; rather, they obliterate awareness and thus constitute usurpation of the sensory pathways by which an external stimulus might reach the cortex. This is deafferentation with a vengeance but it is not the lack of sensory input that Bremer imagined it to be. It is the result of an active blockade of neurotransmission called ‘occlusion.’

The neuronal dynamics of spindle and slow-wave production was first described by Dominic Purpura and his colleagues at the Columbia University in New York. They were later extensively elaborated upon by the late Mircea Steriade working at the Laval University in Quebec. One of the great triumphs of behavioral neuroscience indicates that spindles and slow waves exist not only to guarantee deafferentation by putting the forebrain offline but also to allow the actively deafferentiated brain to process data of relevance to learning and memory. Frederic Bremer and Giuseppe Moruzzi owe Mircea Steriade the honor for resuscitating the deafferentation concept in the service of neuronal plasticity.

The mechanisms by which plasticity may be enhanced by sleep involve pontomesencephalic neurons which are intrinsic to Moruzzi and Magoun’s reticular activating system. As long as tonic input from the brainstem cells of the reticular formation instructs the cells of the reticular shell of the thalamus to fire, they do so, suppressing the spontaneous rhythmic activity of the thalamocortical circuits. In this open-gate condition, the brain is awake and

the thalamus can relay external data to the cortex. At sleep onset, when reticular nucleus activation subsides, the thalamocortical circuits become co-opted by their own intrinsic rhythmicity and are no longer available for their wake-state external monitoring tasks.

This is a prime example of input–output gating by which the brain shuts its eyes, ears, and other sensors to the outside world so that it can attend more effectively to the many internal bookkeeping tasks of sleep. So far, we have emphasized the benefits of development and learning and memory. We will add benefits to temperature control in the next section.

Gyorgi Buzsaki has discovered that the flow of information within the brain is also altered in sleep. Not only are the external gates closed but also the flow of data out of the subcortical hippocampus (toward cortical storage sites presumed to be the home of long-term memory) is favored over flow into the hippocampus (where information is presumably captured and temporarily stored as short-term memory during waking). This observation serves to emphasize the general point that sleep is not so much a question of more or less information processed as about what kind of information processing is favored: Is it capture of information in short-term storage (waking) or is it consolidation and elaboration of long-term memory stores (sleep)?

As indicated above, occlusion is the term which is used to describe the internal occupation of sensory circuits by pseudo-sensory stimuli. Of course, the term ‘pseudo’ is only relative to the provenance, not the significance of such stimuli. Stimuli may be equally as meaningful when

they come from within the brain as when they come from without. Dream consciousness commonly and wrongly ascribes internal stimuli to external provenance. Hence, one of the cardinal features of dream psychology is the conviction that we are awake. This delusional property is just as strong a testimony to how well the brain activation of sleep mimics that of waking as it is a comment on how fully impaired is our insight and judgment during dreaming.

Motor Output Gating

The same Horace Magoun who, in 1949, co-discovered the reticular activating system of the brainstem worked with Ruth Rhines in 1947 and showed that electrical stimulation of the medullary brainstem could induce powerful suppression of spinal reflex activity. Postural muscle tone was observed to suddenly decrease in the decerebrate cat by Philip Bard and David Rioch at the Johns Hopkins Medical School who reported their observation to Michel Jouvet. With Francois Michel, Jouvet had reported periodic obliteration of muscle tone measured as the EMG during the REM sleep of cats.

In 1959, Jouvet reported the effects of preoptine transection of the brainstem at the same level that Frederic Bremer had interrupted to produce the perpetually sleeping *cerveau isolé*. Jouvet was interested in testing the hypothesis that a descending signal from the brainstem to the spinal cord mediated the muscle inhibition of REM sleep. He hypothesized that it was an ascending signal from the brainstem which mediated the EEG activation of REM.

Thus, Jouvet's results killed two birds with one stone. It was from the pontomesencephalic midbrain reticular formation that emanated both commands, an ascending pathway activated the forebrain and a descending pathway inhibited postural muscle tone! Jouvet's 1962 paper proposed, for the first time, that the pontine brainstem was a control region for REM sleep. In other words, the pontine brainstem had a way of waking up the forebrain while simultaneously preventing movement. This combination of changes caused Jouvet to coin the term, 'paradoxical' sleep. "The animal is asleep but the EEG shows it to be awake," he wrote in his laboratory notebooks of that era (**Figure 3**).

The later work by Ottaviano Pompeiano in Moruzzi's lab in Pisa, Italy, and by Michael Chase in the Brain Research Institute at the University of California, Los Angeles (UCLA) showed that the inhibition of muscle tone in REM sleep was mediated by glycine released by fibers impinging on final common path motoneurons at all levels of the brainstem and spinal cord during REM sleep in the cat. Nature had thus tinkered up a mechanism for turning on the upper brain and simultaneously turning off motor output! Of course, the upper brain did not really

wake up – and we will find out why anon – but it did activate; and it did generate eye movements, and we do dream in REM sleep.

The fact that almost all REM dreams are animated indicates that REM sleep is a virtual – or simulated – motor activation pattern for the brain–mind. We move, however fictively, in our REM sleep dreams. The activation pattern is not random or even chaotic as some aspects of dreams might have us believe. Rather it is reliably stereotyped allowing us to stand, walk, and even run – offline as it were – while floating in amniotic fluid in our mothers' bellies or lying safely in our beds. This is what is meant by 'fictive' movement. As far as the brain is concerned, the movement is real in that it is patterned. That neurophysiologically real pattern could be used to create the appropriate connections with other circuits necessary to support and be supported by motor activation. Such a system would be particularly not only useful during development but also in supporting the learning of new motor skills throughout life.

Pontogeniculo-Occipital Waves

Just as spindles have become the EEG signature of NREM sleep, so the PGO wave has become the EEG signature of REM sleep. EEG spindles are primarily corticothalamic. As PGO waves can be recorded in the pons, the lateral geniculate body of the thalamus, and the posterolateral cortex, they are thus also corticothalamic. PGO waves not only are most easily recorded in those visual brain structures in cats but are also widespread in the brainstem and posterolateral forebrain of both cats and humans. From a functional point of view, it is clear the PGO waves convey information about upcoming eye movements from their motoric sources in the brainstem to visual information processing centers of the upper brain. Thus, they are of interest not only to dream image theory but also to broader state-independent aspects of sensorimotor integration. They predict impending changes in visuomotor circuits.

PGO waves are seen as the first clear sign of an impending REM sleep period in the cat. They are 250-mV biphasic EEG deflections of about 25 ms in duration. They occur at first as singlets then doublets and finally in clusters of up to 25 waves as the REMs appear once the EMG and EEG changes are complete. Under favorable conditions, each PGO wave can be seen to be of greater amplitude in the lateral geniculate body (LGB) on the side of the brain to which the eyes are moving.

The firing of an ipsilateral PGO burst cell of the peribrachial pons is the initial event, followed in 15 ms by the PGO wave and in 25 ms by the eye movement. An inescapable conclusion about this sequence is that the burst cell is first apprised of the oculomotor system's intention to produce a saccade to one side or the other.

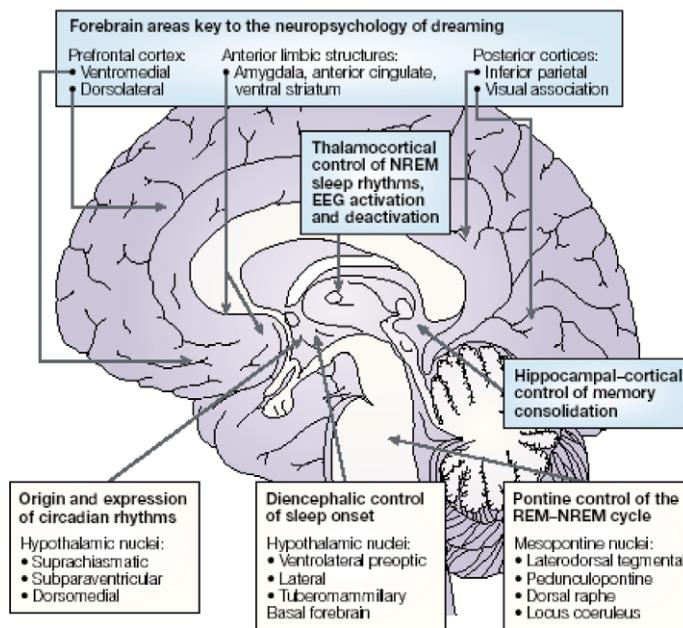

Figure 3 Regions of interest to sleep and dream research are shown on a sagittal schema of the human brain.

The geniculate (and cortex) are then notified presumably so that appropriate adjustments can be made before the eye movement is actually executed. Here is another example of a predictive brain function.

As eye movements are easily visible in REM sleep, it is surprising that it has taken millennia to begin to appreciate their significance for behavioral neuroscience. Of course, they excite our interest as candidate dream image stimuli (or more cautiously, as dream image shapers). However, as important as this hypothesis may be, we are faced with incontrovertible evidence of entirely spontaneous and highly organized sensorimotor integration in sleep. This evidence strongly supports theories of brain development and maintenance by showing that, in sleep, the neural substrate of motor commands and their sensory accompaniments can be activated and run in sleep. Such a capability has significance for the future life of the animal by allowing the offline construction, revision, and tuning of crucial neural circuitry.

Modulation (M)

In 1960, when Michel Jouvet was struggling to explain how the brainstem might mediate waking, sleeping, and dreaming, the Swedish neuroanatomist Kjell Fuxe and his team were describing brainstem neurons, which manufactured and used as their neurotransmitters, the biogenic amines, norepinephrine, and serotonin. Tying these together with dopamine (DA; the already-recognized modulator of the substantia nigra and other diencephalic nuclei), Jouvet imaginatively speculated a tripartite role for these three

biogenic amines: dopamine-mediated waking, serotonin-mediated NREM sleep, and norepinephrine (NE)-mediated REM sleep.

Jouvet's neuropharmacological and lesion experiments in the 1970s provided some evidence for the dopamine (waking) hypothesis and for the serotonin NREM sleep hypothesis. However, subsequent microelectrode studies have clearly shown that all three biogenic amines are released predominantly in waking. The noradrenergic and serotonergic systems are all at their peak during waking, while their output in sleep decreases. DA, 5-hydroxytryptamine (5-HT), and NE must therefore be wake-state mediators. The aminergic neuromodulators, NE and 5-HT, must decrease their influence to allow sleep and especially REM sleep to occur (**Figure 5**).

These discoveries were made in the late 1960s and early 1970s by Allan Hobson and Robert McCarley using chronic microelectrode recording techniques. These techniques were developed by David Hubel and modified by Edward Evarts for early work on sleep, but were then applied to the very successful studies of the visual and motor systems, respectively. One reason that Hubel and Evarts abandoned their pioneering work on sleep in favor of sensorimotor neurophysiology was that their neuronal data of sleep were so counterintuitive. Both NREM and REM sleep evinced less overall decrease in neuronal activity than was expected and it was not at all clear how the massive reorganization of spontaneous neuronal activity could be measured or interpreted.

Based on Jouvet's observations, it seemed imperative to record neurons not just in the cortex (as Hubel and Evarts had done) but also to develop the moveable microelectrode

method for use in the brainstem to follow up on Jouvet's important transection studies, which suggested a control region for REM in the anterior pons. However, the brainstem was not an attractive target; it was in the physical depths of the brain and was characterized by complex neuroanatomy. Besides, microelectrode recording there was problematical because of adventitious movement. Many neuroscientists doubted that the relatively small cells of greatest interest could be resolved or identified and then held for sufficiently long times to be informative.

REM-On and REM-Off Cells

As it turned out, Hobson and McCarley did encounter many difficulties. However, there were as many pleasant surprises, such as:

1. The pontine reticular formation contains numerous huge (75 M) neurons which send their axons into the spinal cord from which they can be unequivocally identified as reticulospinal. When the animal's head is immobilized, such neurons are easily isolated and held through 10 successive NREM–REM sleep cycles, during each of which they undergo robust and reliable increases in excitability in REM sleep. They share this REM sleep excitability increase with the cholinergic neurons they were initially considered to be. Hobson and McCarley worked out their quantitative measures of REM sleep generation for this population of REM-on cells.
2. The spontaneous firing of REM-on cells was typically suppressed (in waking) and only gradually increased firing in NREM sleep. With REM sleep onset, their firing rates increased exponentially. Intense bursting was associated with the REMs and often preceded them. The exponential increase in spontaneous activity of these REM-on cells at the onset of each REM period peaked in the first half of the REM period, declined slowly thereafter, and dropped precipitously at REM offset as the NREM–REM cycle began again.
3. After their brainstem neuron recording sessions became standardized, Hobson and McCarley discovered three loci-containing cells of an exactly opposite type which they therefore called 'REM-off cells.' To their surprise, these smaller and regularly firing REM-off cells were localized in the locus ceruleus, the dorsal raphé nucleus, and the peribrachial region, all brainstem areas known to contain aminergic neurons. The metronome-like firing pattern of REM-off cells during waking was stereotyped and regular at rates of $2\text{--}4 \text{ c s}^{-1}$. These rates declined in NREM and the cells often stopped firing completely in REM, only to resume firing again in post-REM waking. Using microwires, it was possible for Ralph Lydic to record

from these small REM-off cells for 7 consecutive days. In each and every REM period, Lydic observed cessation of firing by raphé neurons.

The Reciprocal Interaction Model

Based on the out-of-phase discharge of the putatively cholinergic REM-on cells and aminergic REM-off cells, Hobson and McCarley proposed in 1975 that the two cell groups were interconnected so as to constitute the oscillator shown in **Figures 4 and 5**. The model shared the formal characteristics of a mathematical model first introduced to explain reciprocally fluctuating levels of prey and predator populations in field biology. Most important, the model was testable using neuropharmacological techniques.

AIM: A Brain–Mind State Space Model Based on Activation (A), Information source (I), and Modulation (M)

In the past 35 years, our scientific knowledge of sleep and dreaming has advanced much more than in all of previously recorded human history. Many egregious errors have been reversed so that, today, we stand on the threshold of a new vision of the human brain–mind and its surprising capabilities. To assist the reader to comprehend the import of these discoveries, we narrate the story again through the emergent AIM model. We do not insist that this model is necessarily the best one that we could have devised. It is certainly incomplete in ways that we will point out. However, we will show that a long list of otherwise disconnected facts each may be assimilated and understood in terms of the model.

Three factors have clearly distinguished themselves from this list of facts. The state of the brain–mind is a combined function of:

1. activation: the degree to which the brain is turned on;
2. information source and fate: the degree to which input–output gates are open (while internal stimuli are excited or inhibited); and
3. modulation: the chemical microclimate of the brain which is determined by specialized neurons in the brainstem.

Before defining and discussing each of these three factors note, let us note that factors A, I, and M can be quantified and arrayed to form the three dimensions of a virtual state space as shown in **Figure 6**.

Depending upon the value of A, I, and M, the state of the system at any given time, t , is denoted as a single point in that space. As A, I, and M change in time, the point migrates to new positions in the state space. Thus AIM is, in effect, a four-dimensional model.

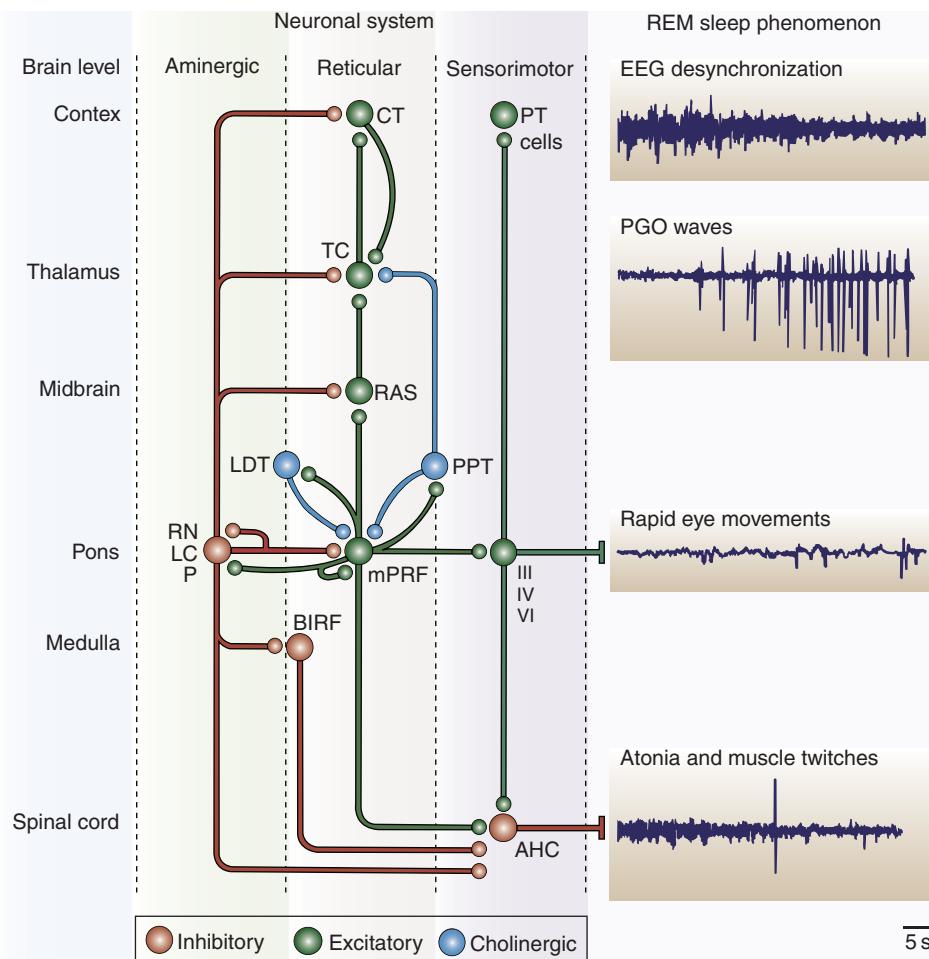

Figure 4 Cellular mediation of REM sleep phenomena. The polygraphic manifestations of REM sleep in the cat are displayed on the right side. The neurons and circuits thought to mediate those changes are shown on the left side.

- Factor A: activation is taken as the x -axis of the model. It represents the energy level of the brain–mind system. The high values of A fall in the right side of the state space and are essential for all normal values of A. Both waking and dreaming states have high values of A.
- Factor I: information is either external or internal in source and results in either real or fictive behavior, depending upon the condition of input–output gates and the excitability of intrinsic sensory and motor gates and circuits. This factor, which is measured on the z -axis of the model, determines one of the important differences between waking and dreaming. Waking is both interoceptive and exteroceptive, whereas dreaming is almost entirely interoceptive. In other words, waking is characterized by high values of I, whereas in dreaming I is low. In addition to this shift in the provenance of sensory data, motor output is blocked so that the internally generated sensory stimulation does not result in motoric actions.
- Factor M: modulation (shown on the y -axis of the model) determines the way in which the brain–mind

process information and is a function of the modulation ratio of aminergic to cholinergic. When the system is highly aminergic, waking is the result. When aminergic activity is at its nadir, the brain–mind is in the REM sleep dreaming state. The system has gained its sensorimotor freedom from the outside world at the expense of impaired cognitive functions.

Waking (W) and REM (R) are both high A states but they are differentiated from each other by both I and M. Low values of I and M are shared by dreaming, whereas waking has high values of both. As already noted, NREM sleep has intermediate values of all three variables.

As the values of A, I, and M are constantly changing, the point solutions of A, I, and M are seen as a sequence of dots. Overnight, this sequence forms a series of four to five elliptical trajectories through the state space. Each ellipse corresponds to an NREM–REM cycle. Notice that successive cycles go less deeply into the S (or NREM sleep domain) and go more deeply and remain longer into the REM domain.

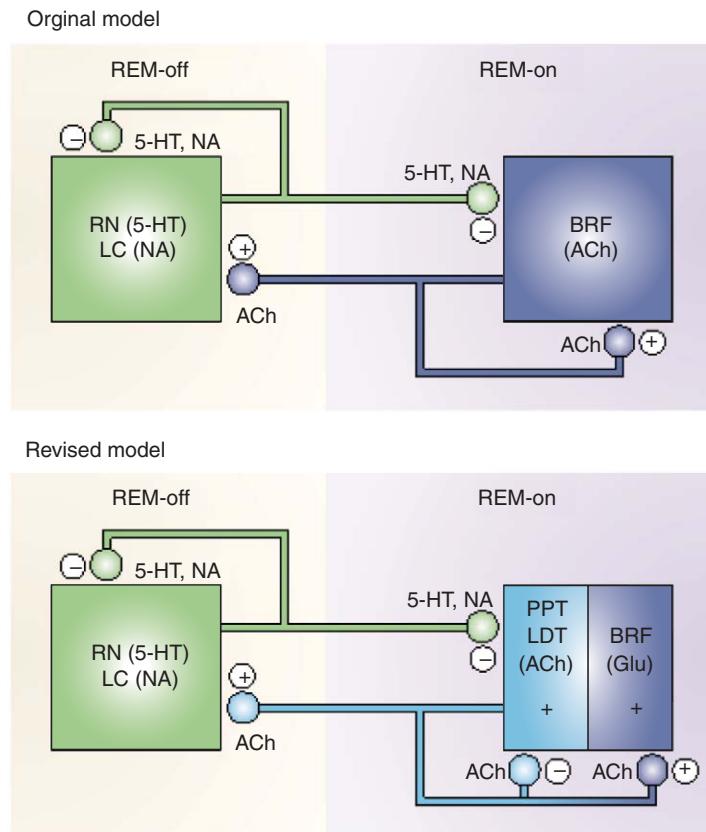

Figure 5 The reciprocal interaction model postulates cyclical changes in balance between REM-on and REM-off neurons of the cat pontine tegmentum in the original and revised versions.

The new four-dimensional AIM model has many obvious advantages over the standard two-dimensional model of sleep science (see **Figure 1**). The most obvious advantage is that because it takes account of basic research data it accounts for important differences between REM and wake. However, the model also provides for changes in trajectory and for important excursions from canonical trajectories that may be seen in sleep disorders. The AIM model also helps us to understand experimental and clinical drug effects. We know that the AIM model is overly simplistic in failing to take account of regional changes in A, activation level, in the brain.

Cholinergic REM Sleep Induction

Microinjecting cholinomimetic drugs enhances cholinergic synaptic efficacy at various sites in the brainstem. Helen Baghdoyan was responsible for systematizing this highly successful experimental paradigm. The short-term REM enhancement that she studied was dose dependent and could be obtained by blocking the enzyme, acetyl cholinesterase, as well as by direct cholinergic agonist

administration. The effects were localized to the pons and could be blocked by atropine. Compare **Figures 1 and 6**.

By 1980, we knew from Marcel Mesulam's anatomical work that the cholinergic neurons of the brainstem were not our paramedian pontine reticular REM on cells. Those paramedian giant cells were, however, cholinceptive, but they probably excited each other and their extended synaptic domains via glutamine. Thus, even though they did not manufacture acetylcholine, they could be excited by it. When first Ennio Vivaldi, and later Subimal Datta and José Calvo, explored the peribrachial PGO burst cell zone in the far-lateral pons, they were able to evoke immediate ipsilateral PGO activity and 24 h following microinjection of carbachol, prolonged (6–7 days) REM enhancement.

Since the development of the reciprocal interaction model, there have been numerous replications of its basic findings, extensive refinements and revisions of a few of its postulates. The model has been incorporated in the circadian-homeostatic schemata of Alex Borbely and in the new flip-flop model of Clifford Saper. It can thus be considered to be widely accepted, which is important since it constitutes the physiological basis of a new

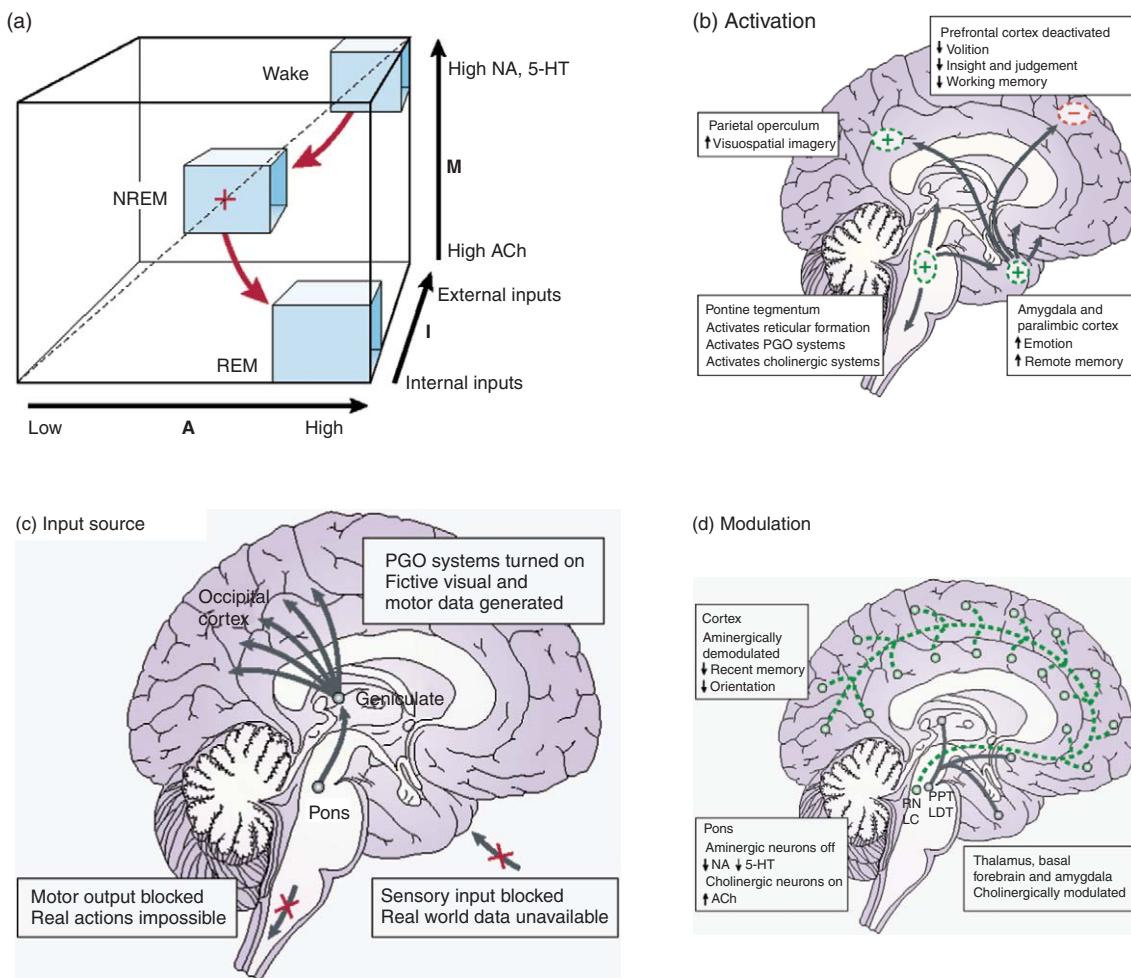

Figure 6 AIM model of brain–mind state control. A three-dimensional state space is constructed based on electrophysiological measures in the cat. (a) AIM state space showing the zones occupied by values from the cardinal states of waking, NREM, and REM sleep. (b–d) Schematized are the variable dimensions of the model: activation, A, input source I, and modulation, M.

approach to the study of dreams. It allows us to integrate the approaches to neuropsychology, learning and memory, and sleep disorders that are taken in subsequent articles.

Dreaming

Dreaming is normally difficult to recall unless awakening from REM sleep occurs spontaneously or by experimental design. REM sleep dreams are normally bizarre, animated, emotional, and nonlogical, suggesting that these anomalies may be cognitive epiphenomena rather than the profound mysteries that many psychologists have supposed them to be. The study of dreaming and REM sleep represents a unique opportunity to understand consciousness and its basis in brain activity.

Until 1975, science had no recourse to a brain-based dream theory. From time immemorial, dreaming had been regarded as otherworldly and spiritual, tied to bodily functions only in symbolic, mystical, and evanescent ways. Even in the works of would-be dream scientists

such as Sigmund Freud, dreaming was regarded as a mental process with no certain connection to any specifiable brain or other bodily process. Aserinsky and Kleitman's 1953 discovery of REM sleep dreaming opened the door to the new science of dreams.

Content and Formal Analytic Approaches

In most subsequent studies, dream researchers have clung to the conviction that a science of dreams could regard content as narrative. The narrative approach to dream content was used to detect the otherwise obscure features of the human personality. Furthermore, content analysis was both scientifically valid and reliable.

Formal Analysis

With the publication of the reciprocal interaction model, Hobson and McCarley articulated the activation synthesis hypothesis, which based its formal approach to dream

data on neurophysiology and sought isomorphisms in correspondence between the physiological and psychological domains.

For example, it was reasoned that if dreaming was predominantly visual then the visual brain should be activated in REM sleep. If REM sleep was a brain state and dreaming was a mind state, then REM sleep-dreaming might be a unified brain-mind state. More surprising was the discovery that dream vision was always associated with hallucinated body movement even though the body was actively immobilized in REM sleep. Since animal work had indicated brainstem motor pattern activation in REM, it was obvious to propose that dream movement was as fictive as was dream vision. The visual and motor systems were thus unified in the creation of visually rich, motorically active dream scenarios. It was intrinsically difficult to reduce these scenarios to stories and to narratives without losing important details such as movement. An important implication of these insights was that REM sleep dreaming was our conscious experience of an internal model of the world.

The initial success of formal analysis then led to a series of studies of dream form which had the goal of making activation synthesis a scientifically sound, brain-based dream theory. Hobson never denounced the psychodynamic emphasis on dreaming as an emotionally meaningful experience worth sharing with a family member, a friend, or even a therapist. Activation synthesis even stressed that insights about the otherwise overlooked aspects of the self might result from such discussion. But activation synthesis denied, vigorously, that such meaning as could be found in dreams was disguised and obtainable only through psychoanalytic decoding. In this section, we restrict our attention to those studies of dreaming which have neurobiological relevance.

Dream weirdness

It was the ill-defined strangeness of many dreams that tempted Freud to develop his disguise-censorship hypothesis in the first place. When dream weirdness was descriptively and dispassionately analyzed, it was found to be both robust and reliably identifiable in REM sleep reports. Most surprisingly, dream weirdness reduced to the discontinuity and incongruity of dream times, places, persons, and actions. This common dream feature was thus a case of microscopic disorientation. The Aristotelian unities are fractured in dreams just as they are in organic mental syndromes of which dreaming suggested itself as an example!

Dream amnesia

Dream recall is notoriously evanescent. Subjects rarely remember detailed dream plots despite laboratory evidence that there might be as much as 2 h of dreaming per night. Subjects are often aware that they have been

dreaming only to find that their recall evaporated rapidly after awakening.

Despite all the evidence for memory's fallibility at the edges of sleep, it was generally assumed that dreaming was fashioned out of stored memories. Yet, when subjects were asked by Magdalena Fosse and her co-workers to identify the memory sources of dream plot items, they were unable to trace more than 20% of their dream details back to previous wake-state experience. Whole dream plots, not just details, appeared to be synthesized *de novo*. This experimental finding indicated that the activated, input-output gated, and demodulated brain was capable of a high degree of creativity. Far from deforming and degrading a previous experience in the interest of protective disguise, the dreaming brain-mind was every bit as creative as a surrealist artist.

In other words, the formal approach to dreaming had suggested that, in REM, the brain-mind was both amnesic and confabulatory, as well as visually hallucinated and disoriented. These four qualities define the organic mental syndrome. It was thus possible to suggest that dreaming was not like delirium, it was delirium by definition.

Dream emotion

Dreams may be intensely pleasant (as when we behold remarkable scenes, have deeply gratifying social relationships, or even defy gravity and fly). They may also be intensely unpleasant (as when we are anxious owing to such incomplete arrangements as nudity or improper dress, turning up unprepared and in the wrong place for an exam or a lecture, or arriving at a transport terminal without the proper documents). Worse yet, we may perceive ourselves to be pursued by hostile characters whom we must fight. Such dreams may be accompanied by elation or by fear and anger. Social emotions such as shame, sadness, or guilt are surprisingly rare in dreams.

This finding suggests the hypothesis that dream emotion is not what we would expect if dreaming were autobiographically inspired. Instead, dream emotion may reflect the automatic enactment of highly adaptive survival-related behaviors. This hypothesis substitutes Darwin for Freud and behavioral offense (fight) and defense (flight) for the disguise of forbidden wishes as critical to understanding REM sleep dreams. The neurobiological and psychodynamic dream theories come close to each other here in their acknowledgment of the importance of instinctual drives, but the functional emphasis is entirely different.

The characterization of dream emotion in Darwinian terms is not only relevant to models of cerebrogenesis but also contributes to the functional theory that adaptive behaviors are being prepared and rehearsed every night of our lives. We stand ready to be afraid, to fight, or to flee whether or not we ever really do so in waking reality. We

have rehearsed these life-saving scenarios during our sleep. This is the essence of Michel Jouvet's survival theory, recently taken up by Antti Revonsuo. Whether or not one remembers the dreams does not matter. The brain keeps its own record of the fixed action pattern it has rehearsed and is ready to enact it, when called for, in waking.

Dream movement

Having discovered that dreamers were constantly moving through a dream space, Helene Porte set out to use fictive dream movement as a test of three dream theories. She reasoned that the Freudian model would not preferentially predict one kind of movement over another, nor would the activation-only theories of David Foulkes or John Antrobus predict a ubiquity of somatic movement in dream scenarios. Only a brain-based theory which gives pride of place to major movement pattern generation makes such a prediction.

Confirming McCarley and Hoffmann, Porte found that almost every sentence of every REM sleep dream report contained an action verb and that a great majority of those verbs connoted lower extremity movement. That is to say, postural displacement was a rule of dream movement. This is autobiographically unpredictable since many of us engage in fine motor activity such as reading, writing, typing, computing, or talking on the telephone during the daytime and only rarely in waking do we walk, run, ski, or fly. Our dreams are quite different from our waking habits in that vigorous athletic scenarios are common but sedentary activity is rare. Could that be because major movements of the body have higher survival value?

Dream thinking

Content analysts, such as William Domhoff, often deny that dreaming is either bizarre or illogical. This not only

flies in the face of commonplace experience but also runs against the robust findings of other scientists. While it is true that there is some dream content that is not characterized by discontinuity and incongruity and there is some dream thought which is logical, there is far less of both kinds of thinking than in waking and waking consciousness is almost never as grossly bizarre and nonlogical as dreaming.

To investigate the question of the frequency and quality of dream thought. Fosse *et al.*, first counted the references to thinking in 3000 reports elicited from normal students. As they led their normal waking and sleeping lives, these students were automatically beeped and asked to describe their mental content in the minutes before the signal. Their sleep was objectified through a portable home-based system (See **Figure 7**).

Thinking and hallucination are reciprocally state-dependent mind states. Dreaming is strongly hallucinatory and weakly cognitive while waking is weakly hallucinatory but strongly cognitive. Hence, the brain-mind is programmed to do one thing or the other. It either imagines or it thinks critically, but it does not do both at the same time. This reciprocity is so robust as to suggest a general law of psychology. The law, which states that a person is either rational and nonhallucinatory or irrational and hallucinatory, is true of both normal and abnormal mental states. Dreaming is not only delirium, by definition, but it is also formally akin to other forms of mental illnesses.

Dream logic

Roar Fosse's finding that references to thinking were rare in REM sleep reports might indicate an important deficiency in reasoning capacity that could tip the normative balance away from the examples of logical reasoning that are sometimes seen in dreams.

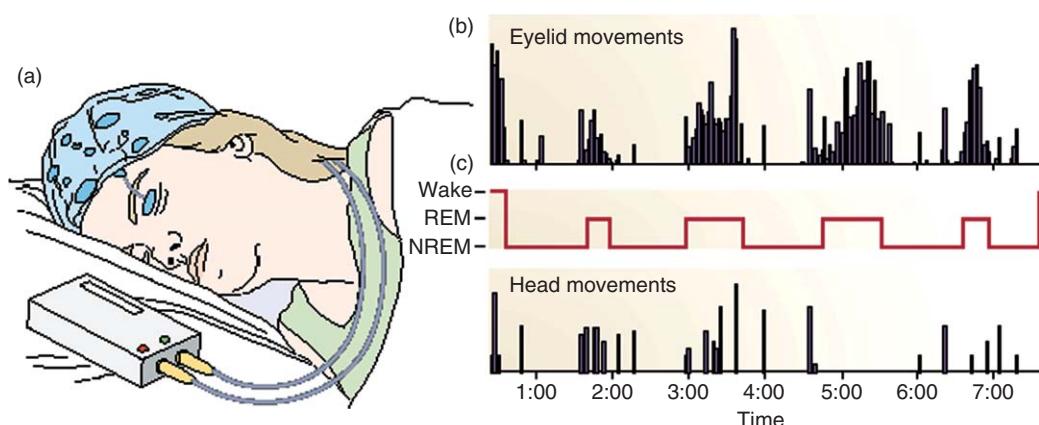

Figure 7 Human subjects, sleeping at home, give reports of mental activity which can be compared across the states of waking, NREM and REM sleep. See **Table 1** for a summary of results.

Table 1 Some formal properties of dream consciousness

<i>Phase I 1980–1994 Laboratory and unmonitored home reports</i>	
Perception. Vision and sense of movement predominate	Hoffmann and McCarley (1981)
Bizarre cognition. Reduces to discontinuity and incongruity	Hobson <i>et al.</i> (1987)
Fantasy. Chimeric characters common in dreaming absent in fantasy	Williams <i>et al.</i> (1992)
Children. Adult-type dreaming begins at age 5	Resnick <i>et al.</i> (1994)
Emotion. Anxiety (fear), elation, and anger present	Merritt <i>et al.</i> (1994)
Plot Sequence. Gradual drift of subject within scenes	Sutton <i>et al.</i> (1994)
Radical shift of subject between scenes	
Splicing. Judges cannot recognize continuity across scenes	Stickgold <i>et al.</i> (1994)
<i>Phase II. 1995–2004: Home dreams with physiological monitoring</i>	
Nightcap. REM report word length $7 \times$ NREM	Stickgold <i>et al.</i> (1994)
Movement Perception more common in REM	Porte and Hobson (1996)
Character recognition is arbitrary. ‘Just so’	Kahn <i>et al.</i> (2000)
Thinking and hallucinating. Reciprocal across states	R. Fosse <i>et al.</i> (2001)
Contrasting with waking and REM	
Memory source in waking identified in only 20% of dream incidents	M. Fosse <i>et al.</i> (2003)
Gender of dreamer assessed accurately slightly above chance	Kahn and Hobson (2007)
<i>Phase III. 1995–present: Home dreams with physiological monitoring – focus on secondary consciousness (metacognition)</i>	
Theory of mind. Dreamer recognizes mind of other dream characters	Kahn <i>et al.</i> (2002)
Logic - some thinking rational, most not rational	Hobson and Kahn (2005)
Authorship. Reports of subjects incorrectly grouped by judges	Hobson and Kahn (2007)
Schizophrenia. Patients and normals have equally bizarre dreams	Scarone <i>et al.</i> (2008)
Patients, but not normals, also have bizarre TATs	
Logic. Illogicality of most dream events is unnoticed	Hobson <i>et al.</i> submitted for publication

To try to capture this possibly diminished cognitive capacity. David Kahn and Allan Hobson constructed a measure of logical inference that could be used by judges who scored reports from REM dream and waking in normal subjects.

Many dream features were found to be associated with logical oversights that were unnoticed by the dreamers. For example, riding a bicycle in London traffic with a long-handled tree trimmer was not noticed as either bizarre or nonlogical by the dreamer but, in the light of waking, was found to be so by the judges. The implication is that dream thinking is not only impoverished by virtue of its rarity but the thought impoverishment is a manifestation of a state-dependent impairment of the capacity to generate logical inference. Without the capacity for logical inference, it is impossible to notice the presence of dream bizarreness. Thus, critical thought declines in quantity and quality together with the tendency toward the cognitive discontinuity and incongruity detected in bizarreness scoring.

Dreaming and Mental Illness

The formal similarities between dreaming and mental illness include the internally generated percepts (hallucinations) and inferentially deficient thought (delusions). Both features are distinctly disadvantageous if they occur in waking. When they do, we still call the new state a ‘mental’ illness even though it is clearly a disorder

of the unified brain-mind. This is because we cannot yet see how a physical object, the brain, could possess self-awareness. We thus remain language dualists even if we are philosophically committed to monism.

For the past century, psychiatry has properly regarded dreaming as potentially informative. Now, we see just how prophetic this hypothesis may be. Instead of being simply a mental illness, major psychosis may be thought of as a functional disorder of the brain-mind. As such, it may well share features with normal dreaming, another functional alteration of the brain-mind. In my writings, I have attempted to show how this scenario might play out in order to establish a firm link between apparently abstract and irrelevant details of basic research and clinical problems of the greatest complexity and practical importance for our theory of both sanity and insanity.

Chief among the encouraging signs for this concept are the potent effects on psychotic symptoms of the many psychoactive drugs which interact with the brain’s own state-control chemicals, the neuromodulators. The neuromodulators we attempt to influence with prescription drugs are the same substances which sleep research has shown to be fundamental in orchestrating the state-dependent characteristics of the normal brain-mind. The control of brain-mind state as studied over the normal sleep-wake-dream cycle is clearly of crucial psychobiological significance in understanding both the normal vicissitudes of consciousness that we all experience, and also those unwanted distortions that beset those

humans with hallucinations, delusions, emotional exaggeration, and memory problems.

Schizophrenia and dreaming

In the early days of the sleep lab era (1953–75), dream content analysts were quickly attracted to laboratory studies of sleep and dreaming in patients in order to test psychoanalytic dream theory. They were disappointed. Whether they predicted more or less REM as the basis of one or another reading of Freud's theory, they found neither.

Recently, Silvio Scarone and his colleagues in Milano asked their schizophrenic patients to keep a dream journal. With those patients who were compliant he also used the projective Thematic Apperception Test (TAT) test to elicit wake-state control reports. In a small but promising sample, Scarone showed that bizarreness scoring of schizophrenic and normal dreams revealed no difference between the two groups. However, schizophrenics reacted bizarrely to the same TAT cards that normals read without introducing bizarre mentation. This preliminary result indicates that the brain–mind of waking schizophrenia patients operates as if it were asleep. The schizophrenic brain–mind lacks the sharp differentiation between the states shown by normal subjects.

The results do not imply an identity between schizophrenia and dreaming. They only suggest a formal similarity. That formal similarity may also be found at the level of brain function. Normal and abnormal states may thus show changes in underlying neuromodulatory mechanisms. Reductionism is successful when it explains a wide range of phenomena with a few basic assumptions. The brain–mind of a schizophrenic patient awake is formally similar to that of a dreamer, whether the dreamer is schizophrenic or normal.

The Artistic and Literary Aspects of Dreams – Dream Content and Dream Form Revisited

While a dream report may contain a story line or plot, dreams themselves are not literary exercises. They are multimedia experiences or films rather than short stories or any other collection of mere words. They are polysensory experiences to which story-like narrations may be fit but from which they do not necessarily derive. Dream content – as in a dream report – is therefore not entirely irrelevant but neither is it a basic or foundational element. We do not write down dream stories, take them to a scenarist in the brain, then proceed to create a *mise en scène*. In the brain, it would appear to be quite the other way around. The scenario is the primary product and the report is derived from it. The report is therefore but a pale copy of the dream and we should not forget this important fact.

Dreaming is a holistic primary experience and verbal accounts of it are woefully inadequate and limited. Some dream observers become so frustrated by the inadequacy

of words to represent their experience that they resort to drawing. The drawing captures in a single sketch many descriptive facts that cannot be matched by words. Thus, to say that a picture is worth 1000 words is to suggest that a single drawing is worth 10 dream reports (the average length of which is less than 100 words). In **Figures 7 and 8**, we have drawn attention to some of these features in one work, the *Dream Drawings of the Insect Man*. These drawings not only help us to illustrate our formal analytic approach but they show dreaming to be both emotionally salient and creative as is particularly clear in **Figure 8**.

In addition to many drawings to illustrate bizarre dream architecture, such as buildings without doors, or incongruous dream objects, like the truck in a flower garden or the ingenious but impossible filing system for research notes (**Figure 8**), the Smithsonian insect scientist devoted over 50 of his drawings to describe anomalous trajectories such as running to third instead of first base, circling in his car in a parking place too narrow to allow even one turn, and two golf balls colliding improbably, while still aloft. All of these events can be described in words but they are more simply illustrated by drawings.

Why Do We Dream?

When we dream, we see, feel, imagine, and assess events in our minds. Our minds are thus theaters where we witness, with or without critical comment, a virtual reality of such enormous complexity as to match the complexity of the world itself. It is difficult to resist the idea that the mental experience of dreaming evolved to help us be aware, in a predictive way, of the reality of the world that we live in.

One of the major functions of dreams must thus be to create, maintain, learn from, and modify our mental model of the world. That we do as well as we do in adapting to that world is a testimonial to our power to create and recreate reality inside our heads. The same could be said to be consciousness itself. Waking, consciousness, and dreaming reveal internal models of our world which allows us to evaluate, to plan, to adjust our strategies for living in that world. It is not so much that we are protecting consciousness from invasion by our own desires as it is that consciousness is helping us to recognize and fulfill those desires.

We need, always, to be prepared for unforeseen and potentially harmful events. Hence, dreams are frequently fearsome. However, we also need to know a good thing when we see one so we must also learn to be impulsive enough to make possibly profitable personal decisions. Tentative liaisons are of obvious significance to our goal of procreation. Given those twin assumptions, it is not so surprising to find that dream emotion is predominantly

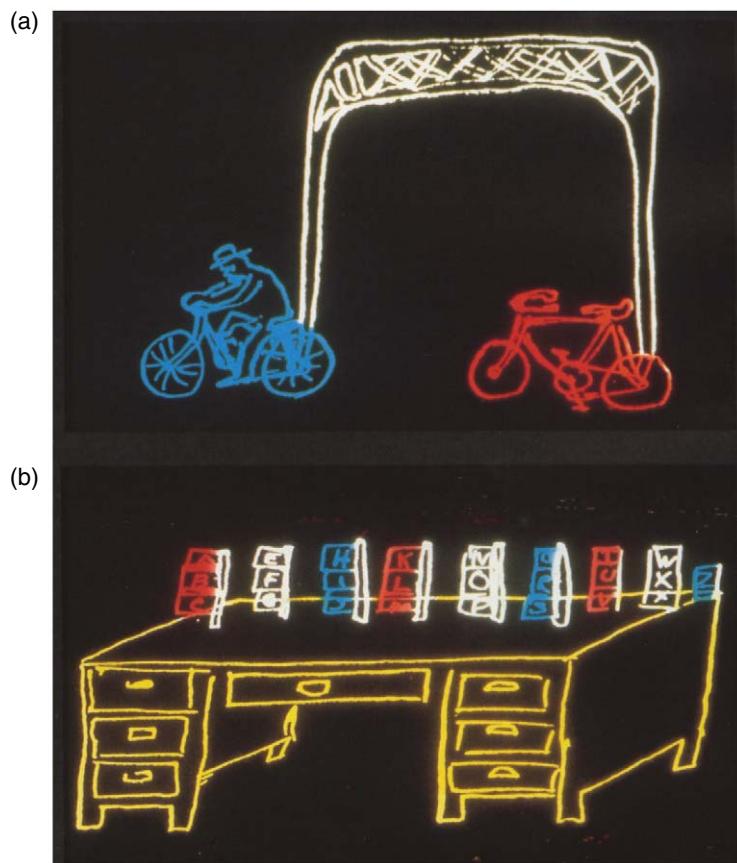

Figure 8 Two drawings from the journal of a Smithsonian insect specialist who recorded and illustrated 256 dreams in the summer of 1939. Both show content that is certainly bizarre but emotionally salient and even creative. Above is his dream bicycle built for two with the bachelor dreamer pedalling alone. Below is his dream desk-top computer whose alphabetized set of flags allows him to access notes and drawings stored in the drawers.

negative but occasionally ecstatically positive. We practice seeing and moving in a coordinated manner and we practice complex movement behaviors at least 1.5 h a day. This is not exercise for the muscles, but it certainly is exercise for the sensorimotor programs of the brain. Dreaming allows us to fraternize experimentally with a wide variety of social peers. Dreaming is thus safe, progressive calorie conservative, and compatible with other important procedures such as refurbishing thermal control.

Functional Implications

For the first 40 years of the sleep science revolution (1953–93), attention was so sharply focused upon the description of heretofore hidden phenomena and their mechanistic causation that functional questions were not even asked, let alone answered. It was not so long ago that many sleep scientists claimed that sleep function was entirely unknown. Now that sleep has many known functions whose scientific analysis is proceeding apace, we can anticipate a future, which will undoubtedly reveal many more. Our burgeoning

knowledge of sleep and dream function will eliminate forever the naive notions that sleep is a waste of time and is a behavior which can be done without.

Sleep Deprivation is Fatal to Rats

Allan Rechtschaffen is a psychologist who succeeded Nathaniel Kleitman as head of sleep research at the University of Chicago. While decrying our lack of understanding of sleep function, he designed experiments which indicate that sleep is essential to life. The death that accompanies the prolonged sleep deprivation of rats is characterized by defects in the regulation of both dietary and thermal homeostasis and by a loss of immune function, so that ultimately the sleep-deprived animal cannot prevent its own intestinal bacteria from invading its blood stream causing death by overwhelming sepsis.

Rechtschaffen's experiments were simply designed but heroically difficult to run. Two rats (one the index case and another, the control) were placed on opposite sides of the wall that divides a Lucite tube into two compartments, each

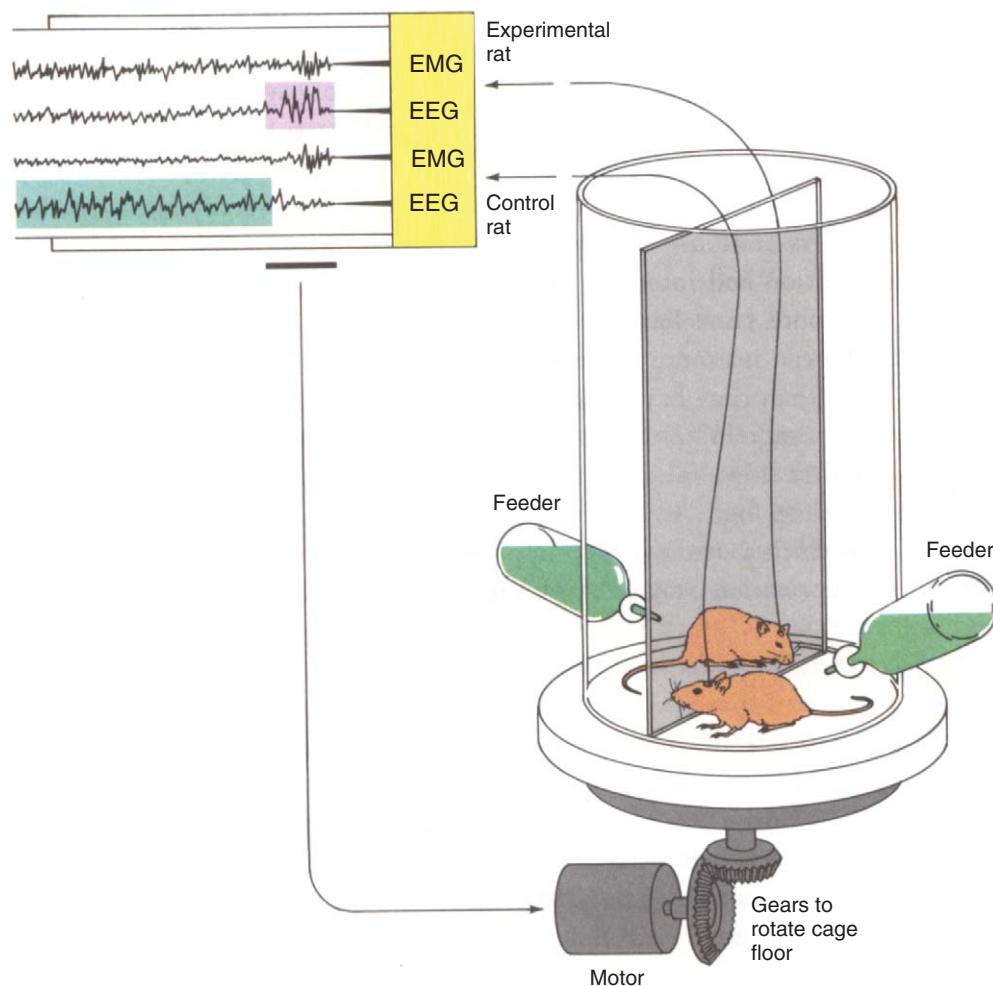

Figure 9 Experimental setup of Rechtschaffen experiments. Whenever the index rat tries to sleep, it is aroused by movement of the cylinder floor. The control rat can get plenty of sleep when the index animal is feeding or grooming.

supplied with *ad lib* food and water and a cable for recording physiological signals on a polygraph (Figure 9).

Whenever the index rat tries to sleep, cage floor movement wakes it up. The control rat can sleep whenever the index animal grooms or feeds. With this simple apparatus, the index rat loses 95% of its sleep while the control rat gets 95% of his.

The time course of degeneration is stereotyped. After 2 weeks, skin lesions appear in the index rat. By week 3, the index rat consumes increasing amounts of food in a vain effort to maintain body weight and keep its body temperature stable. Sleep deprivation has already produced a negative calorie drain. The index rat thereafter develops frenetic heat-seeking behavior and becomes susceptible to infection by intestinal flora to which it is normally immune. These infections and the associated starvation are universally fatal within 4 weeks of deprivation.

If only REM sleep is deprived, the same course of events is complete after 6 weeks. As REM takes up

only 15% of sleep time, this observation shows that REM has more than twice the functional power against deprivation than NREM sleep. This conclusion follows from the calculations of sleep deprivation in the two experiments: 440 h in total sleep deprivation as against only 136 h in the case of selective REM deprivation. The hypothesis that REM is super-sleep derives, in part, from this threefold difference. At the same time, REM is twice as effective in reducing NE and 5-HT output. This reduced expenditure could not only conserve neuromodulator but also allow much more effective aminergic receptor resensitization. Sleep deprivation, which is intrinsically stressful, drives the NE and 5-HT systems maximally and prevents any possible recovery of the efficacy of those systems.

Despite extensive experimental effort, Rechtschaffen was unable to specify the mechanism of the fatal dysfunctions it produced. From these studies, it can nonetheless be concluded that sleep serves thermal and dietary calorie control.

Sleep and Learning

Rechtschaffen's sleep-deprived rats were not cognitively impaired in any obvious way. However, they were not tested to see if their capacity to capture and incorporate new information was compromised.

The effort to establish a sleep effect on learning long-antedated Rechtschaffen's work has always had strong adherents despite the relatively weak effects of deprivation on learning capacity, and the relatively small gains in learning incurred through sleep. The most recent – and successful – program in this domain has been led by Robert Stickgold using the Karni–Sagi visual recognition task (VRT). In the VRT, subjects are asked to fixate the center of a computer screen and to signal recognition of an anomalous stimulus array as soon as possible after it appeared on the screen. Appeared is in quotes because subjects were not consciously aware of their quite accurate and rapid stimulus detection. As subjects get better at the task, the task is made more difficult until the learning curve becomes flat.

The timing, kind, and duration of subsequent sleep has small but consistent effects on subjects' skills on retest. If they have slept badly, they show no learning whatsoever. Fair sleep helps them perform at the level they attained with training. Good sleep actually improves their performance. This is true sleep learning and can only be explained by supposing that the subjects' brains were somehow running the learning paradigm during their subsequent sleep.

These results have been confirmed by others using a wide variety of experimental tests of sleep learning. Complimenting Stickgold's results of sleep favoring procedural learning have been Jan Born's studies, which suggest that semantic or narrative learning may also benefit from sleep. Sleep deprivation has been shown by Jim Horne to interfere with cognition when subjects attempt complex reasoning tasks.

Genetic research on sleep will soon confront the limitations of the genome to prescribe every neuronal address and every neuronal function. In that confrontation, the importance of developmental mechanisms, such as the early establishment and abundance of REM sleep *in utero*, will be investigated. It is almost a foregone conclusion that these studies will reveal sleep to favor certain aspects of the construction and operation of the mammalian brain. When this is done, we may be better able to appreciate the functional significance of sleep in the development and maintenance of the many cognitive abilities that, together, constitute consciousness.

The Neuropsychology of Sleep and Dreams

Since 1990, the field of sleep and dream science has been invigorated by the advent of brain imaging technology. This work has inspired an upsurge in the

long-dormant clinical study of sleep and dreaming. At the outset, however, it is now clear that the study of sleep and dreams is a mainstream endeavor of medical neuroscience.

Positron emission tomography studies

It is remarkable that the findings of the three original PET studies were so consistent. This consistency of findings by Pierre Maquet, Alan Braun, and Eric Nofzinger bespoke a combination of methodological power and phenomenologic robustness. The brain really does change state in sleep. It does so in a way that is easily observable and readily understandable, thanks to positron emission tomography (PET).

NREM sleep is associated with a global decrease in blood flow indicating a net fall in neuronal activity. Both conclusions fit with independent measures. When Kety and Schmidt measured cerebral blood flow in sleep using the Fick principle method about 30 years ago, they concluded that forebrain activity declined about 20% in NREM sleep. Microelectrode studies have confirmed a net decrease in neuronal activity. Although some cortical and thalamic cells increased their firing rate, most neurons throughout the brain decreased rate, on the order of 20–50%. NREM sleep is thus an unquestionably deactivated state of the brain.

It should be emphasized that even taking these data at face value, the brain remains 50–80% as active in NREM sleep, when consciousness is entirely lost or markedly obtunded. This means, therefore, significant information processing may go on even though consciousness is lost. The decline of cerebral activity in sleep is only relative and not absolute as Sherrington and Pavlov seem to have assumed. This recognition should keep us vigilant, especially with respect to functional hypotheses concerning the role of NREM sleep in learning and memory.

It was the magnitude and extent of brain activation in REM sleep revealed by PET studies that surprised the scientific world and moved dream theory to a new level of scientific credibility. With one important exception, the brain activation in REM sleep was global; with one exception being the dorsolateral prefrontal cortex, a brain region essential for executive ego functions. The failure of this region to reactivate correlates well with the cognitive deficiencies in dreaming. Executive ego functions such as: working memory, orientation; volition; self-reflection; and attention are all weakened as in REM sleep.

The brain regions that become more active in REM than in quiet waking were equally interesting from the psychophysiological point of view. These include the pontine brainstem (known to be important to REM through animal studies); the amygdala, the deep frontal white matter, and the parahippocampal cortex (consistent with the intensified emotional spectrum of dreams); and the parietal operculum (known to be important in spatial

sensory perceptions which is keenly sharpened in dreams). That the brain–mind is an integrated system with specific changes associated with its several states is now widely accepted.

Changes in dreaming following stroke

Mark Solms, a South African neuropsychologist working in London, asked stroke victims if they had noted any changes in their dreaming after their strokes. Complete cessation of dreaming was reported by patients whose strokes affected either the parietal operculum or the deep frontal white matter, two of the regions known to be hyperactivated in REM sleep. This correspondence between the brain imaging data and subjective experience strengthened the hypothesis that dreaming was correlated with differential activation of the brain compared to waking and that this differentiation helped to explain the changes in consciousness in two states.

Summary and Conclusions

Sleep serves survival by means of its energy conservation functions. However, sleep is functionally significant in other ways as well. Through its association with nesting and pair-bonding, sleep is also a constructive behavior: sleep facilitates reproduction. Ethologists need to take account of these obvious facts. It also facilitates development of the brain in the young and that provides lifelong opportunities for adaptive information processing.

The most recent and exciting theories see sleep and waking as not only mechanistically but also functionally reciprocal. In those higher animals which are conscious, many of the cognitive modules of conscious experience are activated in REM sleep as if dreaming were a virtual reality state allowing for practice of many important cerebral subroutines. Once considered inert or even deathlike, the richness of sleep can now be appreciated

as elaborate internal brain activity, which runs behind an only apparently quiescent façade provided by the quelling of motor output.

Glossary

Adrenocorticotropic hormone (ACTH) – A peptide hormone synthesized in the anterior pituitary and released into the blood during the HPA-axis response to aversive stimuli. ACTH binds to receptors in the adrenal cortex and induces the release of glucocorticoid hormones.

Arousal – A complex physiological, sensory, behavioral, and emotional state that determines the physiological readiness for activity and the reactivity to internal and external stimuli, including emotional reactivity.

Corticotropin-releasing factor (CRF) (also known as Corticotropin-releasing hormone (CRH)) – A

neuropeptide that was isolated by Vale and colleagues in 1981 based on its ability to induce the release of ACTH from the anterior pituitary. In addition, CRF – via actions in extrahypothalamic regions – is an important mediator of autonomic and behavioral responses to aversive or stress-related stimuli.

Glucocorticoid hormones – Cortisol in the human and fish, corticosterone in most nonhuman vertebrates; these are steroid hormones that mobilize energy resources and, thus, prepare the organism for action during a stressful state. The synthesis and release of glucocorticoids are stimulated by ACTH.

Hypothalamic–pituitary–adrenal (HPA) axis – A neuroendocrine cascade, involving the hypothalamic CRF, pituitary ACTH, and adrenocortical glucocorticoid hormones, that is a hallmark of physiological responses to aversive or stress-related stimuli.

Stress – A physiological state, manifest by an adaptive syndrome that works in the direction of producing a return to homeostasis.

will use the term ‘arousal state’ to refer to a specific level of arousal, and the terms ‘arousal-promoting’ and ‘arousal-generating’ to refer to mechanisms that promote a higher state of arousal. Wakefulness is a form of arousal, but so is rapid eye movement (REM) sleep, albeit lower on the arousal continuum than wakefulness. Sleep is an arousal state that can be subdivided into non-rapid eye movement (NREM) and rapid eye movement (REM) sleep; both states are actively promoted by the brain via distinct mechanisms. Sleep is on the lower end of the arousal continuum with coma and death being the lowest levels of arousal.

Arousal-Promoting Mechanisms

Glutamatergic neurons within the brainstem reticular formation and several other neurotransmitter systems, some closely associated with the reticular formation, promote arousal. These neurotransmitters include the monoamines, serotonin (5-hydroxytryptamine; 5-HT), norepinephrine, dopamine, and histamine, the choline derivative acetylcholine (ACh), and the neuropeptides orexin-A and B, also called hypocretins, hypocretin-1 and 2. The activity of each of these systems is correlated with arousal states, with elevated activity during the active phase of the sleep–wake cycle (**Figure 1**).

Brainstem Reticular Formation

Arousal-generating systems include specialized groups of neurons in the brainstem and forebrain that increase cortical activity. A cornerstone of neural mechanisms underlying increased arousal, including wakefulness, is the brainstem reticular formation. Reticular formation neurons – located in the midbrain, pons, and medulla – have long, branched axons that project widely to regions of the hypothalamus, basal forebrain, thalamus, cerebellum, cortex, and spinal cord (**Figure 2**). The reticular formation inhibits sleep-promoting neurons and activates cortical neurons. Signals transmitted to the thalamus are relayed to broad regions of the cortex, where these signals maintain an alert, conscious state. This specific component of the reticular formation is referred to as the reticular activating system (RAS). Reticular formation neurons are responsive to every major ascending sensory modality, including somatosensory, thermosensory, nociceptive, vestibular, and auditory stimuli, and to visual stimuli, relayed via the superior colliculi. General

Introduction

Arousal is a dynamic state that exists in a continuum from low states of arousal to high states of arousal/wakefulness. An organism with high arousal is one that is more alert to sensory stimuli, more behaviorally reactive, and more emotionally reactive. Arousal can refer to general arousal, or to more specific forms of arousal, such as sexual arousal, playful states, anxious states, or fear states, which are defined by specific contexts and behavioral correlates. We

anesthesia, alcohol, sedatives, and sleep-inducing drugs inhibit RAS activity and result in a loss of alertness or consciousness. Extensive damage to the RAS can induce coma. The motor component of the reticular formation regulates somatic motor function, autonomic responses, heart rate, blood pressure, and respiration. Thus, increased excitability of the reticular formation can lead to facilitation of both sensory and motor function. In what will become a common theme discussed below, reticular formation neurons can be made more excitable by stress-related neuropeptides, such as corticotropin-releasing factor (CRF), and stress hormones, such as glucocorticoids. Thus activation of stress-related neural circuits or the hypothalamic–pituitary–adrenal (HPA) axis can co-opt normal arousal mechanisms, amplifying sensory responsiveness, vigilance, attention, and behavioral reactivity. The majority of neurons in the reticular formation use glutamate, an excitatory amino acid, as a neurotransmitter.

Serotonin

Serotonergic neurons are predominantly located in the brainstem raphe complex, a midline complex closely associated with the reticular formation within the mid-brain, pons, and medulla. A significant number of serotonergic neurons are located within the pontomesencephalic reticular formation itself. Although serotonergic neurons within the pontomesencephalic reticular formation may play a critical role in the regulation of arousal, their functional attributes have not been studied due to the highly scattered distribution of this cell group. The majority, but not all, of the serotonergic neurons have firing rates that are correlated with behavioral state, with high levels of neuronal firing during active-waking states, and progressively lower firing rates during behavioral quiescence, NREM and REM sleep. Similarly, the expression of the rate-limiting enzyme for 5-HT synthesis in the brain, tryptophan hydroxylase 2 (*tpb2*) varies in a diurnal manner as do tissue and extracellular concentrations of 5-HT in many brain regions (Figure 1(b)). *tpb2* mRNA expression rises just before the active phase of the diurnal cycle, while *tpb2* protein expression and tissue and extracellular 5-HT concentrations are elevated during the active period of the diurnal cycle. Diurnal variations in *tpb2* mRNA expression are dependent on the circadian variation in glucocorticoid secretion, with elevated glucocorticoids promoting *tpb2* expression (Figure 2).

Norepinephrine

Cortical-projecting noradrenergic (norepinephrine-producing) neurons are localized primarily in the pontine locus coeruleus (LC) and are involved in orientation,

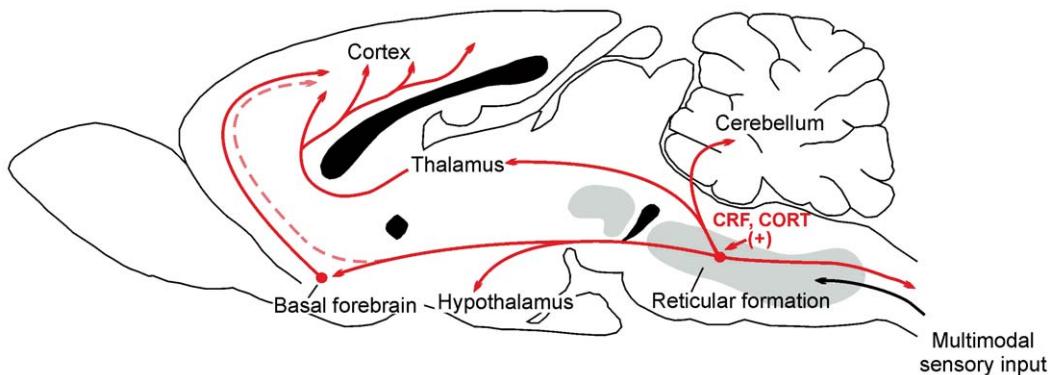

Figure 2 A highly simplified schematic representation of the brainstem reticular formation and its ascending and descending projections. The reticular formation is indicated by gray shading in the midbrain, pons, and medulla. Reticular formation neurons are responsive to every major ascending sensory modality, including somatosensory, thermosensory, nociceptive, vestibular, auditory stimuli, and visual stimuli. Ascending projections to the forebrain travel along a dorsal pathway to a thalamocortical projection system or along a ventral pathway to the lateral hypothalamus and basal forebrain. Although some reticular formation fibers continue along the ventral pathway to the cerebral cortex (pink dashed line), large numbers of cells in the reticular formation project to the basal forebrain where cholinergic neurons give rise to widespread projections to the cerebral cortex. Thus the basal forebrain acts as an extrathalamic relay system from the reticular formation to the cerebral cortex. Reticular formation neurons can be made more excitable by stress-related neuropeptides, such as CRF, and stress hormones, such as corticosterone. Thus activation of stress-related neural circuits or the HPA axis can co-opt normal arousal mechanisms, amplifying sensory responsiveness, vigilance, attention, and behavioral and emotional reactivity. For a comprehensive review of the chemoarchitecture, ascending projections and descending projections of the reticular formation, see Jones BE (1995) Reticular formation: cytoarchitecture, transmitters, and projections. In: Paxinos G (ed.) *The Rat Nervous System*, 2nd edn., pp. 155–171. New York: Academic Press.

attention, and maintenance and enhancement of cortical activation. Like the majority of the serotonergic neurons, the firing rates of LC neurons are highest during wakefulness, lower during NREM, and virtually absent during REM sleep. The expression of the rate-limiting enzyme for norepinephrine synthesis in the brain, tyrosine hydroxylase (TH) varies in a diurnal manner as do tissue and extracellular concentrations of norepinephrine in many brain regions. Extracellular concentrations of norepinephrine peak soon after dark onset (the active phase for rats, **Figure 1(c)**). Likewise, the activity of dopamine β -hydroxylase (DBH), which converts dopamine to norepinephrine, varies in a diurnal manner. Norepinephrine is an important modulator of multiple components of the arousal system. For example, noradrenergic fibers innervate the dorsal raphe nucleus, and activation of α_1 -adrenergic receptors there increases the firing rates of serotonergic neurons.

Dopamine

Dopaminergic neurons are located primarily in the substantia nigra (SN) and ventral tegmental areas (VTA), but are also present in the rostral part of the raphe complex and in specific regions of the hypothalamus and olfactory bulb. Dopaminergic neurons include the mesostriatal dopaminergic system projecting from the substantia nigra to the striatum and frontal cortex, and the mesolimbocortical dopaminergic system projecting from the VTA to limbic structures, including the nucleus

accumbens, and to the cortex. Although dopamine neurons are reported to show similar firing rates across the sleep–wake cycle, dopaminergic systems are important for behavioral arousal and motor activity, possibly via interactions with other arousal-promoting systems, or via actions of dopaminergic neurons that have not been widely studied, such as those in the rostral part of the raphe complex. Although the evidence suggests no change in the mean firing rates of dopaminergic neurons in the VTA and SN across the sleep–wake cycle, extracellular concentrations of dopamine and its metabolites 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) show changes across the diurnal cycle in the striatum and nucleus accumbens (**Figure 1(c)**). The increase in extracellular dopamine concentrations and dopamine metabolism, apparently without changes in firing rate, may represent diurnal variation in TH activity, dopamine synthesis and release, or the rate of dopamine clearance in the projection regions.

Histamine

Histaminergic neurons are localized in the posterior hypothalamus within the tuberomammillary nuclei from where they project to virtually the entire central nervous system. The firing rate of histaminergic neurons varies across the sleep–wake cycle, with the highest rates during waking and the lowest rates during REM sleep. Extracellular concentrations of histamine in the hypothalamus also vary across the diurnal cycle (**Figure 2(c)**).

Knock-out (KO) mice lacking the synthetic enzyme for histamine, histidine decarboxylase (HDC), show an altered circadian rhythm in wheel running and locomotor activity. Antihistamines can cause drowsiness. Histamine is an important modulator of multiple components of the arousal system. For example, histaminergic fibers innervate the dorsal raphe nucleus, and activation of histamine receptors there increases the firing rates of serotonergic neurons.

Acetylcholine

The cholinergic neurotransmitter system is also important in the regulation of behavioral and cortical arousal. The major cholinergic pathways in the brain arise from two populations of cholinergic neurons – one located in the brainstem, the other in the basal forebrain. Cholinergic neurons of the brainstem are located in the mesopontine tegmentum (including the pedunculopontine tegmental nucleus (PPTg) and laterodorsal tegmental nucleus (LDTg)) and in the medullary reticular formation. These neurons project to the SN, LC, and midbrain raphe complex and also project to the lateral hypothalamus and basal forebrain where signals are relayed to the cerebral cortex. This basal forebrain relay to the cerebral cortex is constituted of cholinergic neurons located in the magnocellular preoptic nucleus, substantia innominata (SI), medial septum (MS), and ventral and horizontal limbs of the diagonal band of Broca (VDB and HDB, respectively). Cholinergic neurons in the MS and VDB project to the hippocampus, and this pathway has been suggested to be involved in mechanisms underlying arousal associated with fear and anxiety-related states. In general, cholinergic neurons discharge at their highest rates during active waking and REM sleep, and virtually cease firing during NREM sleep. In the cortex, extracellular concentrations of acetylcholine change across the diurnal cycle; this effect is more pronounced in the sensory cortex than in the motor cortex. Although the extracellular concentrations of ACh are elevated during the dark (active) phase, converging lines of evidence suggest that in some brain regions (basal forebrain, hypothalamus, etc.) extracellular concentrations of ACh are greater during REM sleep than during waking.

Orexin/hypocretin

Orexin/hypocretin neurons are localized in the perifornical area of the lateral hypothalamus and are necessary for the maintenance of waking and behavioral arousal. An absence or reduction of the orexin/hypocretin peptide or receptors results in narcolepsy with cataplexy. Orexinergic neurons project widely to the forebrain, including the cerebral cortex, brainstem, and spinal

cord, and – like the ACh-basal forebrain system – orexinergic neurons project to the subcortical relays of the basal forebrain. Orexin/hypocretin modulates multiple arousal-promoting neurotransmitter systems, including noradrenergic, histaminergic, and serotonergic neurons. Orexinergic neurons fire selectively during waking and cease firing activity during both REM and NREM sleep. In the hypothalamus, extracellular concentrations of orexin/hypocretin (**Figure 2(c)**), and orexin/hypocretin mRNA expression also vary in a diurnal manner.

Sleep-Promoting Mechanisms

Sleep is often characterized by a common species-specific posture, reduced motility, higher arousal thresholds (i.e., stronger sensory stimuli are needed to induce a response), and reduced behavioral responsiveness to environmental stimuli. Sleep is most commonly defined by changes in the electroencephalogram (EEG), also referred to as brainwave activity. During active wakefulness, cortical EEG is predominantly a fast (15–25 Hz or cycles per second (cps)), low-amplitude/voltage waveform called beta EEG, whereas during quiet wakefulness cortical EEG is a synchronous waveform of 8–12 Hz called alpha EEG. Compared to wakefulness, the sleep EEG is generally slower and of higher amplitude. Sleep physiology can be divided into deep NREM and REM sleep stages with sleep-generating mechanisms varying between these stages. In the adult human, NREM and REM sleep alternate throughout the night approximately every 80–120 min.

NREM sleep

NREM sleep is dominated by slow (<8 Hz), high-amplitude (>20 μ V) synchronized EEG activity. In the human, NREM sleep is divided into stages 1, 2, and stages 3/4. Stage 1 is a light stage of sleep that occurs early during the wakefulness–sleep transition and lasts for a few minutes. Stage 1 sleep consists of a dominant theta (4–7 Hz) EEG waveform and the presence of vertex sharp waves – a fast negative deflection maximal at the vertex (apex). Stage 2 sleep makes up approximately 50% of total sleep time and occurs in equal amounts across the night. Stage 2 sleep consists of a dominant theta EEG waveform with the presence of sleep spindles and K-complexes. Sleep spindles are a synchronous sinusoidal EEG waveform of 12–14 Hz in the shape of a spindle with duration of at least 0.5 s. Spindles represent an inhibitory waveform between the thalamus and cortex that prevent sensory information transfer from subcortical to cortical areas. The K-complex is an EEG waveform with a well-delineated negative voltage-deflection immediately followed by a positive voltage-deflection with duration

of ~0.5 s. K-complexes occur in response to environmental sensory stimuli and are also endogenously generated. Arousal thresholds are higher in stages 1 and 2 sleep compared to wakefulness, yet behavioral responses to all forms of sensory stimuli often still occur. Many physiological processes slow down or are less active during NREM sleep when compared to wakefulness. For example, eye movements, respiration, muscle activity, heart rate, and whole body and brain metabolic rate are all lower and relatively stable during NREM sleep compared to wakefulness. Sleep is promoted by the inhibition of the RAS and is associated with a thalamocortical disassociation mediated by the inhibitory neurotransmitter γ -aminobutyric acid (GABA). Cholinergic neurons in the basal forebrain and brainstem, serotonergic neurons in the midbrain raphe nuclei and noradrenergic neurons in the LC decrease their activity during the wakefulness to sleep transition. The diminished release of ACh and norepinephrine affects the activities of thalamocortical and cortical cells, most notably to reduce responsiveness to afferent signals. GABAergic thalamic reticular nucleus neurons are responsible for the production of sleep spindles along thalamocortical pathways. Neurons in the ventrolateral preoptic nucleus (VLPO) of the hypothalamus are sleep active. Ventrolateral preoptic nucleus neurons promote sleep via GABAergic projections that inhibit excitatory histaminergic cells in the posterior hypothalamus and inhibit excitatory noradrenergic and serotonergic cells in the brainstem. NREM sleep is promoted by the activation of neurons in the VLPO, basal forebrain, nucleus of the solitary tract, and raphe nuclei, which project to and inhibit wakefulness-generating centers and the cortex. Stage 3/4 sleep (also referred to as slow-wave sleep (SWS)) is the deepest stage of sleep and is dominated by a slow, delta (0.5–2.5 Hz), high-amplitude (>75 μ V), synchronized EEG waveform. Slow-wave sleep occurs mostly during the first half of the night and is driven by homeostatic sleep drive. While neurobiological mechanisms of sleep homeostasis are not completely understood, there is strong evidence that the neuromodulator adenosine plays a role in homeostatic sleep drive. Adenosine levels build up with time spent awake and promote sleep by inhibiting wakefulness-promoting cholinergic basal forebrain neurons and by activating sleep-promoting neurons in the VLPO. The wakefulness-promoting drug caffeine exerts its effects primarily by blocking the effects of adenosine. Other endogenous sleep-promoting substances include immune factors such as prostaglandin D2 (PGD2), interleukin-1 (IL-1), and muramyl peptides.

REM sleep

REM sleep is defined by low-amplitude desynchronized theta EEG activity with the presence of saw-tooth waves

at the cortex. REM sleep is also characterized by the presence of pontine-geniculate-occipital (PGO) waves as well as hippocampal theta EEG activity. Compared to NREM sleep, REM sleep is considered the sleep state with the highest physiological arousal. Respiration, heart rate, and brain glucose utilization are more variable and activity can be as high as that observed during wakefulness. However, skeletal muscle activity is actively inhibited during REM sleep. REMs and other phasic activity such as middle ear muscle activity may be present during REM sleep.

Cholinergic neurons in the reticular formation are active during REM sleep, primarily those located in the pontine tegmentum. However, there are special populations referred to as REM-ON neurons that fire only during REM sleep, REM-OFF neurons that fire during wakefulness and are off during REM sleep, and a population of cholinergic neurons that fire during both REM sleep and wakefulness. GABAergic REM-ON neurons are located in the sublaterodorsal nucleus/peri-LC and the periventricular gray matter, and GABAergic REM-OFF neurons are located in the ventrolateral part of the periaqueductal grey matter and the lateral pontine tegmentum. REM-ON neurons inhibit REM-OFF neurons and thus promote REM sleep. Reciprocal inhibitory interactions between the REM-ON and REM-OFF neurons are thought to be involved in REM-sleep regulation. In addition stimulation of serotonergic, noradrenergic, or histaminergic cells will inhibit REM sleep. Orexin/hypocretin neurons also regulate REM-sleep timing via activation of the LC. Disinhibition of GABAergic neurons in the pons may also be involved in REM-sleep generation.

Stress Influences on Arousal/Sleep

There is currently no consensus in neurobiology on the definition of stress. However, the stress research pioneer Hans Selye suggested that "Stress is a state, manifest by an adaptive syndrome that works in the direction of producing a return to the unchallenged state of the body." The adaptive responses involved in restoring homeostasis during a stressful state include the activation of the autonomic nervous system and activation of the HPA axis, leading to the release of glucocorticoid hormones. This broad definition still has value, although in practice, the current usage of the term is often restricted to responses to aversive stimuli, and states with a negative valence. For example, voluntary exercise – which for many is not an aversive experience – activates both autonomic and HPA-axis responses that contribute to a return to homeostasis. Thus, according to Selye's definition, this would be considered a stressful state, but according to common usage, it would not. Here we will align more

closely with Selye's definition, as it is first and foremost the stress-related neuromodulators, such as CRF and CRF-related neuropeptides, and glucocorticoid hormones, that are acting on arousal circuits in the brain, although the cognitive appraisal of the situation (aversive or not aversive/controllable or uncontrollable) has important implications for physiological, behavioral, and emotional outcomes.

A general discussion of the HPA axis and neural mechanisms regulating responses to stressful or aversive stimuli can be found elsewhere in the encyclopedia. Overall, evidence suggests that stress-related neuromodulators, including CRF, CRF-related neuropeptides, and glucocorticoids, increase the excitability of arousal-promoting circuits. Thus, during a stressful state, the overall effect is to amplify arousal, leading to increased reactivity to sensory stimuli, increased behavioral reactivity, and increased emotional reactivity. The precise physiological, behavioral, and emotional consequences of this amplification depend on the context.

Brainstem Reticular Formation

Studies in vertebrates have shown that the stress-related neuropeptide CRF has predominantly excitatory effects on the neuronal firing rates of reticular formation neurons. One example of CRF modulation of reticular formation neuronal excitability is in the paradigm of fear-potentiated acoustic startle. Corticotropin-releasing factor released in the caudal pontine reticular formation increases tone-evoked neuronal activity and is critical for fear potentiation of acoustic startle. The source of the CRF acting on reticular formation neurons includes the descending CRF-containing projections arising from the central nucleus of the amygdala – an important structure controlling emotional behavior.

Consistent with the role of CRF, glucocorticoid hormones have direct actions at the level of the reticular formation. Corticosterone can act rapidly, presumably via nongenomic mechanisms, to either increase or decrease neuronal firing rates of reticular formation neurons. The effect of corticosterone is dependent on the context. Thus, the core of the arousal-generating circuitry is under direct control by stress-related neuropeptides and stress-related hormones, demonstrating how a stressful state can alter the baseline state of arousal. These mechanisms have likely evolved as adaptive mechanisms to create a higher level of arousal under conditions when the homeostatic state of the organism is threatened, leading to heightened sensory reactivity, behavioral reactivity, and emotional reactivity required to cope effectively with the stressful challenge.

Serotonin

Stressful stimuli increase serotonergic neurotransmission. CRF-containing fibers, possibly arising from the central nucleus of the amygdala and the bed nucleus of the stria terminalis, form synaptic contacts with serotonergic neurons in the dorsal raphe nucleus. Populations of serotonergic and GABAergic neurons in the raphe complex express CRF type 2 (CRF₂) receptors. A low level of CRF type 1 (CRF₁) receptor expression has also been reported in the raphe complex. CRF has biphasic effects on the neuronal firing rates of serotonergic neurons within the dorsal raphe nucleus. At lower concentrations, CRF inhibits serotonergic neuronal firing rates, while at higher concentrations, it increases them. The inhibitory effects of CRF are mediated by activation of CRF₁ receptors, while the excitatory effects are mediated by activation of CRF₂ receptors. These effects on neuronal firing rates are consistent with the effects of CRF on extracellular 5-HT concentrations in forebrain targets of serotonergic neurons. The endogenous ligands mediating these effects are not certain but could include CRF itself, which has high affinity for CRF₁ receptors and moderate affinity for CRF₂ receptors, urocortin 1 (Ucn 1), which has high affinity for both CRF₁ and CRF₂ receptors, or Ucn 2 or Ucn 3, which are both high-affinity ligands for CRF₂ receptors. Activation of the central nucleus of the amygdala increases extracellular 5-HT concentrations in forebrain targets of the dorsal raphe nucleus, and this can be prevented by blockade of CRF₂ receptors within the dorsal raphe nucleus. Stress and CRF also increase the activity of TPH – the rate-limiting enzyme in the biosynthesis of 5-HT – via phosphorylation-dependent mechanisms.

Serotonergic neurons also express glucocorticoid receptors (GRs). Glucocorticoids can acutely increase the neuronal firing rates of a subset of serotonergic neurons, and following prolonged treatment cause a desensitization of the normal 5-HT_{1A}-receptor-mediated negative feedback mechanisms, resulting in increased excitability of serotonergic neurons. Stress increases the expression of TPH mRNA, but the neurochemical mechanisms involved are not yet clear. However, as glucocorticoids are responsible for the diurnal variation in *tpb2* mRNA expression (**Figures 1(a) and 1(b)**), it seems likely that glucocorticoids may contribute to stress-induced increases in *tpb2* mRNA expression. Glucocorticoids are permissive for stress-induced increases in TPH activity, apparently via actions within the central nucleus of the amygdala, but have no effects on TPH activity by themselves. Thus, in conclusion, glucocorticoids play a critical role in the normal diurnal variation in *tpb2* mRNA expression (and, therefore, presumably, 5-HT synthesis and release), while stress neuromodulators, including CRF or CRF-related

neuropeptides acting at CRF₂ receptors, and stress-induced increases in glucocorticoids appear to further increase serotonergic neurotransmission via various, complementary mechanisms.

Norepinephrine

Like the serotonergic system, stressful stimuli also activate noradrenergic systems. CRF-containing terminals have been detected in apposition to noradrenergic neurons in the LC and retrograde tracing experiments have suggested that this CRF innervation comes from the nucleus gigantocellularis of the reticular formation and the paraventricular nucleus of the hypothalamus, among other sources. Almost all noradrenergic neurons in the LC express CRF₁ receptors. Direct administration of CRF into the LC increases the firing rates of noradrenergic neurons and this increase is associated with increased extracellular concentrations of norepinephrine in forebrain targets of the LC. Stress-related stimuli can increase TH mRNA and protein expression.

The LC contains a high density of GRs. As opposed to *tpb2*, evidence that glucocorticoids modulate TH mRNA expression or TH activity in adults is lacking.

Dopamine

Stress induces the release of CRF in the VTA and increases extracellular dopamine concentrations in limbic forebrain structures. CRF-containing nerve terminals in the VTA are made up of asymmetric synapses that are mostly glutamatergic and symmetric synapses that are mostly GABAergic. The synapses between CRF-immunoreactive axon terminals and TH neurons are asymmetric, and hence likely to be glutamatergic, suggesting that glutamatergic neurons containing CRF may be part of the stress-related neuronal circuitry that modulates dopaminergic neuronal activity. Dopaminergic neurons express CRF₁ receptors in both the VTA and SN and CRF₂ receptor mRNA has recently been detected in the VTA using reverse transcription-polymerase chain reaction (RT-PCR). Consistent with these findings, CRF increases the firing rates of dopaminergic neurons in the VTA.

Some, but not all, dopaminergic neurons in the VTA and SN appear to contain GRs. Stress increases the strength of excitatory synaptic transmission in midbrain dopamine neurons and this effect can be prevented by a GR antagonist.

Histamine

Although stress-related stimuli have been shown to activate histaminergic neurons and histaminergic neurons appear to play an important role in the stress response,

the interactions between CRF, glucocorticoids, and histaminergic systems are not well understood. This is an important subject for future studies.

Organic Cation Transporters

Organic cation transporters (OCTs) are a family of multi-specific, bidirectional, carrier-type permeases that transport organic cations, including 5-HT, norepinephrine, dopamine, and histamine. These transporters include OCT1, OCT2, and OCT3, also known as the extraneuronal monoamine transporter. As opposed to the presynaptic, high-affinity, low-capacity sodium-dependent transport mechanisms (5-HT transporter, norepinephrine transporter, dopamine transporter, etc.), OCTs are low-affinity, high-capacity transporters that are expressed widely in postsynaptic neuronal and glial cells. The transport activity of OCT3 is inhibited by corticosterone in the low nanomolar range, suggesting that inhibition of monoamine clearance by corticosterone may contribute to stress-induced increases in extracellular monoamine concentrations.

Acetylcholine

The cholinergic system plays an important role in the modulation of arousal systems by stressful stimuli. CRF-containing fibers innervate both brainstem and basal forebrain regions containing cholinergic neurons. Most of the cholinergic neurons in the brainstem and basal forebrain co-express CRF₁ receptors. Intracerebroventricular administration of CRF increases ACh release in the hippocampus and increases neuronal activity in brain regions associated with the cholinergic system and arousal including the MS and LDTg. It has been hypothesized that CRF (via CRF₁ receptors) activates cholinergic neurons in the LDTg projecting to the LC.

GRs are present (albeit at low concentrations) in regions of the basal forebrain and brainstem that contain cholinergic neurons including the MS, nucleus of the diagonal band of Broca, SI, and LDTg. However, it is unclear if GRs are present in cholinergic neurons. Stressful stimuli or the subcutaneous administration of corticosterone increases extracellular concentrations of ACh in the hippocampus. Nicotinic and muscarinic receptor agonists have been reported to increase plasma corticosterone concentrations via interaction with the noradrenergic system.

Orexin/hypocretin

Synaptic contacts between CRF-containing terminals and orexin/hypocretin perikarya have been observed in the hypothalamus. Orexin/hypocretin neurons

express CRF receptors, and there is some evidence for activation of orexin/hypocretin neurons during stressful states.

Thus, in summary, stress-related neuromodulators (CRF, corticosterone, etc.) can co-opt normal arousal mechanisms (the brainstem reticular formation, monoaminergic systems, cholinergic systems, and orexin/hypocretin systems) and potentially amplify sensory responsiveness, vigilance, attention, and behavioral and emotional reactivity.

Models of Insomnia

The psychophysiological model of insomnia provides strong support that insomnia is a disorder of 'hyperarousal.' Specifically, patients with insomnia compared to healthy controls show:

1. increased sympathetic arousal as indicated by reduced heart rate variability and higher circulating norepinephrine levels;
2. higher HPA-axis activity as indicated by higher cortisol levels immediately prior to sleep or during the beginning of the sleep episode;
3. higher functional magnetic resonance imaging (fMRI) brain activity of brainstem arousal systems during sleep;
4. higher cortical arousal as indicated by increased beta EEG activity during sleep, as well as reduced delta and theta EEG activity during NREM sleep;
5. increased processing of auditory stimuli during sleep as evidenced by changes in event-related brain potentials;
6. higher frontalis and mentalis muscle electromyography (EMG) activity during the sleep transition;
7. higher core body temperature,
8. higher whole-body metabolic rate, and
9. increased latency to fall asleep at all times of day.

The cognitive model for insomnia is complementary to the psychophysiological model in that stressful life-events and excessive worry lead to physiological and cognitive arousal, acute insomnia, and conditioned arousal associated with sleep. The physiological and cognitive arousal contributes to behaviors and thoughts that occur near or when patients think about the sleep. These include ruminations and worry about not being able to sleep and the consequences of insomnia for the next day. Often, many of these thoughts are considered dysfunctional and inaccurate. Regardless, these thoughts are considered to be precipitating events for acute insomnia and perpetuators for chronic insomnia. Over time, insomnia increases the worries about sleep and

physiological and cognitive arousal eventually lead to chronic insomnia.

Psychopathology

Chronic stress states, via effects of CRF-related neuropeptides, glucocorticoid hormones, and other stress-related neuromodulators, are likely to play an important role in disruption of sleep that is associated with a number of stress-related neuropsychiatric disorders, including generalized anxiety disorder, posttraumatic stress disorder (PTSD), panic disorder, and affective disorders.

Glossary

Chronic variable stress (CVS) – This involves a combination of a number of different stressors that are usually applied in a random fashion over an extended period of time. CVS in animal models is used to mimic the effects of chronic stress while minimizing possible habituation to a given stressor.

Individual differences – For a given measure within a defined population, wide variation is often found that defines the normal distribution. An important new development in behavioral neuroscience and other disciplines has been to take advantage of this variance and separately analyze how different components of a population (e.g., those at one or both ends of the spectrum) respond differently to a given treatment or to stressors. This approach of using individual differences is often accompanied by an examination of the genes and environmental history of the individuals.

Sex differences – Within a given species, any detectable difference between male and females can be considered a sex difference. Body morphology and mechanisms of reproduction are overt examples of sex differences. In behavioral neuroscience, sex differences can include differences in brain neurochemistry, hormones, and reactivity to stressors between males and females.

Social behavior – Any intraspecies interactions between individuals can be considered a social behavior. General social behaviors can include communication, allo-grooming, and aggression. Reproductive social behaviors can include partner preference and mating behavior. Maternal social behaviors can include nursing, licking and grooming of offspring, and offspring protection. Within these secondary headings, a number of subcategories exist. For example, there are a number of forms of aggression, including territorial, mate guarding, fear induced, and dominance. The final forms of social behaviors can differ dramatically among species.

While exhibiting social behaviors an individual may experience a stressor that will alter social performance. A number of factors make stress and social behavior a highly complex topic. First, there is a wide range of possible stressors and social behaviors which can interact. Second, not all stressors uniformly inhibit social

behaviors, rather some social interactions can be enhanced. Third, some stressors are themselves a social behavior, such as aggression. Fourth, stressors can trigger the emergence of a social behavior, such as aggression or alarm calling, which involves vocalizations by individuals to alert conspecifics of an imminent threat. Fifth, some social behaviors can mitigate the effects of a stressor through a process called ‘social buffering’ whereby the process of performing social behaviors itself will dampen response of individuals to a stressor. Social buffering can be adaptive by minimizing the negative effect of a stressor on ongoing behaviors. Finally, individual differences and sex differences within a species can strongly determine the effect of a stressor on a behavior. One goal of behavioral neuroscience is to understand the complex interactions of stress and social behaviors.

Effects of Stress on General Social Behaviors

As shown in [Table 1](#), a number of studies have been conducted examining the effects of stress on a range of general social behaviors. Some of the most commonly studied general social behaviors and how those are affected by stressors are discussed. The relevance, or adaptive value of these responses, will also be provided, if it is known. The mechanisms by which stress modulates behaviors will be provided in some cases.

Communication

In humans, conversation is a social behavior, and changes in speech occur in response to stress. For example, voice pitch (specifically, the fundamental frequency floor) is elevated with stress, but this effect was only found in individuals either exhibiting high anxiety or reporting low anxiety. Further, for females reporting low anxiety, cognitive stress increases the precision of articulation, whereas emotional stress decreases this precision. A change in voice pitch or precision of articulation could be adaptive for communicating the stress state of an individual to others. Pitch changes would involve physiological changes in muscle tension, but how stress alters the nervous system pathways regulating pitch is not known.

Alarm calls are emitted by individuals of certain species to alert others of the group of impending dangers.

Table 1 Overview of effects of applied stressors on different social behaviors

Stressor (timing)	Effect	Social behavior	Species
Physical stress	↔	Communication	Bird males
Infection (juvenile)	↓	Communication	Bird males
Food restriction (juvenile)	↓	Communication	Bird males
Cognitive stress	↑	Articulation	Human females
Emotional stress	↓	Articulation	Human females
Cognitive/emotional stress	↑	Voice pitch	Human (subgroups only)
Predator stress	↓	Communication	Birds
Predator stress	↑	'Alarm calls'	Many species (incl. birds)
Restraint stress	↑	Allo-grooming	Rat
Crowding	↓	Allo-grooming	Chimpanzee
Rearing deficits	↓	Allo-grooming	Rhesus monkeys
Restraint stress	↓	Male aggression	Rat
Crowding	↓	Male aggression	Chimpanzee
Social isolation	↑	Male aggression	Mouse, rat
Footshock (acute)	↑	Male aggression	Mouse, rat
Electroconvulsive shock (acute)	↓	Male aggression	Rat
Electroconvulsive shock (chronic)	↑	Male aggression	Rat
Predator stress	↑	Mobbing	Many species
Conditioned defeat	↓	Male aggression	Hamster, mouse
Swim stress	↓	Partner preference	Prairie vole females
Swim stress	↑	Partner preference	Prairie vole males
Low social status	↓	Mating	Marmoset, tamarin
Restraint (acute)	↓	Lordosis	Rat female
CVS	↓	Ejaculation	Rat male
Social stress	↓	Mounting	Mouse male
Combat stress	↓	Mating	Human males
Social stress	↓	Mating	Meerkat
Restraint (chronic and acute)	↔	Pup retrieval	Mouse
CVS (pregnancy)	↑	Pup retrieval	Mouse
Social-defeat stress (pregnancy)	↑	Pup retrieval	Rat (high anxiety)
Male exposure (acute)	↓	Pup retrieval	Rat
Restraint (pregnancy and lactation)	↑	Pup licking/grooming	Mouse
CVS (pregnancy)	↓, ↑	Pup licking/grooming	Mouse
Social crowding (pregnancy)	↓	Pup licking/grooming	Rat
Limited nesting material	↓	Pup licking/grooming	Rat
CVS (pregnancy)	↓	Nursing	Mouse
CVS (pregnancy)	↑	Nursing	Rat
Social (acute)	↓	Nursing	Rat
Social (chronic)	↔	Nursing	Rat
Social defeat (pregnancy)	↑	Maternal defense	Rat (low anxiety)
Restraint (pregnancy)	↓	Maternal defense	Mouse
CVS (pregnancy)	↓, ↑	Maternal defense	Mouse
Restraint (acute)	↓	Maternal defense	Mouse
Restraint (chronic during lactation)	↔	Maternal defense	Mouse

↑ = elevates behavior; ↓ = decreases behavior; ↔ = no effect on behavior.

These are conserved in social species and are found in a range of taxa, including birds, rodents, and primates. Here, we see a unique social behavior emerge only with stress and in the context of a threat.

In songbirds, singing by males can be used to attract mates. Canaries injected with malaria as juveniles and zebra finches experimentally exposed to stress (including food restriction) as juveniles, both produce simpler songs as adults, indicating developmental stress can alter adult outcome. However, application of a weight to the tail feathers for 48 h does not alter song repertoire in Whitethroats, suggesting song can be resistant to some

stressors. While alarm calls described above are produced by some birds in response to predatory threat, a predator can similarly induce decreased singing. This decrease in singing (which can also be induced by human presence in a laboratory setting) may be adaptive to decrease detection from predators. The neuropeptide, corticotropin-releasing factor (CRF), can be released centrally in association with a response to stress, and indirect evidence suggests CRF mediates a decrease in singing with stress. For example, central injections of CRF decrease song produced by white-crowned sparrows in association with territory defense.

Allo-Grooming

The grooming of conspecifics occurs in a wide range of species. In rats, 1 day following a single restraint stress or repeated restraint stress, males show an elevation of grooming other males that they confronted in a neutral arena. This elevation of grooming coincides with a decrease in aggression, suggesting it is an appeasement behavior. In contrast, in captive chimpanzees, the social stressor of crowding decreases allo-grooming. The increased crowding occurred on cold days when the chimpanzees were housed indoors and the density increased, so behavior of the same group of animals could be compared when crowding and conditions differed. For chimpanzees, the decrease in allo-grooming also accompanied a decrease in aggression and was suggested to be a strategy for limiting the possibility for conflict. In rhesus monkeys, allo-grooming decreases if the animals were exposed to a rearing stress. In this case, 50% of the monkeys were reared by their mothers (considered the control) and the other 50% were reared using bottles and a nursery care staff. The lack of full maternal care as a stressor was employed for the first 3 months of the monkey's life and the monkeys were evaluated from 18 to 36 months of age. Norepinephrine (NE) and CRF are released centrally in association with a stress response and research suggests that both can promote self-grooming behavior. However, to what extent the circuitries of allo-grooming and self-grooming overlap, is not clear.

Aggression

Aggression is a highly variable social behavior when examined across species and within a given species. In general, aggression can be motivated by resource control (or a challenge to that resource) or by danger of harm or death to the individual. Resource control can include territorial aggression, parental aggression, dominance aggression, or mate acquisition. Aggression due to danger can include fear-induced aggression. In this latter case, the response to stress is adaptive because the emergence of this aggressive social behavior may be critical for self-preservation. Stressors can elevate, impair, or have no effect on the different forms of aggression. For example, in male rats, restraint stress reduces aggression when the males are tested in a neutral arena. However, social isolation (which is considered a stressor) is a common tool for elevating aggression in male rats and mice. While acute electroconvulsive shock impairs resident-intruder intermale aggression in rats, bidaily treatment for 7 days elevates this form of aggression. Here, we see an example where possible habituation to a treatment may alter outcome. Footshock can elicit increases in male aggression in rats. In some mouse strains, however, footshock elicits increased aggression

and this depends upon age, but other strains show no effects, regardless of when examined. This finding highlights that, even within a species, differences in how populations respond to a stressor are found. In chimpanzees, crowding stress results in decreased aggression. The act of aggression can be considered a trade-off because it can bring with it gains in different forms, and it also increases the risk of injury to the individual. A stressor may alter the perception of the gains/risks ratio and thereby have complex effects on the production of aggression.

Cortisol or corticosterone (CORT) is released peripherally from the adrenal gland in association with a stress response and physical exertion, such as aggression output. Exogenously applied CORT facilitates aggression in adrenalectomized rats, suggesting that increases in CORT could feed-forward to promote some forms of aggression. However, CORT can also be without effect on some forms of aggression or even enhance a defeat response (see below). Interestingly, CRF injected centrally promotes stress-induced aggression, but impairs resident-intruder aggression in rodents. NE has been found to promote some reactive forms of intermale aggression and antagonizing the beta-adrenergic receptor reduces aggression in humans. Inhibition of the alpha 2 adrenergic receptors can either promote or inhibit intermale rat aggression. Thus, it is likely that both CRF and NE mediate some of the complex effects of stress on aggression.

In response to a potential predator, a number of species act collectively to ward off the intruder in what is termed 'mobbing behavior.' For example, a group of crows may attack a larger raptor and this involves vocalizations, chasing, and swoop attacking the potential predator. Interestingly, birds from unrelated species can be found mobbing together to protect a region. In some squirrel species and in some nonhuman primates, such as tamarins, mobbing behavior can be triggered by snakes. Mobbing behavior is adaptive because it provides cohesion among a group and allows the group to deter a potential threat that could not be accomplished by any one individual. How a predator stress might elicit a mobbing behavior is not known; however, it would be expected that activation of fear-induced aggressive routines within individuals would be an important component.

Conditioned Defeat

Conditioned defeat is a model for social stress whereby a male rodent is repeatedly defeated by another (usually larger) male. The outcome of conditioned defeat is that the male shows decreased aggression when tested later, even if the opponent is smaller and the focal male is defending his territory. Defeated males can also show increased submissive behaviors and avoidance of

conspecifics. In association with defeat, a heightened stress response has been found that could correspond to elevated central release of CRF. Indeed, conditioned defeat in hamsters has been linked to CRF actions in dorsal raphe and bed nucleus of stria terminalis as antagonizing the CRF receptors in either region suppresses the effects of defeat. Injections of the γ -aminobutyric acid-A (GABA-A) agonist, muscimol, into amygdala also reduces the defeat response, suggesting a role for this region in the response to stress. CORT itself has little effect on submissive behavior, but CORT application along with the experience of defeat elevates levels of defeat behavior in mice, suggesting the timing of CORT release is important. Conditioned defeat can be considered adaptive because if an individual has almost no chance of winning an aggressive encounter, then submissive behavior may be the best way to avoid harm.

Effects of Stress on Reproductive Behaviors

A number of studies have examined the effects of stress on reproductive social behaviors (Table 1). Some of the most commonly studied reproductive behaviors and how those are affected by stressors are discussed.

Partner Preference

An interesting example of sex differences in response to a stressor is seen in prairie voles. Males usually do not form a partner preference when cohabited with females for 6 h, but females do form a preference in this time course. When a forced-swim-stress test (which involves placing a rodent in water without access to a platform) preceded the 6-h cohabitation period, males showed a preference for the females when they were examined later using a three-chambered choice apparatus. In contrast, females given a stressor before cohabitation lost their preference for the male. These results could reflect sex differences in life-history choices, whereby in a high-stress environment the female is inclined to delay reproduction, while the male is inclined to promote reproduction. For male prairie voles that showed elevated partner preference with stress, exogenously applied CORT also promoted partner preference in adrenalectomized males. For female prairie voles that showed decreased partner preference with stress, however, applied CORT reduced their preference. Further, if CORT is removed through adrenalectomy, then partner preference is elevated in females. Recent work indicates a role for dopamine acting in nucleus accumbens on partner preference, but how stress would differentially affect those pathways in males and females, is not known.

Mating Behavior

Mating behavior here indicates the ability to successfully mate and bring an offspring to term. Sexual behavior is a motivated behavior and the ability to reproduce successfully also involves functioning of the hypothalamic-pituitary-gonadal (HPG) axis. Of all the social behaviors evaluated here, the effect of stress on mating behavior across species is the most uniform. Stress has a predominantly inhibitory effect on mating behavior. Sites of stress impairing mating can either occur in terms of motivation or the HPG axis. The impairment of reproduction by stress may be adaptive because if environmental conditions do not favor reproduction, it may be valuable to wait until more favorable conditions exist. In humans, a number of studies have shown that exposure to a variety of stressors decreases reproduction. For example, for combat veteran males suffering from posttraumatic stress disorder (PTSD), sexual dysfunction was found, including up to 85% with some form of erectile dysfunction. In one study, sexual desire was found to be decreased with PTSD, but in another it was not. For couples in a stable relationship, an incremental negative effect of stressors on sexual behavior has been found, including induction of a hypoactive sexual desire in men and women. Interestingly, female sex drive was strongly impaired by 'internal stress' that originated within the couple such as conflicts, whereas male sexual dysfunction was strongly regulated by critical life events. Unemployment has been found to correlate with a low sex drive. Research suggests CRF, CORT, and serotonin signaling may mediate some of stress's effects on sexual behavior.

Decreased reproduction may also occur by an elevation of spontaneous abortions, especially in the first trimester. Anovulation in females can be elevated by a variety of stressors, while a decrease in semen quality in males can be induced by psychological stressors. Male medical students in Brazil exhibited significant decreases in sperm concentration and motility of spermatozoa in association with examinations. In a study in Denmark, negative effects of stress were only found for males in the lowest quartile for sperm concentration. In a third study, immediate death of a close family member correlated significantly with decreased sperm performance, but other psychological stress levels did not. The exact mechanisms by which stress alters this element of the HPG axis are not clear.

Studies in other animals are in line with the studies in humans. In marmosets and tamarins, nonhuman primates, low social status is associated with decreased reproduction. Anovulation is a common mechanism for decreased mating behavior. In rats, exposure to restraint stress reduced the number of oocytes and decreased the lordosis quotient when measured later in the same day. Male rats exposed to a chronic mild stress exhibited a decreased

capacity to ejaculate. Dominant male mice exposed to a social stressor, whereby they were allowed to observe the subordinate mouse interacting with a female for 9 days, showed a significant impairment in sexual behavior, including levels of mounting. In a field study on cooperatively breeding meerkats, it was found that dominant females could suppress reproduction in subordinate females by harassing them and socially isolating them. This finding suggests that members of a species may actively exploit the inhibitory effects of stress on mating behavior.

Effects of Stress on Maternal Behaviors

Maternal behaviors are important social behaviors between mother and offspring. They can also include interactions of mothers and conspecifics as the mother protects her offspring. An overview of how stress can alter maternal behaviors is provided in **Table 1**.

Pup Retrieval

In mice, the application of chronic variable stress (CVS) during pregnancy triggered a faster time to retrieve pups. Interestingly, these effects are only observed when mothers are presented with offspring produced by stressed mothers (as compared to offspring produced by nonstressed mothers). Thus, a complication of studies where stress is applied during pregnancy is that direct effects on offspring occur *in utero* and offspring interactions with rearing mother can affect behavioral outcome. In rats that were stressed during pregnancy by subjecting the females to restraint and exposing them to aggressive attacks by a lactating female, an increased retrieval speed was observed. In the latter case, however, only rats bred for high anxiety showed this response, whereas rats bred for low anxiety did not, suggesting individual differences contribute to how an animal responds to a stressor. In rats, acute exposure to a male prolonged the retrieval. In mice, neither acute nor chronic restraint stress applied during lactation altered the timing of retrieval. The enhancement of retrieval by a stressor may be adaptive because it would rapidly bring offspring together and improve the ability for the mother to buffer the offspring from stressful conditions.

Pup Licking and Grooming

Restriction of nesting material may act as a stressor and in rats this treatment triggered decreases in licking and grooming of pups. For mice that were restrained for 2 h per day for 10 days during pregnancy and also restrained during lactation, an increase in grooming of offspring was observed. Exposure to light and restraint during

pregnancy for 7 days, however, did not alter pup-grooming levels in rats in a separate study, indicating pup grooming is not always altered by stress. As for pup retrieval, a subset of studies indicates that exposure to stress *in utero* alters some aspect of pup physiology or behavior that then alters the maternal grooming behavior. In the same study in mice, CVS applied during pregnancy triggered both an increase (when control pups were used) and a decrease (when stressed pups were used) in time spent licking and grooming offspring. Social crowding of rats during pregnancy resulted in decreased grooming of pups and this effect was seen when control pups were being raised by stressed and nonstressed mothers. In addition, pups born to stressed mothers elicited lower grooming from both stress and control rat mothers. A decrease in pup grooming by stressors could be adaptive if the mother needs to reallocate time and resources away from the nest. However, elevated grooming by stressors may be adaptive if the grooming helps to buffer offspring from the effects of stress.

Nursing

During lactation, acute exposure to a male rat increased latency to nurse for female rats; however, longer-term chronic exposure to both males and other lactating females did not have this effect, suggesting some habituation to the stimulus. For CVS applied during pregnancy, decreases in nursing were found in mouse mothers, but in rats increases in nursing were observed. A decrease in nursing by stress could be adaptive if the female needs to alter her allocation of resources. However, keeping nursing levels buffered from stress effects or elevating nursing with stress would benefit offspring development.

Offspring Protection

The protection of offspring during lactation (also termed maternal defense or maternal aggression) is highly conserved among mammalian species. In mice, application of acute restraint or swimming stress significantly decreases the time a female spends protecting offspring. However, repeated application of restraint stress during lactation had no effect, suggesting a habituation to the stressor. Restraint stress applied daily during pregnancy or CVS applied during pregnancy decreased the maternal defense in mice. However, in a separate study, application of restraint and heat during pregnancy elevated the maternal defense. Similarly, in rats, application of a social-defeat stress during pregnancy elevated the offspring protection. However, this effect was only seen in rats bred for low anxiety and not in rats bred for high anxiety, suggesting that a pre-existing anxiety state can strongly affect the stress responses. In mice, centrally

administered CRF strongly impairs offspring protection, but peripheral CORT is without effect, suggesting that stress impairs this behavior through central, not peripheral, systems. The decrease in offspring defense by stressors may be adaptive in species with high rates of reproduction, such as mice, because offspring protection involves risks to the mother. If conditions are not optimal for rearing offspring, then deferring offspring protection to a second or third litter, when conditions improve, may result in improvement of the overall reproductive rates.

Individual and Sex Differences in the Reactivity to Stressors

As indicated above, in some studies whether stress alters a social behavior is only noted when populations are subdivided. For example, rats bred for low anxiety do not respond to stress in the same way as rats bred for high anxiety, although they were originally derived from the same strain. In humans, speech is altered by stress, but only within certain subgroups. Thus, a complexity of examining stress actions on social behaviors is that individual differences can strongly affect outcome. In one example that does not involve a social behavior, the size of the hippocampus inversely correlated with level of PTSD in war veterans. However, this correlation was also seen if the hippocampal size of the twin brother was substituted in the correlation, even though the twin had no military experience. This outcome strongly suggests that pre-existing size of hippocampus and/or other inherited features predispose some individuals to PTSD. As indicated above, PTSD can affect reproductive behaviors in humans. An understanding of individual differences in any study can strengthen conclusions about stress effects on social behaviors.

In addition to individual differences, sex differences in response to stress can be found. As described above for partner preference, male and female prairie voles have an opposite response to stress. During lactation there is a suppressed reactivity to stress in females, while a dynamic change in reactivity is not seen in most males during their life history. Thus, individual differences, sex differences, and stage of life history, all of these can influence response to a stressor and should be incorporated into analysis of stress actions on social behaviors.

Complexities of Stress

In addition to individual differences and sex differences that can affect outcome in response to a stressor, a number of other features add to the complexity of stress and social behavior relations. When attempting to examine the

effects of stress on social behaviors either across or within species, it is valuable to appreciate how variable stress can be. For example, restraint is a simple form of stress, but its application can be highly variable. Restraint can be brief (5 min) or much longer (hours); it can be used once or repeated many times before measuring a behavior. The timing at which animals are tested after the end of the stress application also can vary from immediate to hours or even days. In mice, a 30-min restraint significantly decreases the time a female will protect her offspring, but only if the female is tested immediately following the end of restraint; no effect is seen 15 min or 2 h after restraint. Restraint for rodents can involve placement in a clear-Plexiglas tube or involve Velcro straps and in many cases it has not been evaluated whether the form of restraint affects outcome. Thus, for a stressor as simple as restraint, a number of details must be considered when evaluating results across studies, including timing and form of restraint.

As described above, social conditions and behaviors can act as stressors. Crowding is commonly evaluated as a stressor, but this is complex among species and rearing environment. Isolation is considered a stressor in most rodents, but cohabitation can also elicit high levels of stress among individuals within the established hierarchy. For example, in the visible burrow system in rodents, a limited number of male and female rodents live together and establish hierarchies that play a role in access to food and mates. Subordinate animals in this system show signs of chronic stress. Understanding where an animal sits within a hierarchical system and how it perceives stress from that position is important for untangling how social stressors modulate behavior. As with any other stressor, the timing and duration of exposure to a social stressor is important.

A general question is how or why stress can both elevate and decrease some social behaviors. Classical studies demonstrated that shock can elevate learning at lower levels, but impair learning at higher levels, highlighting that a stressor can have an inverted U-shaped response on a dependent measure. For some social behaviors, such as pup grooming, increases and decreases in response to stress are found and it is possible that stress has an inverted U-shaped effect on these behaviors. If an inverted U-shaped response accounts for some of the social behavioral responses to stress, then it is important to understand an animal's baseline level of behavior (where it sits on the curve) and to what extent that individual perceives the stressor.

Different types of stress can also be applied to an animal during development (*in utero*) or during rearing. Again, the type of stressor and the duration of the stressor can vary dramatically. In these cases, often, the effect of stress is not evaluated until the animal reaches adulthood, which adds an even greater possibility for variability

among studies. Given that so many aspects of a ‘common stressor’ can be altered, it is rare that all parameters of a common stressor are identical in different studies. In addition, how the dependent social behavior is measured can vary greatly across studies. The dependent social behavior output across species will always differ to some extent, hence, any cross-species comparisons need to be done cautiously. Attention to the specifics of the stressor (timing, form, and duration), individual differences, sex differences, strain or species differences, and behavioral testing differences, may all contribute to alternate outcomes.

Role of Social Behaviors in Mitigating Response to Stressors

A number of studies across a wide range of taxa have shown that the presence of conspecifics of a species confer a ‘social buffering,’ whereby the individual shows a mitigated stress response when presented with a stressor. In most of these studies, CORT levels are used as the dependent measure to evaluate changes in stress reactivity. For example, for female guinea pigs living with a male and another female, a reduced CORT response is found if that female is exposed to a novel environment and a cage mate is also present. The presence of a novel individual does not confer the same effect. The isolation of social partners acts as a stressor to elevate CORT in marmosets, but exposure to vocalizations by the partner alone was sufficient to significantly decrease the CORT response and this has been termed ‘vocal buffering.’ Young goats showed a suppressed CORT response when they were with their mother and exposed to a human. Moreover, normally shy young goats display a suppressed CORT response to humans if they are accompanied by conspecifics that display a bold behavior. In human males, support from their opposite sex partner prior to a public-speaking stress test resulted in a significant buffering of the CORT response. Interestingly, for females, support from male partners did not have this effect. When given a demanding computer test to induce CORT increases, both men and women showed suppressed CORT responses if they were exposed to a video that relayed supportive commentary. Laboratory rodent species showed decreased basal CORT levels and a decreased CORT reactivity to stressors when they were group housed (relative to isolated); however, as indicated above, crowding can have the opposite effect. For male rats, co-housing for as little as 24 h can reduce aspects of the stress response to footshocks. Furthermore, being tested while with the cohort reduces the stress response.

A dramatic example of social buffering is found in lactating females, whereby the process of being maternal

confers a protection from stressors. For example, in breast-feeding women, a decrease in CORT is found in response to an exercise stress test and a psychological stress test. In lactating rats, contact with offspring during lactation, including nursing, supports both decreased CORT release and suppressed anxiety when exposed to a stressor. Interestingly, no suppression of CORT is found if an intruder male is the stimulus, suggesting the female responds to certain stressors during lactation, but not to others.

Social buffering is reciprocal in mothers and offspring. Heightened licking and grooming of pups by mother rats result in a decreased CORT response in the offspring when tested with a stressor as adults. An increased expression of glucocorticoid receptors in hippocampus, possibly due to demethylation of the receptor gene, has been linked to the suppressed CORT response in offspring.

With evidence of increased stress pathologies in humans, it may be especially important to focus studies on the neural basis of social buffering to identify ways to improve reactivity to stressors.

Glossary

ACTH (adrenocorticotrophic hormone) – Pituitary hormone promoting synthesis and release of glucocorticoids by the adrenal cortex.

Corticotropes – ACTH-producing cells in the anterior pituitary gland.

Corticotropin-releasing hormone (CRH) – Hypothalamic neuropeptide responsible for release of ACTH by the pituitary.

Facilitation – Enhanced hypothalamo-pituitary-adrenocortical (HPA) axis responsiveness to novel stressors in chronically stressed individuals.

Glucocorticoid negative feedback – Glucocorticoid inhibition of hypothalamic neurons and pituitary corticotropes, limiting activation of the hypothalamo-pituitary-adrenocortical (HPA) axis. It can occur in fast (seconds to minutes) and delayed (hours to days) time domains.

Glucocorticoids – Cholesterol-derived steroid hormones responsible for the modulation of gene expression and cellular activity in brain and periphery. It is commonly released following stress.

Habituation – Reduced HPA responsiveness caused by repetitive exposure by a given stimulus.

Hypothalamo-pituitary-adrenocortical (HPA) axis – Neuroendocrine system responsible for the release of glucocorticoids.

Limbic system – Set of interconnected telencephalic and diencephalic structures that collectively regulate memory and emotion.

specific response of the organism to any challenge” has since gone through numerous revisions, due to the emerging discovery of stimulus-specific aspects of physiological responses. In general, current thinking holds that stress is a real or anticipated threat to homeostasis or an anticipated threat to well-being. Real physiological threats (e.g., blood loss) trigger largely reflexive responses that do not require higher-order cognitive processing. In contrast, the ability to anticipate threat requires the organism to interpret the significance of multi-modal sensory stimuli with respect to previous experience or innate response programs.

This article focuses on neuroregulatory processes governing activity of the hypothalamo-pituitary-adrenocortical (HPA) axis following stress. The HPA axis is one of the critical systems involved in the stress response. A summary of the organization of the HPA axis is presented elsewhere in this encyclopedia. Whereas the HPA axis is a key component of the stress response, it is important to note that activation of this system represents but one manifestation of stress. Stress also engages the sympathetic nervous system and adrenal medulla, which trigger cardiovascular and respiratory responses (among others) and the so-called ‘adrenaline surge’. Sympathoadrenal activation comprises the classic fight-or-flight response, enabling rapid reactivity to stressors. The peak HPA-axis response is engaged slightly later in time (on the scale of tens of minutes), and should not be considered part of the fight-or-flight reaction. In fact, some believe the HPA response is critical for recovery from the initial sympathetic response, acting to limit the disruptive effects of the initial stress response.

The ‘Stress’ Concept

The origin of the stress concept, first articulated by Hans Selye, was based on observed similarities between the physiological consequences of a wide variety of noxious stimuli. Selye’s original conclusion that stress is “the non-

Excitation of HPA-Axis Stress Responses

Paraventricular nucleus corticotropin-releasing hormone (CRH) neurons are activated by neural inputs from a number of possible sources (Figure 1). Stressors signaling homeostatic challenge (commonly referred to as systemic

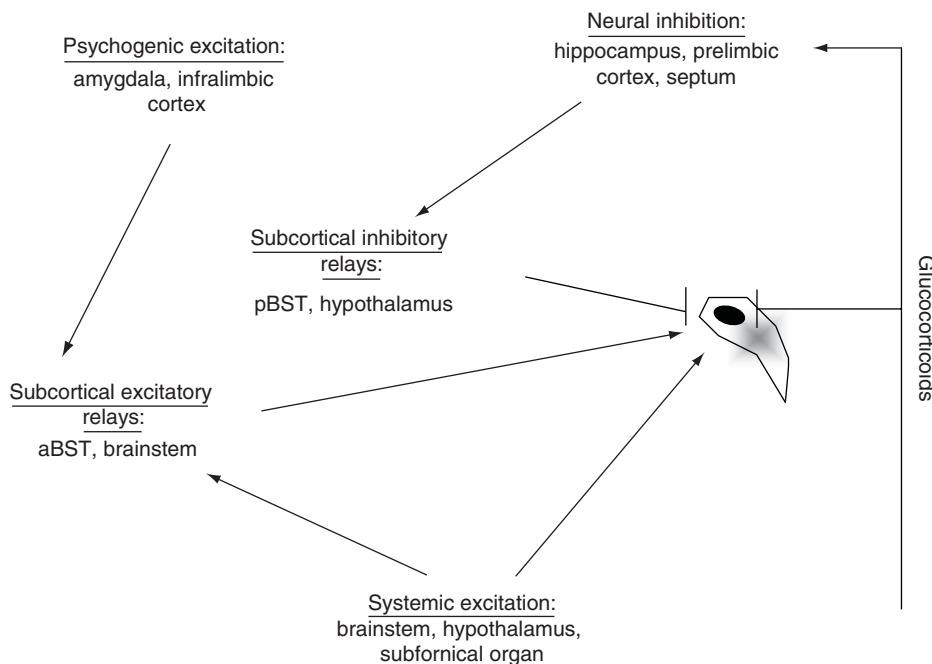

Figure 1 Neural regulation of stress responses: mechanisms. PVN neurons can be activated by multiple pathways. Reflexive activation occurs in response to homeostatic perturbations and are communicated to the PVN by brainstem, hypothalamic or circumventricular organ (subfornical organ) feedforward input. Anticipatory stressors are initiated by limbic interpretation of multimodal sensory input, and involve relays in subcortical sites that in turn project to the PVN, such as the anterior bed nucleus of the stria terminalis (aBST). Some excitatory input may be channeled through brainstem pathways also used for reflexive responses. Inhibition of PVN neurons is mediated by direct, fast feedback actions on PVN CRH neurons as well as input from other brain regions, including the hippocampus, prelimbic cortex, and lateral septum. These upstream structures are in receipt of glucocorticoid information and are involved in delayed negative feedback inhibition of the HPA axis. As was the case for limbic excitatory inputs, neural inhibitory information is channeled through subcortical relays, including the posterior BST (pBST) and several hypothalamic nuclei, including the preoptic area and dorsomedial hypothalamus. Limbic inhibitory regulation occurs largely by transsynaptic inhibition, i.e., excitation of inhibitory PVN-projecting neurons. Excitatory and inhibitory limbic input may overlap in these subcortical sites, providing an opportunity for summation upstream of the PVN. Arrows denote excitation, bars inhibition.

stressors) are mediated by neurocircuits providing direct excitation of paraventricular nucleus (PVN) neurons. For example, HPA-axis activation by blood loss (hemorrhage) is mediated by activation of brainstem norepinephrine neurons that project directly to the PVN. Activation of the HPA axis by fluid imbalance appears to be triggered by angiotensinergic neurons of the subfornical organ, which sense increases in circulating angiotensin II. Negative energy balance signals are relayed to the PVN by the arcuate nucleus, which activates CRH neurons by release of excitatory peptide messengers (such as neuropeptide Y and agouti-related peptide). Responses to systemic stress are thought to be reflexive, that is, they do not require engagement of cognitive processes.

In contrast, anticipatory HPA-axis responses are mediated by multisynaptic limbic forebrain circuits. The amygdala and ventral divisions of the medial prefrontal cortex (e.g., infralimbic cortex) appear to be critical for anticipatory release of glucocorticoids. These brain structures are involved in memory and emotional processing. Thus, the HPA-axis response may be thought of as a systemic mediator of limbic system action. In general,

the amygdala and prefrontal cortex have no direct inputs to the PVN, and require synaptic relays in subcortical structures such as the bed nucleus of the stria terminalis, preoptic area, and lateral hypothalamus. In many cases, subcortical relays also receive homeostatic information, providing a means for the integration of descending limbic input with ongoing physiological state.

Inhibition of the HPA Axis: Glucocorticoid Negative Feedback

Activity of the HPA axis is controlled by negative feedback, a process whereby the end-products of the stress response (glucocorticoids) inhibit their own release. Glucocorticoid feedback involves both genomic and non-genomic mechanisms. Fast feedback inhibition occurs within minutes, and is responsible for rapid termination of PVN activation and adrenocorticotrophic hormone (ACTH) release following stress. Rapid inhibition of the HPA axis is believed to be mediated by membrane receptors in the hypothalamus and/or pituitary, and is almost

certainly nongenomic. Delayed feedback occurs over a more extended time frame, and is thought to be mediated in large part by genomic actions of the nuclear adrenocorticoid receptors (glucocorticoid receptor (GR) and mineralocorticoid receptor (MR)). Both GR and MR act as ligand-activated transcription factors, modifying expression of a large number of genes. The MR has a very high affinity for endogenous glucocorticoids and is thought to regulate circadian secretory rhythms. In contrast, the GR is extensively bound by high levels of glucocorticoids (e.g., during HPA-axis stress responses), and appears to be the main factor in delayed glucocorticoid inhibition of stress responses.

Feedback effects are evident at the level of the brain, pituitary, and adrenal (Figure 1). The brain is the most sensitive mediator of negative feedback. Glucocorticoid receptors are expressed in multiple brain regions, many of which contribute to integration of the feedback signal. In particular, hippocampal and medial prefrontal cortex GRs appear to be required for inhibition of anticipatory HPA-axis responses. As was the case for the amygdala and stress excitation, hippocampal and medial prefrontal cortex neurons do not project directly to the PVN. Inhibition of the HPA axis is mediated by connections between excitatory neurons of the hippocampus and medial prefrontal cortex with inhibitory neurons in the bed nucleus of the stria terminalis, medial preoptic area, dorsomedial hypothalamus, and lateral septum.

Fast feedback inhibition occurs at the level of primary secretory cells. Glucocorticoids rapidly inhibit PVN CRH neurons by way of membrane actions, involving mobilization of endocannabinoids and presynaptic inhibition of glutamate release. Similarly, glucocorticoids inhibit pituitary ACTH release by inducing annexin 1 translocation to the cell membrane of folliculostellate cells, which then bind to corticotropes and inhibit secretion.

Glucocorticoids are not the only source of HPA-axis feedback inhibition. There is ample evidence for glucocorticoid-independent inhibition of PVN neurons by neural mechanisms. For example, peripheral metabolic signals (e.g., sucrose load) can reduce HPA-axis activation in the absence of glucocorticoid signaling.

HPA-Axis Regulation by Chronic Stress

Most organisms undergo periodic exposure to prolonged stress. Prolonged (or chronic) stress can cause long-term modifications at all levels of the HPA axis (see Table 1). In the brain, experimental chronic stress regimens increase biosynthesis of CRH and other ACTH-stimulatory factors (e.g., arginine vasopressin) in the PVN, reflecting increased drive of the central limb of the HPA axis. Chronic stress regimens promote synthesis of pituitary proopiomelanocortin, the precursor molecule for ACTH, and increase

Table 1 Effects of acute and chronic stress on the HPA axis

pituitary ACTH stores. In addition, chronic stress increases adrenal size and causes enhanced sensitivity to ACTH, resulting in increased resting glucocorticoid levels as well as increased cumulative exposure to steroids over time. The latter effects are evident in glucocorticoid-sensitive peripheral systems. For example, the thymus gland undergoes significant atrophy under chronic stress, a pathology that is directly mediated by glucocorticoid secretion.

The net impact of chronic stress on the HPA axis varies along dimensions of predictability, intensity, and duration. Mild, predictable stress regimens (e.g., repeated short restraint in rats) cause significant HPA-axis habituation, reflected in decreased responses to stressors over time and minimal long-term change in HPA-axis endpoints (Figure 2). Habituation is most evident in paradigms that employ repeated exposure to the same stressor. In contrast, prolonged increases in HPA-axis output are most pronounced when stress exposure is unpredictable (e.g., regimens using random exposure to multiple stressors), persistent (e.g., social instability), or severe (e.g., chronic pain). Some extremely severe stress regimens (e.g., prolonged social stress) can even produce HPA-axis hyporesponsiveness, a phenomenon attributed to stress-induced adrenal exhaustion.

In most stress regimens, the capacity of the HPA axis to respond to a novel stress experience is maintained throughout periods of chronic stress. Thus, during chronic stress, the HPA-axis response to a new stimulus matches or exceeds that observed in controls that were not exposed to chronic stress (Figure 2). This phenomenon is referred to as HPA-axis facilitation, and usually occurs in the context of increased glucocorticoid secretion. Thus, chronic stress appears to inhibit glucocorticoid feedback inhibition of HPA-axis responses to previously unexperienced stressors. Chronic stress facilitation ensures that the organism can still mount an adaptive

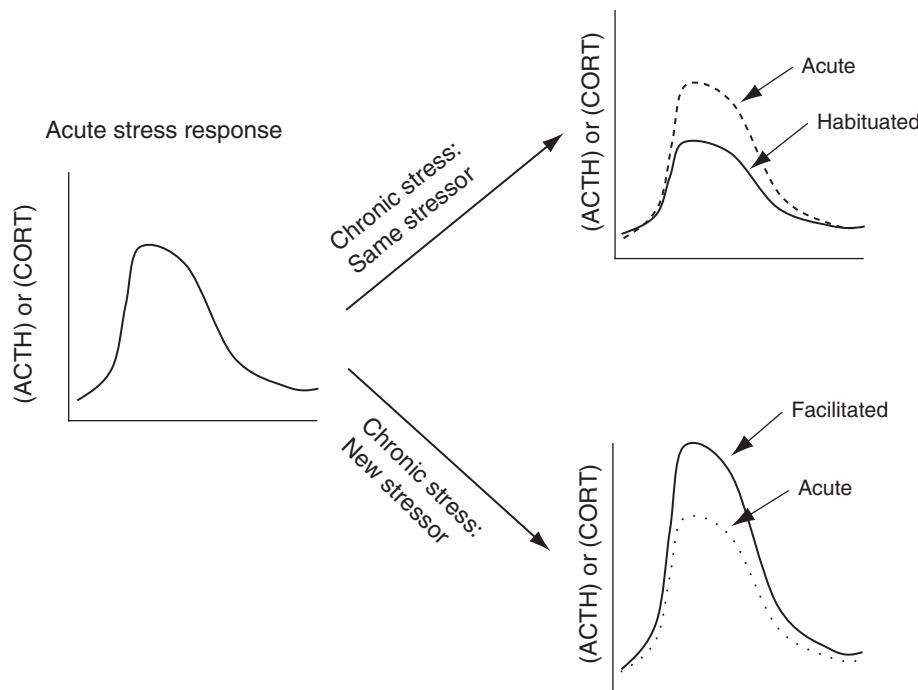

Figure 2 Habituation and facilitation of HPA responses after chronic stress. Typically, repeated exposure to the same stressor produces significant habituation, resulting in a progressive decrease in the HPA-axis response (ACTH or glucocorticoid (GC)) to the repeated stressors. When animals are exposed to chronic stress and given a new stressor, HPA-axis responses are typically augmented, consistent with response facilitation.

response to a novel threat, and is an important aspect of HPA-axis function.

Long-Lasting Effects of Chronic Stress

Chronic stress can affect HPA-axis function long after cessation of stressor exposure. Long-term effects of stress are most notable when exposure occurs in early life. For example, maternal deprivation causes persistent enhancement of HPA-axis (as well as behavioral) stress reactivity into adulthood. The profound impact of early stress is associated with remodeling of stress-regulatory brain circuits, consistent with glucocorticoid effects on neural development. One of the early-life effects of stress on HPA-axis regulation may be mediated by epigenetic modification of DNA. In rodents, good mothering is associated with alterations in DNA methylation in the promoter region of the glucocorticoid receptor, resulting in permanently elevated receptor expression, increased feedback signaling, and decreased HPA-axis stress responsiveness later in life.

In adults, long-term effects of chronic stress are more subtle, but remain physiologically relevant. For example, chronic social stress causes persistent increases in body adiposity, a consequence with implications for long-term health. Moreover, chronic unpredictable stress produces a late-emerging, long-lasting hypofunction of the HPA

axis, wherein responses to stressors are significantly blunted. The latter observation is of relevance to diseases that are accompanied by decreased HPA-axis activity (e.g., posttraumatic stress disorder).

Glucocorticoids negatively affect processes governing dendritic plasticity, neurogenesis, and neuronal cell death. Many of the brain regions subject to negative neuromodulatory effects of glucocorticoids (prefrontal cortex, hippocampus, and amygdala) regulate HPA-axis function. These data have led some to suggest that stress-induced neural impairments lead to further increases in glucocorticoid secretion, producing a feed-forward loss of HPA-axis control. Progressive loss of HPA-axis control is thought to contribute to age-related HPA-axis dysregulation and decreased neuronal viability.

Individual Differences, Stress and Health

Individual differences in HPA regulation are common. Genetic background, social status, and early background/experience contribute to the overall impact of stress on the HPA axis in both acute and chronic time domains. For example, colony housing of rats produces a dominance hierarchy, resulting in a single dominant rat and several subordinate animals. Despite housing under identical conditions, subordinates exhibit elevated HPA-axis function,

whereas dominants do not. Similarly, animals selected for low behavioral reactivity to novelty have decreased HPA-axis reactivity relative to high-responding counterparts. These individual differences likely affect the overall perception of acute or chronic stress severity, which then determines the net output of the HPA axis.

Stress is believed to be a major factor in diseases such as depression and posttraumatic stress disorder, both of which can be accompanied by HPA-axis dysfunction (hyper- and hyposecretion, respectively). However, only a subset of chronically stressed individuals develops these disorders, suggesting that genetic, social, and/or experiential determine individual vulnerability to HPA-axis dysfunction and mood disorders. Additional research efforts need to elucidate factors that are responsible for increased vulnerability in some individuals, and stress resistance and resilience in others.

Glossary

Ghrelin – A 28-amino-acid peptide that is produced predominantly by gastrointestinal endocrine cells and is released during periods of negative energy balance resulting in increased feeding.

Homeostasis – It refers to a state of equilibrium within a system, or the tendency toward such a state among components of an internal system.

Hypothalamic-pituitary-adrenal (HPA) axis – Neuroendocrine system that responds to stress. The interactions among the hypothalamus, pituitary glands, and adrenal glands regulate a variety of physiological processes, including energy storage and expenditure, immunity, and reproduction.

Melanocortins – Posttranslational products that are derived from proopiomelanocortin prohormone, including adrenocorticotropic hormone (ACTH), α -melanocyte-stimulating hormone (α -MSH), and β -endorphin. Melanocortins are involved in the regulation of the stress response, energy balance, inflammation, learning and memory, thermoregulation, and analgesia.

Metabolic syndrome – It generally refers to a collection of metabolic abnormalities, including glucose intolerance (type 2 diabetes, impaired glucose tolerance, or impaired fasting glycemia), insulin resistance, central or abdominal obesity, dyslipidemia, and hypertension.

Neuropeptide Y (NPY) – A 36-amino-acid peptide neurotransmitter found in the brain and autonomic nervous system. NPY is secreted in the hypothalamus and is associated with physiological processes, including regulation of energy balance, learning and memory, and epilepsy. Its main effect is increased food intake and decreased physical activity.

The field of stress research has generated growing interest in response to the escalating number of psychopathologies associated with chronic stress in humans. One of the major physiological effects of stress is on food intake and body weight ultimately resulting in anorexia or obesity. A better understanding of the mechanisms through which chronic stress can lead to these pathologies will enhance the development, effectiveness, and efficiency of rational clinical therapies.

Stress, the HPA Axis and Body Weight

Stress activates the hypothalamic–pituitary–adrenal (HPA) axis and is associated with increased activity of a spectrum of physiological systems. When an organism is challenged, it reacts by initiating a stress response. Briefly, the stress response involves two main physiological systems, the sympathetic branch of the autonomic nervous system and the HPA axis, which mediates the effects of perceived threat or stress in the periphery. The sympathetic response responds rapidly and exerts immediate influence over a wide range of organ systems, including the cardiovascular, respiratory, gastrointestinal, renal, and endocrine systems. Details about the activation of the HPA axis is discussed elsewhere in this encyclopedia.

The secretions of the HPA axis are normally maintained within strict limits to circumvent problems, because chronic activation or dysregulation can be associated with the development of disease states in animals and humans. As an example, the effects of acute and chronic stimulation of the HPA axis on the cardiovascular system have been examined in various animal models of social stress. The main conclusion of those studies is that if the stressful stimulation is either severe and acute or sufficiently long and chronic (even if it is milder stimulation), the same consequences result. That is, intense acute stress can result in cardiac dysfunction leading to coronary artery disease, hypertension, and even death in previously healthy animals. In contrast, if the stimulation is milder but lasts for a longer period of time, similar pathophysiological consequences may ensue even after the stimulus is terminated. The same principle may be applied to other stress-related pathological states, such as obesity.

Humans face social stress to varying degrees on an almost daily basis. Interpersonal relationships are dependent upon the interactions among people and on an individual's position in society. Social stress derived from these interactions can be one of the most important sources of stress in human life and play a critical role in the development of stress-related disorders and disease. Human studies indicate that psychosocial and socioeconomic challenges are related to the development of hypertension, osteoporosis, and depression. In addition, increased cortisol levels have been associated with obesity-related conditions, including visceral obesity, insulin

resistance, dyslipidemia, and cardiovascular disease. A recent study of young healthy men exposed to long-term stress revealed that chronic stress results in increased abdominal obesity and early signs of metabolic syndrome, suggesting that stress plays an important role in the genesis of metabolic abnormalities. In that study, subjects lost both fat and lean body mass during the first stressful episode and subsequently regained body weight as fat resulting in an overall decrease in protein mass.

Although epidemiological studies document associations between stress and changes in feeding behavior, body weight, body composition, and overall energy homeostasis, the specific mechanisms through which these changes are produced remain unknown. Further complicating the matter are the conflicting reports of weight loss or weight gain in response to stress. The response to stress is complex and involves many known, and likely many unknown, players that together modulate feeding, weight regulation, and overall energy homeostasis. The type, duration, and intensity of the stressor as well as individual differences in responding also impact the behavioral and physiological effect of the stressful experience. Animal models provide a valuable means to study the effects of stress in a controlled environment and have produced more data that more strongly implicate a critical role of the HPA axis in the regulation of food intake and body weight. The remainder of this article focuses on information derived from animal models and the current state of our knowledge regarding stress and energy homeostasis.

Animal Models of Stress and Influences on Food Intake

The central and peripheral mechanisms that mediate the effects of stress on body weight and food intake are complex and are currently the topic of active research. Animal models facilitate exploration of the metabolic and feeding changes that occur with stress. It is clear that the stressor type, duration, and intensity all play a role in determining an animal's response to stress. In addition, the developmental window during which stress occurs influences the short- and long-term consequences. We first discuss stress occurring during critical developmental periods followed by a summary of adulthood stress and its effects on energy homeostasis.

Early Life Stress

Events during fetal life or during the early postnatal period and adolescence have significant effects on developing offspring. The development of the HPA axis is influenced by both prenatal and postnatal factors and can essentially program offspring for altered feeding

behavior and obesity as adults. Glucocorticoids are associated with the regulation of body weight, food intake, and blood glucose levels, and exposure to glucocorticoids during early development alters function of the HPA axis that can lead to later vulnerability to obesity or other eating disorders. Other neural circuits that regulate energy homeostasis are also sensitive during early development and can have adverse consequences for the offspring.

Prenatal stress

Maternal stress during pregnancy has significant effects on offspring and those effects depend on the type of stress used and timing of stress during gestation. Repeated restraint stress has been widely used in rodent models of prenatal stress, but the stress is usually applied in a predictable manner. Thus, the animal comes to predict the stressor and stress responses diminish over repeated trials. A model of chronic variable stress (CVS) involves several different stressors applied in a random order and at random times over several days. This is more akin to the unpredictable nature of stressors normally encountered by an organism, including humans and is the focus of the discussion in this section.

The influence of prenatal stress on offspring could depend on species as well as on the timing of the stress. For example, CVS in rats predisposes to hyperphagia, greater weight gain, and increased adiposity in adulthood, particularly when provided with high fat diet. Impaired glucose tolerance and abnormalities in structure and function of the cardiovascular system also result. These outcomes are usually observed when the stress occurs during the last week of gestation. However, in mice, prenatal stress administered during the first or third weeks of pregnancy appears to be critical time windows in rodents in affecting body weight, food intake and glucose tolerance in offspring. These studies indicate that there are differences in the timing of stress and the metabolic parameters that they affect. This is not surprising as each period during gestation involves development and maturation of different organ systems or neural pathways which may be more vulnerable during different time windows. Thus, the specific mechanisms that are responsible for the effects on body weight and food intake during different periods during gestation are unclear but may involve very different pathways.

The important aspect of studies of prenatal stress is how those specific maternal responses translate to the fetus and program metabolic outcomes. The mediators involved in metabolic programming or predisposition to altered energy homeostasis include among others glucocorticoids, insulin and leptin. These hormones can cross the fetal-placental barrier from maternal circulation to the fetus. Stress and excess maternal glucocorticoids may have an effect prenatally by programming increased

susceptibility to stress or altered energy homeostasis in adulthood. Placental 11β -hydroxysteroid dehydrogenase (11β -HSD) serves to buffer the developing fetus from excess glucocorticoids, others have found that while this is true in response to acute stress, the upregulation of 11β -HSD is insufficient during chronic stress. Future studies are required to explore the role of 11β -HSD in the phenotypes observed. Similarly, both leptin and insulin are trophic factors that act during the pre- and postnatal periods and can significantly disrupt normal development of neural systems important in the maintenance of energy homeostasis.

Early postnatal and adolescent stress

Maternal separation (MS) is a postnatal stress paradigm that disrupts the mother–pup interaction has long been used since Seymour Levine established it in the 1950s. Brief separation from mother is viewed as a psychological stressor, whereas longer separations are considered to add a physiological aspect due to the lengthy disruptions of maternal regulatory influence on the pup, such as body temperature maintenance, physical contact, and excretion processes. MS has differential effects dependent upon the duration of separation and the age at which stress is applied.

Longer periods of MS from 2 to 24 h during the first week of life attenuates body weight gain during development and decreases food intake. These parameters may be influenced by the alterations in mother–pup behavioral interactions and the reduction in maternal milk secretion due to decreased suckling stimulation from the pups. It is important to point out that MS can also produce physiological endocrine changes in the rodent pup that could impact development of the neural circuits that regulate body weight and food intake independently of the psychological aspects of MS stress itself. As an example, plasma leptin and glucose are reduced during MS while ghrelin increases. The postnatal leptin surge that occurs between postnatal weeks 1 and 2 has an important role in programming the development of hypothalamic feeding circuits such as the neuropeptide-Y (NPY) system and thus interruption of that surge by MS could program greater food intake and obesity in offspring.

In contrast, shorter periods of MS from 5 to 15 min during the first 2–3 weeks of life reduce HPA axis responsiveness to stressors in adulthood. Literature suggests that the long-term effect of short periods of MS attenuates the adult HPA axis response to stress by increasing maternal care to the pup when they are returned to the nest. Greater maternal care behavior is associated with decreased ACTH and corticosterone response to acute stress, increased hippocampal glucocorticoid expression, enhanced glucocorticoid feedback sensitivity, and decreased CRH expression. Since CRH is a well-known hormone that decreases food intake, lower amounts of

CRH in short-term MS pups would not suppress food intake to the same degree as a control rat, thus resulting in greater food intake and body weight gain.

Currently, it is not known whether exposure to early life stress in and of itself causes increased food intake and body weight gain. Stress during early development has also been associated with development of behaviors reminiscent of those observed in depressed, anxious or schizophrenic patients. These neuropsychiatric conditions themselves impart a high risk for obesity and metabolic disease in humans.

Social Stress in Adulthood

Social stress induces a greater hormonal and cardiovascular response compared to other models of stress, such as foot shock or restraint, and thus has greater face validity in modeling stressors experienced by humans. Chronic social subordination stress in rats and mice typically involve social hierarchies (e.g., visible burrow system or VBS) or social interactions between conspecifics resulting in dominant–subordinate relationships (resident-intruder or social defeat stress). Social subordinates typically exhibit submissive behaviors, show less reproductive behavior and endocrine function, and generally have higher plasma corticosterone levels, all parameters indicating that they experience a greater degree of stress in these paradigms.

Intermittent acute social stress increases plasma corticosterone and ACTH and raises resting body temperature. Body weight gain and food intake in the socially subordinate animals is attenuated. In contrast, with repeated episodes of social stress in a resident-intruder paradigm, food intake increases specifically during the light cycle. However, this increase in food intake *per se* is not sufficient to affect body weight.

It appears that social stress affects feeding behavior and body weight dependent on a multitude of factors, including the chronicity of stress as discussed above and post-stress housing environment. For example, stress has different effects on animals that maintain contact with conspecifics, whether it is constant group housing or maintaining sensory, but not physical, contact with dominant animals. Group housed rats form dominance hierarchies and can remain co-housed for up to 2 weeks. Socially subordinate rats in this situation lose significant amount of body weight. The changes in body mass are associated at least in part to decreased food intake. Analysis of meal patterns suggests that meals taken by subordinate rats are smaller and spread throughout the dark and into the light cycle. Thus, in addition to a significant impact on the amount of food consumed, chronic stress also disrupts regular meal patterns and feeding behavior that in turn contributes to altered energy homeostasis in socially stressed subordinate rats. In contrast, dominant rats maintain their body weight, but alter

their body composition by losing adipose tissue and increasing lean tissue. These observations suggest that social dominance, which is also associated with some degree of stress as determined by elevated glucocorticoid levels albeit significantly less than that of the subordinate, also has an impact on energy homeostasis.

Allowing social subordinates to recover from stress demonstrates that effects of stress on food intake suppression are persistent in some models while others report a rapid escalation in food intake to compensate for lost body weight. Hyperphagia during the poststress period concurrent with an endocrine environment of high glucocorticoids and low androgen levels favors deposition of fat rather than lean tissue. Furthermore, this condition results in subordinates having a higher proportion of adipose tissue concentrated in the visceral fat depot compared to controls and dominants after recovery. Visceral adiposity is a risk factor for the development of symptoms of metabolic syndrome such as cardiovascular disease and diabetes. Consistent with increased body fat, social subordinates become hyperinsulinemic and hyperleptinemic compared to dominants and controls after recovery. Together these data suggest that cumulative effects of chronic social stress may result in the development of symptoms related to the metabolic syndrome.

Stress effects on diet choices

Palatable food (i.e., foods that are calorically dense and have high amounts of carbohydrates or fat or both) consumption is increased following stress. Although intake of standard chow decreases such that total food intake remains the same, the proportion of calories derived from fat is increased and can lead to the development of visceral obesity. Indeed, increased sensitivity to stress in humans has been associated to obesity and binge-eating disorder. Evidence that stress-related factors participate in diet choices following stress come from, for example, CRH-R2-deficient mice which are more vulnerable to stress and have a higher preference for high-fat diet when exposed to chronic variable stress.

Subordinate rats exhibit anhedonic behavior that persists after social stress and do not increase their consumption of a carbohydrate solution even when in negative energy balance, although this behavior may be specific to the solution's macronutrient composition. However, subordinate behavior may change if they are presented with diets composed of different macronutrients to consume, such as high fat diet, or if they are provided with a choice of macronutrients. It has been suggested that individuals consume more palatable food during stress in an attempt to reduce the negative effects of a chronic stressor. It has been suggested that having a choice of which macronutrient to consume can play a significant role in macronutrient influences on the

negative effects of stress. These are intriguing considerations that warrant future study.

Potential Mediators

The connection between stress and energy mobilization for appropriate responses is well established. However, with sustained activation of the stress axis the very responses that are meant to be adaptive, such as increased energy consumption, can become maladaptive to produce pathophysiological consequences. Obesity is one consequence that results from greater energy consumption, decreased activity and leads to more severe disease conditions such as cardiovascular disease and diabetes. The regulation of stress and energy homeostasis share some of the same neuroendocrine pathways, thus suggesting important interactions among these two systems and may lead to better management of stress to avoid negative consequences.

CRH-containing neurons are located in the paraventricular nucleus of the hypothalamus, one of the major centers that control food intake and energy balance. Central (intracerebroventricular, ICV) administration of CRH decreases food intake in rats and has also been implicated in the anorectic effects of leptin. Thus, increased CRH during stress not only activates the HPA axis to initiate the stress response, it also functions to suppress food intake. CRH receptor-1 (CRHR1) and receptor-2 (CRHR2) are involved in the stress-induced inhibition of food intake in rodents. CRHR2 knockout mice exhibit greater nocturnal food intake and this is manifest through increases in meal size rather than meal frequency suggesting a deficit in satiating value of food in these mice. Thus, the CRH system is likely intimately involved in the stress-induced changes in food intake and meal patterns. Glucocorticoids, in contrast, generally exert an opposite effect on food intake. During the stress response it may be the case that CRH initially functions to inhibit food intake. However, glucocorticoid secretion may then be involved in stimulating food intake once its inhibitory effects suppress CRH release.

The central melanocortin system is well studied in its function in regulation of food intake and body weight. Evidence also suggests that the melanocortin system interacts with the stress system as well. This system is activated by acute restraint and forced swim stress, both considered to be emotional stressors of a processive nature. Alpha-melanocyte stimulating hormone (α -MSH), a cleavage product of proopiomelanocortin (POMC), is expressed in the arcuate nucleus (ARC) of the hypothalamus and inhibits food intake. Emotional stress activates POMC neurons in the ARC and coincides with expression of anxiety-like behavior arising from acute restraint or forced swim stress. ICV administration of SHU9119, a

Table 1 Summary of potential players that mediate the effects of stress on feeding behavior and energy homeostasis

	Influence of stress	Effect on food intake
Corticotropin-releasing hormone (CRH)	Increase	Decrease
Ghrelin	Increase	Increase
Glucocorticoids (corticosterone, cortisol)	Increase	Increase
Leptin	Decrease	Decrease
Neuropeptide Y (NPY) – peripheral	Increase	Increase
Orexin	Increase	Increase
Proopiomelanocortin (POMC)	Increase	Decrease

melanocortin receptor-3 and -4 antagonist, can block the activation as well as stress-induced anxiety-like behavior. Agouti-related peptide (AgRP) is also expressed in the ARC, but was not affected by stress. Thus, POMC activation may be a mechanism through which acute stress-induced anorexia could occur. This was an acute stress study and patterns of activation and behavioral responses to chronic stress remain to be explored.

Some of the systems that are well known to maintain energy homeostasis have been discussed above and are likely to be affected by social stress. However, other central and peripheral neural systems are likely involved and may have an even greater impact on observed changes in appetite, food preference, and body composition following psychosocial stress. The association between mood disorders and obesity is high and new research suggests that some of the same systems that are known to regulate food intake are also affected by psychosocial stress (**Table 1**).

Ghrelin is a hormone produced predominantly by gastrointestinal endocrine cells and is released during periods of negative energy balance resulting in increased feeding. Chronic social stress (resident-intruder stress) increases levels of acylated ghrelin (active form) which correlates with greater food intake and body weight in mice. Ghrelin receptor knock-out mice did not show the hyperphagic response when subjected to social stress, thus implicating ghrelin as one mediator of stress effects on feeding. Ghrelin receptor-deficient mice also exhibited greater depressive-like behaviors. The actions of ghrelin appear to be mediated, at least in part, by activation of orexin neurons in the lateral hypothalamus. Other areas that may potentially be involved include the ventral tegmental area and hippocampus, two areas that have been implicated in mood regulation. These data suggest that ghrelin has a secondary, possibly adaptive role, during stress that may help the animal cope with stress via anxiolytic- and antidepressant-like behavioral adaptations. However, this benefit comes with the caveat of increased food intake and body weight and, perhaps over the long-term, having adverse metabolic consequences.

The peripheral sympathetic NPY system has been implicated in the development of metabolic syndrome

following stress. Stressors of differing intensity and duration have varying effects on body weight and adipogenesis. For example, while physical restraint increased plasma norepinephrine levels and decreased appetite and body weight, cold swim stress is apparently mild enough that mice adapt to the cold water within a few days and exhibit no change in weight. However, intense cold and resident-intruder stressors produce a sustained level of stress to which the mice do not habituate. It is at this more intense level of stress that NPY levels increase. The dietary environment was also a determining factor in the metabolic response to stress. That is, stressed mice gained weight, primarily in the mesenteric fat depot, but only when fed a high fat, high sucrose diet. Furthermore, mice subjected to stress and fed high fat diet gained about 50% more than those mice that were only fed a high fat diet suggesting a stress-related potentiation of diet-induced obesity in this animal model.

Conclusion

Stress strongly influences feeding behavior resulting in long-term effects on body weight, body composition, and food selection. Nonhomeostatic effects of pathways initially implicated only in energy homeostasis have received more attention in mediating the effects of stress on depressive or anxiety-like behavior and food preferences. The range of effects of these pathways have opened up intriguing lines of research that may point to more effective clinical solutions to stress-associated obesity and anorexia.
