Glossary

Acute dependence – A state of dependence on a substance revealed through signs of spontaneous or precipitated withdrawal after acute exposure to a drug or alcohol.

Chronic dependence – A state of dependence on a substance revealed through signs of spontaneous or precipitated withdrawal following long-term exposure to a drug or alcohol.

Conditioned withdrawal – Signs of withdrawal that are elicited or exacerbated by cues that have been paired with withdrawal through a process of associative conditioning.

Precipitated withdrawal – Signs of withdrawal elicited abruptly by administration of a competitive antagonist in a drug-dependent organism.

Spontaneous withdrawal – Time-dependent emergence of withdrawal symptoms upon cessation of drug or alcohol intake in a dependent organism.

Prolonged use of many substances of abuse including alcohol, opioids, stimulants such as cocaine, amphetamines, nicotine, and cannabinoids can lead to a state of dependence that results from the adaptation of organ systems, in particular the central nervous system (CNS; so-called neuroadaptation), to the continued presence of the substance in the system. Dependence on a substance is measured by the emergence of drug-specific clusters of withdrawal symptoms upon cessation of use; these withdrawal symptoms reveal the underlying adaptive responses that have formed, and are typically opposite in nature to the direct effects of the substances themselves.

Animal models utilizing passive exposure to drugs of abuse, and less frequently active exposure by allowing animals to self-administer to the point of dependence, have yielded significant insights into the neurobiological mechanisms mediating dependence on and withdrawal from chronic drug administration – in effect examining substrates mediating the maintenance of an established state of dependence. However, it has been known since the pioneering work of Wikler and Carter, in the 1950s, and Martin and Eades, in the 1960s, that organisms can show withdrawal signs after a single treatment with opioid agonists such as morphine, and that the symptoms of

withdrawal from single treatment qualitatively resemble the symptoms of withdrawal from chronic opioid exposure. This state of acute dependence, defined as “a state in which abstinence [withdrawal] can be demonstrated or precipitated following either a single dose or a short-term infusion of morphine” (see Martin and Eades, 1964, under Further Reading), may provide a means to understanding the neural basis of initial neuroadaptive responses to opioids and other abused substances.

Historical Evolution of the Concept of Acute Dependence

The early work of Wikler and Carter, in 1953, and Martin and Eades, in 1961 and 1964, measured acute dependence on morphine in dogs with a chronic transection of the spinal cord to produce hindlimb paralysis. In this model, spinally mediated reflex activity recovers after a period of time, and is suppressed by morphine treatment, but when acute, high, bolus doses or short-term intravenous infusion of morphine were followed by an opioid antagonist, the antagonist produced hindlimb reflex hyperactivity that is qualitatively similar to what is seen in antagonist-precipitated withdrawal from chronic morphine. Martin and Eades noted, however, that while the spinal reflex hyperactivity was qualitatively similar between dogs treated acutely versus chronically with morphine, both the duration and intensity of reaction to a fixed high dose of the antagonist nalorphine were much greater after chronic morphine administration.

Further work on the topic of acute opioid dependence in the early 1970s employed primarily antagonist-induced jumping behavior in mice to demonstrate that opioid antagonists such as naloxone could elicit increased escape jump attempts when administered 15 min to several hours after high doses of morphine or several other opioid agonists. These studies made significant advances in characterizing the acute dependence phenomenon by:

1. extending the range of agonists studied for their ability to support acute dependence;
2. establishing the time-course between agonist pretreatment and antagonist precipitation that supported maximal withdrawal behavior; and
3. demonstrating through dose-response analysis of naloxone potency that higher doses of naloxone were required to elicit withdrawal jumping after acute

single-dose agonist pretreatment than were required after more chronic agonist exposure. This latter observation was consistent with the earlier demonstrations of Way and colleagues that naloxone's potency to elicit opioid withdrawal signs following different chronic regimens of opioid exposure is inversely related to the severity of dependence.

Reports on withdrawal jumping and spinal reflex hyperactivity following acute morphine treatment were dismissed by some as an epiphenomenon. It was suggested that these findings were most parsimoniously explained as largely species-specific artifactual motoric responses to high doses of agonist and antagonist, but were not indicative of a rapid induction of opioid dependence. Indeed, the doses of morphine employed in these studies were often five- to 10-fold (or more) higher than typical analgesic doses in the studied species.

Despite these early criticisms, interest in acute dependence as a potentially valid and valuable model of the initial adaptive response to drugs of abuse has grown in the past 30 years as subsequent work revealed that acute dependence:

1. could be observed in the human with clinically relevant doses of morphine;
2. could be observed in a variety of species beyond dogs and mice, including rats, gerbils, hamsters, guinea pigs, and monkeys;
3. could be produced by lower doses of opioid agonist that fell within the typical analgesic dose range for a given species;
4. was associated with a much broader subset of the full constellation of opioid withdrawal signs than was initially appreciated; and
5. could be demonstrated with other drugs, including sedatives such as alcohol, benzodiazepines, and barbiturates.

Moreover, as the important distinction between aversive emotional components of opioid withdrawal (e.g., anxiety, depression/dysphoria) and somatic/physiological components (e.g., weight loss, diarrhea, autonomic hyperactivity) became better appreciated, it was discovered that brain systems mediating the negative emotional consequences of withdrawal may be much more sensitive than circuits mediating somatic withdrawal signs to rapid neuroadaptation after initial drug exposure. Finally, demonstrations that repeated intermittent treatment with drugs such as opioids or alcohol at daily, weekly, or even longer intervals led to a progressive increase in the severity of withdrawal signs, and the recruitment of additional signs not observed after single treatments, provided empirical evidence in favor of the notion that acute dependence may indeed represent the initial point on a continuum towards the development of chronic

dependence. **Table 1** provides a summary of key findings, to date, emerging from studies of acute dependence on opioids, alcohol, benzodiazepines, and barbiturates, the details of which are described more fully in the sections that follow.

Acute Opioid Dependence

To date, the majority of studies on acute dependence have employed opioid agonists such as morphine to induce the acute adaptive response. Indeed, opioid dependence – whether acute or chronic – is by far the most thoroughly characterized form of adaptation to substances of abuse. Studies of acute opioid dependence in animals and the human demonstrated that a broad range of opioid agonists, including levorphanol, heroin, methadone (and the structurally related compound levo-alpha-acetylmethadol [LAAM]), fentanyl, hydromorphone, and etorphine, in addition to morphine, produce similar rapid adaptive responses. Partial agonists such as buprenorphine have not been extensively evaluated, but available data suggest that they are considerably less efficacious than full agonists in producing an acute dependence response. While most opioid agonists that induce acute dependence are potent μ -opioid receptor agonists, most also have activity at other opioid receptors. Stimulation of only μ -opioid receptors with highly selective peptide agonists can induce acute dependence with similar intensity to that produced by morphine. Consistent with studies of chronic opioid dependence, while there is evidence that selective acute activation of κ - or δ -opioid receptors also produces a measurable degree of acute opioid dependence as measured by antagonist-precipitated withdrawal, the intensity of withdrawal is significantly reduced relative to that seen with μ -receptor activation. Because morphine is the agonist of choice in the overwhelming majority of acute opioid dependence work to date, further discussion focuses primarily on this classic opioid agonist.

Spontaneous versus Precipitated Withdrawal

The availability of competitive antagonists such as naloxone and naltrexone that can rapidly elicit withdrawal from opioid agonists offers distinct advantages for empirical study of opioid dependence. First, precipitated withdrawal provides a defined time window in which withdrawal signs can be observed, as compared to spontaneous withdrawal signs which may be observed infrequently and at unpredictable times in the hours or days following cessation of opioid agonist treatment. Second, leftward shifts in opioid antagonist dose–effect functions (i.e., increased potency of the antagonist to precipitate withdrawal) occur in proportion to the dose

Table 1 Summary of primary features of acute dependence on opioids, alcohol, benzodiazepines, and barbiturates

	Opioids	Alcohol	Benzodiazepines and barbiturates	
Agonists confirmed to produce acute dependence (most common in bold at top)	Morphine* Heroin Methadone LAAM Fentanyl Hydromorphone Levorphanol Etorphine	Ethanol	Benzodiazepines Chlordiazepoxide Diazepam Zolpidem Abecarnil Alprazolam Clonazepam Lorazepam Midazolam Triazolam	Barbiturates Pentobarbital
Partial agonists less efficacious in eliciting acute dependence?	Yes (e.g., buprenorphine)	N/A	Yes (e.g., bretazenil)	
Observed in human subjects?	Yes	Yes	Not systematically studied to date	
Animal species studied (most common in bold at top)	Mice Rats Dogs Primates Gerbils Hamsters Guinea pigs	Mice Rats	Mice Rats Primates	
Spontaneous withdrawal?	Yes, not commonly studied	Yes	Yes	
Precipitated withdrawal?	Yes	No	Yes	
Antagonists used (most common in bold at top)	Naloxone Naltrexone N-Allyl-normorphine 6-Alpha/beta-naloxol 6-Alpha/beta-naltrexol Methylnaloxonium*	N/A	Flumazenil Ro 15-1788 CGS-8216	
Somatic/autonomic withdrawal signs in animals common to acute and chronic dependence	Escape jumping Paw shakes/wet dog shakes Teeth chattering Swallowing/chewing Eye blinks/ptosis Urination Tachycardia Tachypnea	Reduced seizure thresholds Tremors	Reduced seizure thresholds Muscle hypertonus Abnormal gait Abnormal/arched posture	

Behavioral/emotional signs common to acute and chronic dependence	Suppression of operant responding Conditioned place aversion Anxiety-like behavior Elevated reward thresholds Elevated startle response	Anxiety-like behavior Elevated reward thresholds	Suppression of operant responding (others not systematically examined to date)
Potentiation of withdrawal Severity with repeated agonist:			
Daily intervals	Yes	Yes	Not systematically studied to date
Weekly intervals	Yes	Yes	Not systematically studied to date
Common neural or cellular Substrates of acute and chronic Dependence identified?			
	Yes	Yes	Yes

and duration of agonist treatment. As a consequence, pharmacologists can employ quantitative antagonist dose-response analysis to estimate the magnitude of the underlying state of opioid dependence. Importantly, although opioid-dependent individuals typically experience spontaneous but not precipitated withdrawal, the range of withdrawal symptoms observed in the human or animals during spontaneous versus precipitated opioid withdrawal are quite similar, lending validity to the precipitated approach as an optimal empirical tool for quantitation of opioid dependence. While there is evidence of spontaneous withdrawal in some acute opioid-dependence studies, not surprisingly, these signs are subtle and difficult to detect after just a single treatment, and as a consequence the vast majority of studies employ the antagonist-precipitated approach.

Convergent Symptomatology of Acute and Chronic Dependence

Human

Clinical reports in the early 1970s of a naloxone-precipitated abstinence syndrome upon rescue from opioid anesthesia in otherwise opioid-naïve individuals suggested that acute opioid dependence was a clinically relevant phenomenon. These case reports were followed by systematic empirical investigations of the acute opioid-dependence phenomenon in human subjects. An early study of acute opioid dependence in subjects who had no prior history of recreational opioid use or abuse reported that the competitive antagonist naloxone given 24 h after an intramuscular administration of morphine (10–15 mg per 70 kg body weight) elicited opioid withdrawal-like symptoms such as yawning, nausea, irritability, feeling cold, and feeling sick (see Jones, 1980 in Further Reading). Subsequently Stitzer, Bigelow, and colleagues engaged in a series of parametric analyses of the conditions that support the development of acute opioid dependence. The majority of subjects employed in these studies were individuals with a history of prior opioid abuse and dependence, although the subjects were not currently physically dependent, nor seeking treatment for opioid addiction at the time of study. However, Stitzer and colleagues have also reported a similar spectrum of withdrawal signs following acute opioid exposure in individuals with no prior history of abuse or dependence (Azorlosa et al., 1994 in Further Reading), indicating that a prior history of chronic dependence is not a prerequisite to observe withdrawal following an acute morphine treatment.

In the majority of studies to date, the treatment regimen involved single intramuscular pretreatment with morphine (4–30 mg per 70 kg) followed 2–24 h later by intramuscular naloxone (3–30 mg per 70 kg). Although higher doses of morphine (18–30 mg per 70 kg) supported

a more robust, longer-lasting sensitivity to naloxone-precipitated withdrawal, doses of morphine as low as 8–10 mg per 70 kg – at the upper end of the typical clinical analgesic dose range for the intramuscular route of administration – elicited a significant state of acute dependence.

The most common signs of withdrawal elicited in these studies included:

1. a core set of physiological signs such as decrease in skin temperature and increase in heart rate;
2. observer-rated symptoms including yawning and restlessness;
3. subject-reported symptoms of hot/cold feelings, upset stomach, and irritability;
4. subjective ratings of ‘bad drug effect,’ ‘withdrawal sickness,’ and, in some studies, ‘dysphoria;’ and
5. in some recent studies, hyperalgesia (increased sensitivity to noxious, mildly painful stimuli) when morphine and naloxone were administered by the intravenous, instead of the intramuscular, route.

Other diagnostic criteria of opioid withdrawal such as muscle aches, lacrimation, rhinorrhea, diarrhea, and fever were less commonly or rarely observed after single doses of morphine. Thus, the withdrawal syndrome characteristically seen following acute pretreatment with morphine (8–30 mg per 70 kg) represents a subset of symptoms reported in chronically dependent addicts, and the intensity of symptoms following acute treatment is typically rated as less intense both by observers and the subjects themselves.

Nonetheless, a reliable cluster of physiological, somatic, and subjective withdrawal symptoms appears common to antagonist-precipitated withdrawal from acute or chronic opioid dependence. Since a prior history of opioid dependence is not necessary to elicit withdrawal following single opioid treatment, the convergence of symptoms of withdrawal from acute or chronic opioid dependence suggests that acute dependence may provide a reliable model of the initial stage in the development of chronic dependence.

Animal models

Although, as noted above, many early studies of acute opioid dependence in animals employed high doses of opioid agonist and antagonist to precipitate withdrawal jumping behavior in mice, one early report by Jacob and Michaud in dogs indicated that physiological signs of withdrawal such as hypersalivation, hyperthermia, increased heart rate and respiratory rate, and pupillary dilation could be precipitated by naloxone given 1–5 h after an intravenous injection of a very low dose of morphine (0.1 mg kg^{-1}).

More systematic examination of a broad spectrum of opioid withdrawal signs in a variety of species including mice, rats, hamsters, gerbils, and primates revealed that

certain profound symptoms such as escape jumps, diarrhea, body-weight loss, lacrimation, and rhinorrhea are observed only after high acute doses of morphine ($30\text{--}100\text{ mg kg}^{-1}$, intraperitoneal or subcutaneous); when such signs were observed after lower doses of the agonist ($5\text{--}20\text{ mg kg}^{-1}$), it was typically only after several repeated opioid treatments at daily intervals. In addition, typically these severe signs were precipitated only by higher doses of opioid antagonists such as naloxone or naltrexone.

However, other physiological and somatic signs such as elevations in plasma corticosterone, paw shakes, wet-dog shakes, teeth chattering, swallowing/chewing, eyeblinks, and nociceptive hyperalgesia were reliably observed after $5\text{--}10\text{ mg kg}^{-1}$ doses of morphine – an analgesic dose range in rodents – and could be precipitated by much lower doses of the antagonists. It is noteworthy that these signs are also precipitated by much lower doses of antagonist in rats chronically dependent on opioids than are more profound signs such as withdrawal jumping, diarrhea, and body-weight loss.

Perhaps the greatest utility of the animal models to date has been the identification of reliable markers of the aversive and negative emotional consequences of withdrawal from acute opioid dependence. Antagonist-precipitated withdrawal from either acute or chronic pretreatment with an opioid agonist such as morphine results in suppression of operant responding for food reward and conditioned place aversion. These two indices of opioid withdrawal have been used most extensively to date in characterizing withdrawal from acute opioid dependence. Dysphoria-like signs as measured by elevations in intracranial self-stimulation reward thresholds and anxiety-like signs, as measured by decreased exploration of the open arms of an elevated plus maze, also have been demonstrated during precipitated withdrawal from a single pretreatment with morphine as well as from chronic morphine exposure. While elevations in startle-reflex magnitude are reliably elicited by opioid antagonists several hours following acute pretreatment with morphine, studies of startle magnitude during withdrawal from chronic dependence have yielded mixed results, with different studies reporting elevated, decreased, or no change in startle-response amplitude.

Notably, escalation in withdrawal severity as measured by behavioral indices such as suppression of operant responding for food reward may be observed when morphine is administered repeatedly at intervals of 7 or even 21 days, whereas somatic signs such as those described above increased only when morphine was administered at daily, but not longer, intervals between successive treatments (Schulteis *et al.*, 1999 in Further Reading). Moreover, lower doses of opioid antagonist are required to precipitate the behavioral signs (e.g., $0.1\text{--}0.3\text{ mg kg}^{-1}$ naloxone) than are required to elicit most somatic signs of withdrawal (e.g., $1\text{--}3\text{ mg kg}^{-1}$ naloxone) from acute opioid dependence. These data suggest that aversive and negative

emotional signs of opioid withdrawal may be particularly sensitive to rapid escalation in severity early in the development of opioid dependence.

Factors Influencing Onset and Early Progression of Opioid Dependence

As is the case for withdrawal precipitated from chronic opioid dependence, severity of withdrawal from acute opioid dependence is critically dependent on the amount of agonist administered and the dose of antagonist used to precipitate the withdrawal response. Thus, in both human and animal studies, greater numbers of withdrawal signs are noted, and individual signs increase in intensity, as the pretreatment dose of morphine is increased. Similarly, higher doses of antagonist will precipitate greater intensity of individual signs of withdrawal, and recruit a broader spectrum of signs, following either acute or chronic opioid exposure. It has been known for some time that the potency of antagonists such as naloxone and naltrexone to precipitate opioid withdrawal increases in proportion to the duration of chronic agonist treatment. In the acute-dependence model, the same phenomenon is observed, with the potency of naloxone increasing progressively with repeated administration of single doses of morphine at daily, 7-day, or in some cases even 21-day intervals between successive morphine doses.

Stimulation of opioid receptors by the agonist is critical for the development of both acute and chronic opioid dependence, since coadministration of an antagonist concurrent with the acute or chronic agonist exposure will inhibit the subsequent ability of the antagonist to precipitate withdrawal. Thus, an interval separating the onset of agonist exposure and the administration of antagonist is a vital feature of models of acute opioid dependence. Both in human and animal studies, intervals of 2–12 h between morphine and naloxone/naltrexone administration typically produce maximal intensity of withdrawal for most signs. While certain signs may remain sensitive to precipitation at 18 and 24 h post morphine administration, the antagonists usually lose their effectiveness to precipitate any withdrawal signs by 36–48 h post morphine administration.

Conditioning Processes in Acute Opioid Dependence

While increases in naloxone potency to precipitate withdrawal with repeated intermittent (daily or weekly) pretreatments with morphine do not require that the antagonist be administered after each morphine dose, a number of studies have demonstrated that repeated experience with the antagonist following each morphine pretreatment can further potentiate the severity of withdrawal. Associative conditioning mechanisms support the development of conditioned withdrawal in response to

interoceptive drug cues or explicit external environmental cues that are paired, on several occasions, with precipitated withdrawal from acute intermittent pretreatments with morphine. For example, if naloxone-precipitation of withdrawal from four acute treatments with 5.6 mg kg⁻¹ of morphine at weekly intervals is associated with a discrete tone/light stimulus, subsequent presentation of the tone/light stimulus alone will elicit a significant suppression of operant responding for food reward similar to that produced by naloxone itself (Amitai *et al.*, 2006 in Further Reading). In addition, studies of conditioned place aversion demonstrate clearly that rats and mice can remember and subsequently avoid a distinct context in which they previously experienced antagonist-precipitated withdrawal from acute morphine pretreatment – even when the animals have received only one morphine and antagonist treatment, and hence have only a single opportunity to make the association between withdrawal and the distinct context (Parker and Joshi, 1998 in Further Reading). This suggests that conditioning factors – long believed to be an important factor in the maintenance of an addicted state, and in the promotion of relapse in abstinent individuals who are re-exposed to drug- and withdrawal-related environmental cues – may play an important role very early on in the development of dependence, and the transition from controlled drug use to loss-of-control and compulsive use patterns that characterize addiction.

Neuroanatomical and Neurochemical Substrates of Acute Opioid Dependence

The neuroanatomical substrates contributing to somatic and aversive behavioral indices of withdrawal from chronic morphine dependence have been studied with site-directed injections of a modified form of naloxone – methylnaloxonium – that is relatively lipophobic and hence does not spread rapidly from the site of intracerebral application. Aversive indices of withdrawal (e.g., conditioned place aversion, suppression of operant responding for food reward) both from acute and chronic opioid dependence are precipitated most potently by the application of methylnaloxonium to the nucleus accumbens, central nucleus of the amygdala, and bed nucleus of the stria terminalis (Criner *et al.*, 2007 in Further Reading). Studies involving lesions of some of these same brain regions can also abolish behavioral signs of antagonist-precipitated withdrawal from either acute (conditioned place aversion, elevated startle reflex) or chronic morphine exposure (conditioned place aversion). These studies demonstrate clearly that the expression of withdrawal from acute and chronic morphine involves common neural circuits.

With regard to neurochemical or molecular mechanisms mediating chronic opioid dependence, there is a substantial literature implicating adaptations in intracellular signaling systems such as the adenylate cyclase/cyclic

adenosine monophosphate (cAMP) cascade coupled to opioid receptors via G proteins. Protein kinases of various types alter the phosphorylation state of many proteins involved in the transduction of the opioid-receptor-mediated signaling, including the opioid receptor itself, receptor-coupled G proteins, other kinases, and additional intracellular proteins such as cAMP response-element-binding protein (CREB) which are involved in modifying gene expression. Although relatively few studies have directly examined the cellular adaptations that mediate acute opioid dependence, there are studies which indicate that inhibitors of protein kinases can attenuate the expression of withdrawal from both acute and chronic opioid dependence, as well as the increase in adenylate cyclase/cyclic-AMP signaling that is seen during precipitated opioid withdrawal, indicating at least some overlap in the cellular adaptations between the acute and chronic states of opioid dependence.

There may also be some important differences in mechanisms underlying acute and chronic opioid dependence that remain to be elucidated. For example, as documented above, antagonist-induced precipitation of withdrawal following acute administration of opioid agonists such as morphine is time dependent, with the potency of the antagonist to precipitate withdrawal declines by 24–36 h post morphine administration. However, when repeated treatments with morphine occur 1–3 weeks apart, the severity of withdrawal precipitated by the antagonists is greater with each successive morphine exposure. Clearly, there is some underlying residual trace that allows this progressive increase in withdrawal severity even though acute responsiveness to the antagonist has waned in the interim between successive morphine doses, much like a memory trace that can be maintained long term without the need to actively recall or rehearse the information constantly. Acute-dependence models should prove highly useful tools in distinguishing the transient changes in cellular signaling that temporarily increase antagonist sensitivity following a single dose of morphine from the residual adaptations that mediate the progression of dependence with repeated morphine exposure at infrequent intervals.

Acute Alcohol Dependence

Convergent Symptomatology of Acute and Chronic Dependence

The human

Studies of alcohol dependence and withdrawal cannot take advantage of a competitive antagonist to precipitate withdrawal, and therefore time-course analysis of the emergence and resolution of spontaneous withdrawal signs is the best research method available. Accordingly, withdrawal from chronic alcohol dependence in the

human is characterized by an abstinence syndrome in which symptoms resulting from CNS hyperexcitability emerge in a time-dependent fashion after drinking cessation. In addition to autonomic and somatic symptoms such as hyperventilation, tachycardia, hyperthermia, tremors, and convulsions, the withdrawal syndrome also includes emotional or affective symptoms such as anxiety, restlessness, hyperirritability, and depressed mood/dysphoria.

As is the case with opioid dependence and withdrawal, somatic and affective manifestations of alcohol withdrawal become more prevalent and severe with chronic use, but evidence from the human and animal models indicates that a subset of withdrawal signs may be observed after a single exposure to alcohol. For example, studies of human drinkers recovering from acute bouts of alcohol intoxication have identified withdrawal-like somatic signs such as tremors, and emotional signs such as anxiety/nervousness and depression/dysphoria. This milder form of withdrawal following acute binges of alcohol consumption may be one component of what is often termed alcohol hangover, but it must be recognized that the hangover syndrome reflects more than just an acute withdrawal reaction. Hangover from acute alcohol intoxication may include symptoms resulting not only from withdrawal from acute intoxication, but also from sickness related to build-up of acetaldehyde (the initial byproduct of ethanol metabolism), from dehydration resulting from the diuretic effects of alcohol, and/or from congeners present in certain types of dark liquors such as brandy, wine, whiskey, and tequila that seem to increase hangover but not withdrawal severity relative to clear liquors (vodka, gin, etc.).

Animal models

Acute alcohol dependence has received greater attention in animal models than in human drinkers, but the available data is still quite limited relative to the acute-opioid-dependence literature. A study as early as 1958 by McQuarrie and Fingl identified reductions in seizure thresholds as a common index of somatic withdrawal from both acute and chronic alcohol administration. In the most frequent application of this model, used extensively by Crabbe and colleagues to identify genetic markers of susceptibility to acute alcohol dependence in mice (see also below ‘Acute dependence on benzodiazepines and barbiturates’), a relatively high dose of alcohol (4 g kg^{-1}) which produces blood alcohol levels beyond what even the typical heavy drinker might achieve will induce increased susceptibility to handling-induced convulsions in mice from 4 to 12 h post alcohol administration.

More recent work has identified emotional withdrawal signs from acute bouts of alcohol intoxication, including:

1. increased anxiety-like behavior as measured in the elevated plus maze or in generalization of the acute withdrawal period to the discriminative stimulus effects of the anxiogenic drug pentylenetetrazole; and
2. dysphoria-like behavior, as measured by elevated intracranial self-stimulation reward thresholds.

Although early studies focused on high ($3\text{--}4\text{ g kg}^{-1}$) doses of alcohol to induce these acute withdrawal behaviors, more recently these emotional signs of withdrawal have been demonstrated to occur from 6 to 12 h after doses of alcohol as low as $1.5\text{--}2\text{ g kg}^{-1}$, which produce blood alcohol levels that would not be uncommon after a heavy bout of drinking. In addition, as was the case with acute opioid dependence, repeated bouts of alcohol intoxication at daily or weekly intervals results in a potentiation of the peak magnitude and an extended duration of anxiety-like and dysphoria-like behaviors, suggesting that withdrawal from acute bouts of ethanol intoxication may represent a valid index of the initial adaptive response in the development of chronic alcohol dependence.

Neurochemical Substrates in Acute Alcohol Dependence

As is true for opioid dependence, the literature on neural mechanisms mediating an established state of dependence resulting from chronic alcohol exposure is quite large, whereas the literature dealing with acute dependence is quite limited. To date, some of the best evidence available on potential neurochemical substrates of acute alcohol dependence is provided by genetic analyses in mouse models, where it appears that genes encoding certain subunits of the type-A receptor for the inhibitory neurotransmitter γ -aminobutyric acid (GABA) may account for the sensitivity to handling-induced seizures during withdrawal from an acute dose of alcohol. Notably, alterations in GABA-A receptor signaling are also prominent in dependence on and withdrawal from chronic alcohol.

Acute Dependence on Benzodiazepines and Barbiturates

To date, the literature on acute dependence to benzodiazepines and barbiturates, two classes of CNS-depressant drugs with significant clinical use, is rather limited. A study published in 1986 revealed acute dependence on the classic benzodiazepine chlordiazepoxide (Librium) at relatively high doses ($75\text{--}450\text{ mg kg}^{-1}$) administered to rats. Spontaneous withdrawal was observed between 100 and 124 h after administration of a single injection of 450 mg kg^{-1} chlordiazepoxide, as measured by a number of somatic signs characteristic of withdrawal from chronic benzodiazepine treatment (e.g., tail erection, arched back,

muscle hypertonus). The delayed emergence of withdrawal is accounted for by the high dose of chlordiazepoxide (450 mg kg^{-1} is the acute maximally tolerable dose in rats, well above the required dose to produce anxiolytic and sedative effects), along with the relatively long half-life of its metabolites – a number of which possess significant benzodiazepine activity. Withdrawal could also be precipitated from 28 to 52 h post chlordiazepoxide administration with the benzodiazepine binding-site antagonist RO 15-1788. As is the case with acute opioid dependence, the magnitude of precipitated withdrawal was found to be proportional to the dose of agonist, dose of antagonist, and the interval between the two.

Crabbe and colleagues, as part of their genetic analyses of acute alcohol dependence, reported acute benzodiazepine dependence as measured by antagonist-precipitated increases in handling-induced convulsions in a variety of inbred strains of mice, including selectively bred withdrawal-seizure-prone (WSP) and high alcohol withdrawal (HAW) mice. A broad range of benzodiazepine agonists have been demonstrated to support acute dependence in this model, with half-lives ranging from short (e.g., zolpidem/Ambien, triazolam/Halcion, midazolam/Versed, 1.5–6 h half-lives) to medium (e.g., alprazolam/Xanax, lorazepam/Ativan, 6–20 h) to long (e.g., diazepam/Valium, 20–80 h). The doses of benzodiazepine agonist required to induce acute dependence in this model were within the normal range that produce anxiolytic-like and sedative effects. Some of the shorter-acting benzodiazepines also supported significant spontaneous withdrawal within 6 h of treatment. Finally, acute dependence on barbiturates such as pentobarbital has been confirmed using handling-induced convulsions in mice as an index of spontaneous withdrawal. Available data from genetic analyses of withdrawal-seizure susceptibility following acute pretreatment with benzodiazepines and barbiturates implicate similar neurochemical targets to those identified in studies of acute alcohol dependence (e.g., specific alpha and gamma subunits of the GABA-A receptor).

With regard to behavioral indices of withdrawal from acute benzodiazepine dependence, suppression of operant responding for food reward could be precipitated by the competitive antagonist flumazenil at 18 h after administration of a high dose of chlordiazepoxide (100 mg kg^{-1}) in rats, or 24 hr after the administration of behaviorally active doses of chlordiazepoxide (10 mg kg^{-1}) or diazepam ($3\text{--}5.6 \text{ mg kg}^{-1}$) in squirrel monkeys. The only study, to date, to evaluate intracranial self-stimulation reward thresholds during precipitated withdrawal from acute pretreatment with chlordiazepoxide ($30\text{--}100 \text{ mg kg}^{-1}$) and diazepam ($3\text{--}10 \text{ mg kg}^{-1}$) found no dysphoria-like elevations in reward thresholds (Easterling *et al.*, 2000 in Further Reading), in contrast to what is seen during withdrawal from acute morphine or alcohol pretreatment (see

above). At present, studies with other behavioral indices of aversive emotional consequences of withdrawal (e.g., conditioned place aversion, anxiety-like behavior) are lacking for acute benzodiazepine dependence.

Acute Dependence on Psychostimulants, Phencyclidine, and Cannabis?

Somatic and physiological withdrawal symptoms vary widely across classes of abused drugs, especially when comparing stimulants such as cocaine, amphetamines, or nicotine to sedative drugs such as opioids, alcohol, benzodiazepines, and barbiturates. However, it is well-established that emotional components of withdrawal from chronic dependence (i.e., increased anxiety and depression/dysphoria) are common across most classes of abused drugs studied to date, including stimulants. To date, acute withdrawal from stimulants is a relatively unexplored phenomenon. There are a number of human and animal studies focused on acute tolerance to the physiological and subjective effects of nicotine that have yielded mixed findings, but none include an explicit examination of acute dependence and withdrawal from acute nicotine. Laboratory animal studies of acute dependence with indirect sympathomimetic stimulants are limited to observations by Markou and colleagues that withdrawal from a single injection of d-amphetamine (4 mg kg^{-1}), or three escalating dose injections of 1, 2, and 3 mg kg^{-1} at 6-h intervals within a single day, results in the elevation of intracranial self-stimulation reward thresholds from 8 to 24 h post amphetamine administration, suggesting that acute dependence on stimulants can be measured as transient reward deficits. Acute dependence on phencyclidine (PCP/Angel Dust, $5\text{--}10 \text{ mg kg}^{-1}$) and delta-9-tetrahydrocannabinol (1 mg kg^{-1}), the primary active ingredient in cannabis, similarly has been reported in one study each, as time-dependent (<24 h) withdrawal-induced elevations of brain reward thresholds. Further work is clearly needed to more thoroughly characterize acute dependence on addictive substances other than opioid narcotics and CNS depressants, but the work to date with brain stimulation reward is a promising start.

Motivational Relevance of Acute Dependence and Withdrawal

Not all substance use, whether initiated primarily for pleasure seeking (e.g., euphoria-inducing effects, increased sociability) or for self-medication of stress, mood, or anxiety disorders, leads to compulsive use patterns that characterize addiction, and a significant

research challenge is to understand factors that contribute to the transition from casual, controlled drug use to loss of control/compulsive use in vulnerable individuals. Differential susceptibility to rapid onset of neuroadaptive responses to acute drug administration could serve as one important factor in this process. For example, Stitzer and colleagues who have done the majority of work on acute opioid dependence in the human make note of large individual differences in sensitivity to antagonist-precipitated withdrawal from single doses of morphine across subjects.

Aversive withdrawal reactions following an acute bout of intoxication could serve as a punishing stimulus, deterring further substance use. Within this framework, individuals with reduced susceptibility to acute dependence will show minimal aversive withdrawal symptoms following initial bouts of substance use, and consequently might be at higher risk to develop patterns of excessive use than individuals showing a more profound withdrawal reaction from acute dependence. However, it is also possible that some individuals who are more susceptible to rapid induction of acute dependence, and therefore do experience mild aversive withdrawal symptoms in response to initial substance use, nonetheless choose to engage in repeated drug use due to factors such as peer pressure. In these individuals, progressive increases in severity of withdrawal signs with successive episodes may contribute to the escalation of subsequent substance intake as the individual recognizes that intake effectively alleviates the aversive state experienced during abstinence. For those with preexisting anxiety/mood symptoms who initiated substance use to self-medicate those symptoms, this latter possibility may be particularly prominent, as the user is well aware that self-medication will alleviate the negative emotional withdrawal symptoms. In this fashion, acute withdrawal symptoms from individual bouts of substance use may play an increasing role over time as a motivational stimulus for further consumption through a process of negative reinforcement. Further research employing the models described herein should prove illuminating with respect to the motivational valence of increased susceptibility to acute dependence (i.e., punishing or negatively reinforcing further use), as well as more precisely delineating the neurobiological mechanisms underlying said increased susceptibility.

Alcoholism

M Heilig, National Institute on Alcohol Abuse and Alcoholism, Bethesda, MD, USA

Published by Elsevier Ltd.

Glossary

Alcohol dependence – A problematic term in that it refers to two related, but independent, concepts. As a clinical diagnosis, it refers to the complex syndrome which could otherwise better be called alcohol addiction. At the same time, it is used to refer to physical dependence, that is, the presence of tolerance and withdrawal.

Allostasis (in the context of neuroadaptations to alcohol) – A new, pathological set point for any psychological or physiological measure, which has been achieved by the activation of an opponent process that counteracts the effects of alcohol. For instance, acute intake of alcohol reduces anxiety. Chronic alcohol use will activate opponent processes, so that normal anxiety levels are experienced with alcohol onboard. When alcohol intake is terminated, the influence of the opponent process will be uncovered, as abnormally high anxiety.

Ataxia – Loss of balance and coordination, which, when not caused by cerebellar or other disease, typically reflects suppression of cerebellar function by alcohol or another central nervous system (CNS) suppressant.

Delirium tremens – Shaking madness – the most severe form of alcohol withdrawal, during which there is clouding of consciousness, hallucinations, and somatic symptoms including tremor and hyperthermia. Untreated, this syndrome once had an approximately 20% mortality.

Fermentation (in the context of alcohol production) – The anaerobic conversion of sugar to carbon dioxide and alcohol by yeast.

Heritability (of alcoholism or related phenotypes) – The proportion of risk of the respective condition attributable to genetic factors.

Sedation – Suppression of psychomotor function and general excitability by alcohol, barbiturates, or similar agents.

Seizures (in the context of alcohol withdrawal) – Uncontrolled electrical activity in the brain, which may produce a physical convulsion, minor physical signs, thought disturbances, or a combination of symptoms. Alcohol withdrawal seizures are most commonly motor seizures, typically.

Tolerance to alcohol – The need to consume increasingly higher amounts of alcohol in order to

achieve the same level of intoxication. Together with withdrawal, an integral part of physical dependence. As such, tolerance is often a part of alcohol addiction, and provides support for this diagnosis; but is in itself neither necessary nor sufficient to establish it.

Withdrawal – Signs and symptoms that may emerge upon discontinuation of alcohol intake following an extended duration of high-level intake. It includes both psychological (e.g., anxiety) and somatic (e.g., tachycardia) symptoms (see tolerance, an integral part of physical dependence).

Alcoholism (Alcohol Addiction)

Although definitions of alcoholism vary, most views recognize as a key component a pattern of excessive and repetitive drinking of alcoholic beverages at a level that causes harm to the individual, others, or both. The harmful consequences of excessive alcohol use are unusually diverse, and in addition to medical–physical – as well as psychiatric – problems, commonly include impaired social function and legal problems. Similar to other addictions, a hallmark of alcoholism is that the normal behavioral repertoire is restricted in favor of drug seeking and consumption, and that excessive and harmful use occurs despite realization of its harmful consequences. This points to an impairment of normal behavioral control, and a transition from episodic thoughtlessness, or impulsive to habitual or compulsive drunkenness.

Alcohol as a Drug

The active ingredient in alcoholic drinks is ethyl alcohol, or ethanol (C_2H_5OH), typically produced by fermentation (anaerobic metabolism) of carbohydrates by certain yeast species. Other alcohols are primarily of interest in toxicology (e.g., methanol, butanol) or in the food-processing industry (sugar alcohols, such as xylitol), and will not be discussed further here. Ideally, alcoholism should, therefore, be referred to as ‘ethylysm,’ and corresponding terms should be used whenever possible. The term ‘alcoholism’ is, however, so established in lay language that it will also be used here. Unless otherwise specified, the word ‘alcohol’ will refer to ethanol.

By 4000 BC, production and consumption of alcohol-containing beverages such as wine is solidly documented in hieroglyphic writing from Egypt, while recipes for making wine or beer are found on clay tablets from Mesopotamia that are dated about a millennium later. In ancient Greece, fermented honey – or mead – seems to have been the original alcoholic beverage, but wine-producing skills reached Greece by about 2000 BC. Fermented beverages provided a certain degree of protection against overgrowth of pathogens, such as cholera, in drinking supplies. Because of this, fluid consumption in areas where fresh water was not readily available could, to a large extent, consist of beer or wine. At sea, all fluid carried onboard could be in the form of beer. The alcohol content of these beverages was typically relatively low, probably not exceeding 4%. Of note, antiseptic properties of alcohol are only partial at these concentrations, so other ingredients, as well as crowding out of bacteria by yeast, must have contributed.

Fermented beverages can typically not reach an alcohol content beyond ~15%, because, at higher concentrations, the yeast are metabolically impaired or die. Higher alcohol concentrations, likely leading to a higher addictive potential, can only be reached through distillation. Although there is historical account of small-scale distillation dating to prehistorical times (from Babylonia and Egypt), successful distillation of quantities suitable for human consumption was only achieved by Arab chemists around AD 800–900. By the thirteenth century, this expertise had spread to Europe, and by the fourteenth century, the use of distilled spirits as medicinal elixirs was widespread, for instance, to provide protection or cure from the Black Death.

Psychoactive Properties

In contrast to other addictive drugs, alcohol does not have a unique molecular target, such as a specific neurotransmitter receptor or transporter in the central nervous system (CNS). It was once thought that the CNS actions of alcohol were produced through interactions with membrane lipids, but this view has largely been abandoned. Work with the *Drosophila* odorant-recognizing protein LUSH, instead, suggests that alcohol may interact directly with protein motifs that encode hydrophobic pockets. The main direct targets of alcohol are ligand-gated ion channels, most importantly glutamatergic and γ -aminobutyric acid (GABA-ergic) receptors. Alcohol acutely inhibits glutamatergic, and potentiates GABA-ergic transmission, in both cases through pre- as well as postsynaptic mechanisms. It thus shifts the excitation-inhibition balance throughout the CNS in favor of inhibition. Consistent with this profile, high alcohol doses are hypnotic, while lower doses are sedative and ataxic.

Sensitivity to sedative/ataxic alcohol actions displays considerable individual variation, which is highly heritable. This variation is related to genetic risk for alcoholism. Similar to other sedative-hypnotics, alcohol also suppresses anxiety.

Secondary alcohol targets include several G-protein-coupled receptors, including – perhaps most importantly – μ -opioid and dopaminergic receptors. Through these, alcohol activates classical brain reward circuitry, resulting in positive reinforcement as well as psychomotor stimulation. Genetic and other host factors also determine the degree of these alcohol effects. The sex, age, and genetic makeup of the individual will thus determine the net balance between sedative-hypnotic and psychomotor-stimulating, positively reinforcing alcohol actions.

Following a prolonged history of brain alcohol exposure to repeated cycles of alcohol intoxication and withdrawal, an allostatic shift will occur with regard to molecular, physical, and motivational alcohol actions. Specifically, in the presence of alcohol, opponent processes are progressively recruited that counteract acute alcohol actions. When alcohol is withdrawn, these opponent processes become predominant. For instance, processes opposing the sedative-hypnotic actions of alcohol, when uncovered, will result in the hyperexcitability of alcohol withdrawal, potentially leading to withdrawal seizures, delirium tremens (DT) or withdrawal anxiety. Recruitment of processes opposing the psychomotor-stimulating and positively reinforcing alcohol actions will lead to attenuated reward-system function – as shown, for example, by attenuated signaling within the classical circuitry of the mesolimbic dopaminergic system – and impaired reward function, as illustrated by elevated thresholds for intracranial self-stimulation in experimental animals. Additionally, antireward systems, with corticotropin-releasing factor (CRF) as a prominent example, will be activated in the course of these neuroadaptations, and will, in the absence of alcohol, contribute to shifting affective balance into a negative direction. In a vicious circle, this will set the scene for increased negative reinforcement by renewed alcohol intake.

Alcoholism as a Clinical Condition

If consumed in excess or under the wrong circumstances, alcohol can clearly be harmful to anyone, and warnings against lack of temperance can be traced back to ancient Greece. It has, however, also been recognized that some individuals develop alcohol-use habits which differ from the majority of users. In these individuals, alcohol causes harm related to the overall amount, pattern, and manner of alcohol use. The notion that this type of habitual drunkenness is a disease dates back to antiquity, and Seneca classified it as a form of madness. The modern

term ‘(chronic) alcoholism’ was introduced in a classic paper, in 1849, by Magnus Huss, professor of medicine at the Karolinska Institute, Stockholm, Sweden. Chronic alcoholism quickly became the medical term for a syndrome related to habitual, rather than occasional, drunkenness.

A medical view of alcoholism was originally based on purely pharmacological and physiological phenomena, among which tolerance and withdrawal were key. This refers to the need for progressively increasing doses to produce desired effects, and a withdrawal syndrome when drinking is discontinued. This view, although still widespread among clinicians, is clearly insufficient. Compulsive alcohol use that leads to adverse behavioral and medical consequences does not require that tolerance and withdrawal are present. Furthermore, relapse is a core phenomenon of chronic alcoholism, and classical relapse studies indicate that over a 12-month period, equal proportions of alcoholics relapse within the first month – when withdrawal symptoms might be present – and in the next 11 months, during which withdrawal symptoms are long gone. Clearly, processes other than tolerance and withdrawal must be involved in maintaining the disease process.

In order to capture clinically relevant core phenomena of alcoholism, a focus on behavioral pathology is needed. In this perspective, alcoholism is a condition in which alcohol acquires a pathological degree of motivational salience, restricting the behavioral repertoire of the individual so that alcohol seeking and consumption assume a predominant role at the expense of other behaviors, and the individual loses control over his or her alcohol use. Physical dependence, when present, may contribute to this state, and its development may be a marker of brain plasticity which contributes to the evolution of the behavioral disorder. However, physical dependence may or may not be present, that is, it is neither necessary nor sufficient for the development of clinical alcoholism. Whatever the underlying neural processes, the result is a behavioral and motivational pathology that results in compulsive and excessive alcohol consumption sufficient to – ultimately – cause medical, psychological, socioeconomic, and legal problems.

In this clinical perspective, alcoholism is very similar to other conditions whose disease nature is rarely questioned. It has a considerable component of genetic vulnerability, persists over time, is maintained in part by specific patterns of behavioral choices, and is a major cause of death and disability. A disease view is further justified by the observation that alcohol induces persistent changes in brain function and structure in ways that affect motivation and decision making.

Based on the phenomena discussed above, reasonable consensus has been reached on criteria by which clinical alcoholism can be diagnosed, as reflected by the World

Health Organization International Classification of Diseases (ICD)-10 criteria, and the American Psychiatric Association Diagnostic and Statistical Manual of Mental Disorders, version IV (DSM-IV) criteria. While these tools work quite well in a clinical context, caution is needed when they are applied in non-clinical situations, such as epidemiological studies. People who fulfill these criteria but have never sought treatment appear to be a population that is distinct from those who fulfill such criteria but have also sought treatment. While few clinicians would question the disease nature of people in the latter category, it is questionable whether the former group can be regarded as having a clinical disease.

Etiology

The common belief that alcoholism can be inherited dates back at least several hundred years, as documented, for example, in preserved population registries maintained by the Swedish church. By now, adoption and twin studies have consistently estimated the heritability of alcoholism in the 50–60% range. Some continuing controversy in this area is, therefore, unsubstantiated by data.

Available evidence suggests that the heritability of alcoholism is polygenic, with common estimates of how many loci that contribute currently running close to 20 – each contributing a small effect size. It also appears that ‘alcoholism’ is likely to be a group of phenocopies, that is, conditions that may appear very similar in a cross-sectional, snapshot view, but in fact represent the endpoint of very different trajectories, to which in turn different groups of genes may contribute. For instance, classical adoption studies showed, nearly three decades ago, that early-onset alcoholism with impulsive personality traits has a higher degree of heritability than disease with later onset where high trait anxiety is predominant. Defining less complex intermediate phenotypes provides the hope of identifying more homogenous groups of alcoholics, and thereby facilitating the identification of specific genetic risk factors. As an example, many – but not all – people at genetic risk of developing alcoholism have been shown to respond with a lower degree of sedative–ataxic effects to alcohol. This constitutes an intermediate phenotype that may lead to the discovery of specific genetic risk factors. Another intermediate phenotype, comprised of specific electroencephalogram (EEG) response patterns (P300), has already proved useful for this purpose (see below). In other cases, people with known genetic variants, such as a functional variant of the μ -opioid receptor, show increased subjective responses to alcohol. Other interesting intermediate phenotypes are currently being developed using functional brain imaging.

The first specific genetic factors that were discovered to modulate alcoholism risk were those that confer a

protective influence. Genetic variation in the aldehyde dehydrogenase gene common among people of Asian descent confers decreased capacity for degradation of acetaldehyde – the main alcohol metabolite. Because they accumulate this toxic metabolite, homozygous carriers of this variant have an unpleasant flushing response even to small quantities of alcohol. This clearly reduces their risk for developing alcoholism. More recently, increased susceptibility for developing alcoholism has been linked to variation in genes encoding CNS proteins more directly involved in the pharmacodynamic actions of alcohol. The first successful case in this category was variation in the gene encoding the GABA-A receptor α -2 subunit – first identified using an EEG-based intermediate phenotype, and subsequently directly linked to alcoholism risk. This finding has been confirmed in several independent replications. Variation in the serotonin transporter gene as well as the gene encoding the type 1 receptor for CRF has also been linked to increased risk and, in both cases, seems to interact with adverse life events to produce excessive drinking.

What is inherited is clearly not alcoholism *per se*, but rather an increased disease susceptibility, that is, a risk to develop this condition given exposure to specific environmental risk factors. The most important among these is availability of alcohol. Easy availability clearly increases alcoholism risk, and countries or communities where alcohol is cheap, for example, due to low taxation, and where societal control over sales is low have high rates of alcoholism. Peer and cultural influence have also been described to modulate risk, although they are difficult to dissociate from genetic factors. Several psychiatric conditions increase alcoholism risk – the most important among these being attention-deficit disorder, panic disorder, social phobia, schizophrenia, bipolar illness, and, with the highest quantitative contribution, antisocial disorder. Finally, unemployment, irregular working hours, or working in an environment with high availability of alcohol (e.g., diplomats, journalists, bartenders) increases alcoholism risk.

Clinical Characteristics

Acute Presentation

Alcohol-addicted subjects come to medical attention through an unusually wide range of medical problems. Studies in trauma centers have demonstrated that a large and long-overlooked component of this condition is accidental injury. Accident risk is generally increased by intoxication, but in the absence of addiction, most people confine episodes of heavy drinking to reasonably safe settings. It is when the addictive process pushes heavy drinking beyond these confines, for example, onto the road or into the workplace, that the risk of accidental

injury increases dramatically. Overall, mortality is approximately three- to fivefold elevated in alcoholism. Alcoholics are almost 30 times more likely to die from fatal poisoning, about 15 times more from a fall accident, and about 5 times more liable to die in a car crash. Alcoholism is also a major cause of suicide, ultimately causing death in about 3% of alcoholics. Conversely, a classic study found fatty liver – a condition that only rarely has other causes than alcoholism – in about half of the suicide victims, but only 3% of the general population. Risks of other violent death are also high: the risk of death through homicide or drowning is roughly doubled.

A set of more specific acute conditions, collectively labeled the alcohol withdrawal syndrome, often brings the patient to care when episodes of heavy drinking come to an end. To a large extent, these reflect the rebound CNS hyperexcitability in withdrawal. The common hangover illustrates, in miniature, some of these phenomena – such as headache, increased anxiety, and general malaise. The clinically significant phenomena of withdrawal are, however, absent in hangover. Following prolonged periods of heavy drinking, patients develop tremors, accompanied by a loss of appetite, inability to retain food, sweating, restlessness, and sleep disturbances. Unless confounded by the use of other sedative-hypnotic drugs, this group of symptoms typically peaks within 24 h from discontinuation of drinking, and subsides thereafter. In the most severe cases of CNS hyperexcitability and/or in combination with other risk factors such as fever, seizures can also occur in early withdrawal, occasionally developing into status epilepticus, a potentially fatal condition. Most seizures occur within the first 48 h. Finally, the risk for DT peaks around the third day of withdrawal. DT is a transient, but serious, psychotic condition, with confusion and visual hallucinations, accompanied by whole-body tremor and fever. Unless treated, typically with tapered doses of benzodiazepines, it can last up to a week. Before treatment was available, DT was fatal in up to 20% of cases.

Prolonged heavy drinking leads to an almost complete impairment of thiamin uptake. Some individuals have a low activity of the enzyme transketolase, but as long as thiamin (vitamin B1) is adequately supplied through the diet, this is inconsequential. Loss of absorption, however, will unmask the deficit in these individuals, potentially leading to neuronal death and scarring in the brainstem, cerebellum, and mamillary bodies. This is clinically expressed as Wernicke-Korsakoff's disease, marked classically by a clouding of consciousness, abnormal eye movements, and axial amnesia (both anterograde and retrograde loss of recent memory) accompanied by confabulation, a tendency to make up for the defect without regard for fact. Although one would think that a condition with these rather dramatic symptoms would be readily

diagnosed and treated, most Wernicke–Korsakoff's cases are, in fact, found only on autopsy.

Some degree of liver inflammation is common in the acute phase of alcoholism treatment. It usually resolves without the need for specific treatment, and it is the chronic liver complications that have the greater clinical significance. Other gastrointestinal conditions that are commonly encountered during the acute phase are gastritis, duodenal ulcers, and pancreatitis.

Chronic Disease

Although most often unrecognized, alcoholism is one of the most common causes of psychiatric problems, including insomnia, anxiety, and depression. In most individuals, these problems resolve after about 1 month of abstinence. In a minority, however, it is found that alcohol use has triggered or been comorbid with independent psychiatric disorders, making a careful differential diagnosis paramount.

Alcoholism also causes a cognitive impairment, which will initially resolve within some 6 months of abstinence, but will persist in later stages, reflecting a loss of brain tissue that is at least, in part, irreversible. In older alcoholics, enlargement of both gyri and ventricles is commonly seen on structural imaging as a result of the atrophy of gray matter. This atrophy is likely to in part reflect direct alcohol effects, and in part damage caused by accidents and blows.

Among the almost endless list of medical conditions that chronic heavy alcohol use can lead to, contribute to, or mimic, a few more are specifically enough linked to alcoholism to merit mention here. The classic chronic disease resulting from alcoholism is cirrhosis of the liver, typically preceded by steatosis (a fatty enlargement of the organ). In its most severe form, alcoholic liver cirrhosis leads to liver failure, and is ultimately fatal unless the patient receives a transplant. Chronic alcohol use is a common and commonly overlooked cause of hypertension and related cardiovascular morbidity, but a condition more specifically associated with chronic alcoholism is alcoholic cardiomyopathy, a disease of the cardiac muscle that can lead to terminal heart failure. Thiamin deficiency can chronically lead to polyneuropathy, a degenerative disease of the peripheral nerves with loss of vibratory sensation and proprioception that – together with cerebellar damage – contributes to the characteristically broad gait of late-stage alcoholics.

Natural History

Alcoholism evolves over 5–15 years. This is reflected by the fact that alcohol-related problems are most common among men in the age range of 18–30, but the

development of chronic, clinical alcohol addiction is most common in people between 25 and 50 years of age. Thus, among the many young people whose heavy drinking has the potential to lead to alcoholism, the process is not carried to completion in most cases, and by age 30 many hazardous drinkers will have returned to controlled social alcohol consumption.

Disease with early onset evolves more rapidly than that with onset later in life. Because of this, considerable emphasis has been placed on the harm of alcohol use in adolescence. The hope has been that delaying alcohol use would reduce the risk for rapid development of alcoholism. It is certainly desirable to refrain from alcohol use while the brain is still developing and the individual has not achieved a mature capacity for assessing and handling the risks involved in alcohol use. It is, however, unclear whether age of alcohol-use onset modulates addiction risk once the genetic risk is controlled for.

Alcoholism is a chronic, relapsing disorder. Short-term discontinuation of heavy drinking can readily be achieved in most cases. It is, however, the ability to prevent relapse, that is, a return to heavy drinking, that will determine long-term impact on health and social functioning. Patients with alcoholism are a heterogeneous group, and so are their outcomes. On the one hand, of those people who in epidemiological studies, at some point, fulfill diagnostic criteria for alcoholism, a majority will no longer do so 5–10 years later, and their health and social functioning will not be adversely affected. On the other hand, among clinical cases, that is, treatment-seeking people with an alcoholism diagnosis, about 70% will relapse within 12 months. Key relapse-triggers in this group are sampling a dose of alcohol, being exposed to alcohol-associated cues, or experiencing stress. Although formally fulfilling the same diagnostic criteria, it is unlikely that these groups share underlying pathophysiology. A disease view of alcoholism is certainly justified in the latter, but not necessarily in the former, group.

A particularly contentious issue related to outcomes is whether a return to controlled social drinking is possible for alcoholics. Classical long-term follow-up studies concluded that this may be possible in individuals who had abused alcohol for less than a year, but that, if alcohol dependence has persisted for more than 5 years and reached a certain degree of severity, efforts to return to social drinking lead to relapse for a vast majority of subjects. Other studies challenged this notion, describing considerable proportions of people with alcoholism who successfully returned to controlled drinking. If the heterogeneity of alcoholism is considered, this controversy is likely to melt away. At one end of the spectrum, there are people in whom the critical neuroadaptations of addiction are absent or have resolved. If the risk factors that once contributed to heavy drinking have been eliminated, it is not unreasonable that these individuals cautiously

attempt a return to controlled drinking. On the other hand, if the disease has had sufficient duration and/or severity that the critical neuroadaptations persist, risk of relapse remains very high, justifying the saying “once an alcoholic, always an alcoholic.” Therefore, a major objective of future research is to identify the critical neuroadaptations and their clinically useful biomarkers.

Prevalence of Alcoholism

Epidemiological studies in the United States of America (USA) and Western Europe commonly estimate lifetime prevalence of alcoholism at 10–20% in men and 5–10% in women. Somewhat higher rates are reported from Eastern Europe, while rates reported from countries in the Middle East and in Southeast Asia are much lower. Rates reported from rural areas in Africa are low, but are very high in the rapidly growing slums around the big cities.

Thus, alcoholism is generally common where alcohol is available, and about twice as much so among men than women. Some trends over time can also be discerned. Beyond that, the specific numbers should not be over-emphasized. Attitudes, criteria, and reporting among different countries are rarely comparable. Even when state-of-the-art methodology is used, there is reason for caution when up to one in five men receive diagnosis of a disease that, when present clinically, has considerable mortality and morbidity.

The diagnostic term alcoholism is perhaps better reserved for a condition of sufficient clinical significance to typically bring people to treatment. This is particularly true if a medical view of alcoholism as a disease is to be widely accepted. In other cases, it may be more meaningful to consider hazardous drinking. This refers to the use of alcohol at a level or in a pattern that, although not necessarily reflecting addiction, carries a high risk of negative medical or social consequences. Excellent and simple screening instruments have been developed that identify hazardous alcohol use, with the Alcohol Use Disorder Identification Test (AUDIT) being the most widely used. In people with hazardous drinking but without clinical alcoholism, considerable benefits in terms of reduced healthcare utilization and sick leave have been documented from simply identifying the problem through screening with these questionnaires, for example, in primary care, and providing feedback on the adverse consequences of consumption. The ability of these subjects to change their behavior based merely on information received perhaps most directly illustrates a fundamental difference from a person with an addictive disease.

Treatment of Alcoholism

The concept of treatment is closely related to the choice of outcome measures. Traditionally, abstinence has been the standard measure of success. Given the chronic, relapsing nature of alcoholism, such a notion is naive at best, and harmful at worst. As in any medical condition, a successful treatment is one that reduces morbidity and improves functional outcomes. Reduction of heavy drinking achieves these goals. Similar to most chronic diseases, alcoholism may not necessarily be possible to cure, but can certainly be successfully managed.

Treatments with measurable beneficial effects exist for alcoholism. Unfortunately, a classical systematic review found that the likelihood of a specific treatment being provided to a patient was inversely correlated with the strength of the evidence supporting its efficacy. An equally disturbing inverse correlation was found between the cost of delivering a specific treatment and the strength of evidence in its support. Clearly, while research efforts hope to bring forward new treatments, considerable gains could be achieved by simply implementing what is already known.

‘Detoxification’ – an ill-chosen but widely adopted term that refers to medically supervised withdrawal – has long been a mainstay of alcoholism treatment. Detoxification may be necessary to safely prevent or manage complications and achieve short-term sobriety, but research shows that this intervention has little if any impact on long-term outcomes in alcoholism. The same is true for the widespread and costly 28-day residential treatments. Expensive long-term psychotherapies focusing on underlying psychological problems rather than alcohol use are also as common as they are ineffective.

Among psychological-behavioral treatments, short- and medium-term efficacy has been found for those that are nonconfrontational, specifically focus on the alcohol use, and apply methods that increase motivation for change; actively practice, for instance through role-play, thoughts and behaviors that minimize relapse risk by eliminating or avoiding relapse triggers; practice strategies to avoid progression from a slip to a full-blown relapse; and reinforce alternative behaviors. Among various methods that have successfully applied these elements are motivational interviewing, community reinforcement, and relapse prevention based on cognitive-behavioral therapy principles. While much has been made of the specifics of these therapies by their respective advocates, large-scale studies have failed to show clinically meaningful differences in outcomes between them, or evidence for beneficial matching effects.

Modern pharmacotherapy of alcoholism is in its early days. It was preceded by disulfiram, an inhibitor of aldehyde-dehydrogenase, which was introduced in the 1950s.

Disulfiram does not affect the motivational pathology of alcohol addiction. Instead, it leads to accumulation of acet-aldehyde upon intake of alcohol, resulting in severe flushing and tachycardia thought to deter alcohol use. Unsupervised disulfiram has, however, no documented efficacy, presumably because compliance is low. When used, it has the potential for serious complications. Outside special settings, for example, when short-term abstinence must be achieved to allow a psychiatric evaluation, or with supervised administration to professionals at risk for losing their credentials, disulfiram therefore should have little place in the modern treatment of alcoholism.

The era of modern alcoholism pharmacotherapy started in the early 1990s, with the discovery that the opioid antagonist naltrexone reduces relapse to heavy drinking. This has subsequently been confirmed in meta-analyses of the many controlled trials that followed, and naltrexone is approved for treatment of alcoholism in the USA, Europe, and many other countries. Naltrexone directly inhibits positively reinforcing properties of alcohol that are mediated by endogenous opioids in response to alcohol intake. Average effect sizes in clinical treatment are relatively low. Recent research has, however, shown interesting pharmacogenetic diversity that can help improve outcomes by personalizing treatment. Carriers of a functional 118G variant of the μ -opioid receptor, who constitute nearly 15% of Caucasian populations, appear to respond well to naltrexone, while patients homozygous for the major 118A allele do not seem to respond at all.

The functional glutamate antagonist acamprosate is the second currently approved modern alcoholism pharmacotherapy. Its mechanism of action is less clear. Although meta-analyses of European studies solidly support the efficacy of acamprosate, American studies have not been able to replicate it. Animal data may be helpful in understanding this apparent discrepancy. Basic studies strongly suggest that a hyperglutamatergic state is progressively recruited in alcoholism. In animal models, acamprosate is only effective in subjects with a prolonged history of pronounced dependence. This appears to be consistent with the human data, since the European studies in which acamprosate was found effective enrolled patients with more severe disease than the American studies that did not.

In addition to the currently approved medications, initial positive data are currently available for the 5HT₃ antagonist ondansetron, the anticonvulsant topiramate, and several other experimental compounds. A particularly interesting category among these comprises compounds that target the negative affective states that maintain alcoholism in its later stages, such as antagonists for CRF1 or neurokinin-1 (NK1) receptors. As new target mechanisms are added over the next decade or so, there is considerable hope that effective, personalized alcoholism

treatments that are tailored to the genetics and pathophysiology of the individual patient will become possible.

Animal Models of Behavior: Alcohol Addiction

Glossary

Alcohol reinforcement – In its reinforcing capacity, alcohol increases the frequency of preceding responses, and, accordingly, is called a reinforcer. Alcohol is a primary reinforcer and leads to self-administration.

Allostatic state – A state of chronic deviation of a regulatory system from its normal (homeostatic) operating level is defined as an allostatic state. In the context of drug addiction, this term has been introduced by George Koob and Michel Le Moal and represents a chronic deviation of reward set point by dysregulation of reward circuits and brain stress systems that provide a negative motivational state that drives addictive behavior.

Craving – There are opposing views in the field regarding the term ‘craving,’ whether it describes a physiological, subjective, or behavioral state, if it is necessary at all to explain addictive behavior or is an epiphenomenon which is not necessary for the production of continued drug use in addicts. The World Health Organization (WHO) agreed on the definition of craving as “the desire to experience the effect(s) of a previously experienced psychoactive substance.” Behavioral researchers conceptualize craving within the framework of incentive motivational theories of behavior and modify the definition of craving as “incentive motivation to self-administer a psychoactive substance.” Such an operational definition of craving has the advantage of making the phenomenon of craving accessible to experimental investigation and making it measurable.

Reinstatement – The reinstatement model is the first choice for the measurement of craving and relapse behavior. In this paradigm, animals are trained to self-administer a drug and are then subjected to extinction – that is, they are tested under conditions of nonreinforcement until operant responding appears to be extinguished. When the animals reach some criterion of unresponsiveness, various stimuli are presented. A stimulus is said to reinstate drug-seeking behavior if it causes renewed responding, that is, lever pressing, without any further response-contingent drug reward. At least three conditions can reinstate responding: drug priming – that is the injection of a small dose of the drug, stress, and conditioned stimuli.

Tolerance – Tolerance has developed when, after repeated administration, a given dose of a drug produces

a decreased effect. It is important to note that tolerance does not only develop with alcohol and other drugs of abuse but also after repeated administration with a wide variety with drugs that are not self-administered by animals or used compulsively by man.

Alcohol Drinking in Laboratory Animals

In 1940, Curt Richter observed that laboratory rats consume alcohol on a voluntary basis. In other words, if a water bottle and a bottle with an alcohol solution are presented to the home cage, rats will consume alcohol and some animals will even prefer alcohol over water. The large variability in alcohol preference among individual animals and strains has allowed researchers to selectively breed rats for differential alcohol preference, generating pairs of animal strains that are characterized by particularly low or high alcohol consumption levels. The best-studied pairs of lines were generated in Finland, the United States, and Sardinia. For example, the Finnish model – called Alko Alcohol (AA) and Alko Nonalcohol (ANA) rats – comprises two strains of albino rats based on their selection or rejection of a 10% alcohol solution and water. The AA rats were selectively bred starting in 1963 and voluntarily consume more than 5 gram alcohol per kilogram body weight per day ($\text{g kg}^{-1} \text{ day}^{-1}$), attaining high blood alcohol concentrations, whereas the ANA rats consume less than $0.5 \text{ g kg}^{-1} \text{ day}^{-1}$ of alcohol. Alcohol-preferring rat lines and drinking experiments in a laboratory setting were extremely helpful in obtaining a solid knowledge about the genetic factors modulating initial alcohol consumption and the neurobiological underpinnings of primary alcohol reinforcement processes. However, the question remains whether voluntary alcohol consumption in rodents in a laboratory setting is translatable to the human condition. This might well be the case as chronic high consumption of alcohol already occurred early on in primate evolution. It is suggested that the trait of alcohol consumption is actively maintained during evolution and should therefore be considered as part of the behavioral repertoire of mammals. Thus, data deriving from alcohol-drinking experiments in rodents in a laboratory setting may well translate into the human condition as these animal models show strong face validity. Moreover, because alcohol

reinforcement is mediated by brain structures that have been strongly conserved during evolution (i.e., subcortical structures), rodent-drinking models have also a good construct validity and, therefore, potential for further elucidating the neurobiological basis of alcohol consumption and alcohol reinforcement processes in humans.

A major limitation of these drinking models, however, is that alcohol preference alone does not necessarily indicate addictive behavior but often reflects controlled alcohol consumption. For example, animals from an alcohol-preferring strain have a high alcohol preference but do not meet important criteria of addictive behavior, such as loss of control over drinking. Thus, the animals' alcohol intake decreases dramatically when they are offered alternative diets augmented with sugar. Furthermore, the close correlation of food and alcohol consumption, and the occurrence of alcohol consumption at normal times in the circadian cycle demonstrate that alcohol intake is controlled as part of normal behavior. In contrast, the main symptom of alcohol addiction is the progressive loss of control over the amount and the contextual circumstances accompanying alcohol use. This loss of control results not only in higher alcohol consumption, but also in a compulsive search for, and inability to refrain from, its use even after long periods of abstinence (relapse), especially when the individual is exposed to stimuli previously associated with alcohol consumption. Compulsive alcohol drinking can pervade all life activities of the consumer. As a consequence, life becomes governed by alcohol and the addicted patient can subsequently lose social compatibility (e.g., loss of partner and friends, loss of job, and crime).

According to this definition of alcohol addiction, and in contrast to controlled alcohol drinking, addiction is a behavioral disorder that seems to appear exclusively in humans. This conclusion raises a very important question: If addiction does not appear in animals living in their naturalistic environments, can these animals be appropriate subjects to reproduce alcohol addiction in a laboratory setting? Although addiction can hardly be reproduced as a whole in an experimental situation, specific features of addictive behavior can be adequately modeled. In particular, different phases of long-term alcohol consumption can be consistently observed in laboratory animals.

From Controlled Drinking to Alcohol Addiction

Large epidemiological data sets on alcohol-drinking behavior led to an alcohol-specific symptom progression model for alcohol addiction, describing transition probabilities from one phase to another (nonuse, use, heavy use, abuse, and addiction) in relation to biological, psychological and social vulnerability, and risk factors.

Similarly to the human condition, alcohol drinking in rats over a long time period can be also separated into different phases. The acquisition of alcohol drinking is the first phase, followed by a second phase of controlled alcohol-drinking behavior. As described, most animal work in the past has focused on the acquisition of alcohol drinking or the maintenance of an established controlled alcohol-seeking behavior. A third phase, in which uncontrolled excessive alcohol-drinking behavior occurs, relates to addictive behavior in humans and has been intensively studied in recent years. In this phase, positive reinforcement processes become less important. There is a shift from liking to wanting alcohol as habit-forming properties and opponent motivational processes – mainly triggered by acute, protracted, and conditioned withdrawal – come increasingly into play. Subsequent allostatic dysregulation of the reinforcement system may then occur. One animal model which captures these different drinking phases is the long-term self-administration procedure with repeated deprivation phases.

An Animal Model to Study Different Phases of Alcohol Consumption

In the long-term alcohol self-administration procedure with repeated deprivation phases, Wistar rats receive, in addition to food and tap water, different concentrations of ethanol solutions *ad libitum* in four bottles per cage (5%, 10%, and 20%, reflecting alcoholic beverages consumed by humans such as beer, wine, and spirits). A four-bottle paradigm has the advantage of overcoming initial preference problems. Rats usually prefer lower-concentration alcohol solutions (<6%) over higher-concentration alcohol solutions. Following a period of taste adaptation, a shift toward preference for higher concentrations of alcohol solutions is observed. Furthermore, individual sensitivities and preferences to alcohol solutions are usually observed. The free-choice presentation of various concentrations of alcohol solutions bypasses the problem of individual preferences – in this model, a rat is allowed to drink what it likes most. Indeed, in a four-bottle paradigm, high alcohol intake and preference in common stock rats are observed during the acquisition of alcohol-drinking behavior in male as well as in female rats. After 2 months of continuous access to alcohol, the rats are deprived of alcohol for 3 days. Following this deprivation phase, all alcohol solutions are presented again. This procedure is repeated monthly for the following 10 months. The introduction of repeated deprivation (withdrawal) phases for several days/weeks is crucial in developing an addictive behavior, as the negative consequences of acute, protracted, and conditioned withdrawal triggers further drinking and induces relapse behavior.

The alcohol deprivation effect

Following a deprivation phase, re-presentation of the alcohol solutions leads to a pronounced transient rise in alcohol intake and preference. This is termed the alcohol deprivation effect (ADE). This relapse-like drinking phenomenon is observed across several species, including rats, mice, monkeys, and human social drinkers. The increase in alcohol drinking probably reflects an increase in alcohol-seeking, which, according to self-reports of some alcohol-dependent subjects, can also increase progressively during abstinence and decrease after relapse during a drinking bout. In summary, ADE in long-term voluntary alcohol-drinking rats is used as a measure of high motivation to drink alcohol and as a measure of relapse-like behavior.

In this long-term drinking model, changes in alcohol-drinking behavior occur over time. During the first days of alcohol exposure, male rats have a high daily consumption of around 6 g kg^{-1} and an alcohol preference of 60%. Overall, female rats consume greater amounts of alcohol than male rats. Such a sex difference is also seen in other species such as mice and monkeys. At first glance, this appears to be in stark contrast to observations in humans, since epidemiological and clinical studies demonstrate that women consume less alcohol than men. However, if alcohol intake in humans were to be calculated on a g kg^{-1} base instead of the number of drinks consumed, consumption in females would be much the same or even more than that in males. Thus, contrasting sex differences in humans and animals are mainly related to social barriers in different populations and to an artifact in calculating exact alcohol intake.

After this short initiation phase, large daily fluctuations in drinking behavior are observed though, over a period of months, there is a clear tendency for a decline in alcohol consumption, resulting in a stable average daily intake of between and 4 g kg^{-1} alcohol. In the first 8 weeks of the acquisition phase of alcohol drinking, there is a clear sequence in preferences for the different concentrated alcohol solutions: $5 >> 10 > 20\%$. However, there is a change in this sequence from week 9 onward to $5 < 10 \leq 20\%$. This change in preferences coincides with the introduction of the first alcohol deprivation period and this relation remains stable for up to 1 year. Alcohol-drinking behavior during this time can be regarded as controlled (phase of maintenance). However, following repeated ADEs, alcohol-drinking behavior can become uncontrolled and compulsive. Uncontrolled drinking behavior can be assessed by the adulteration of the alcohol solution with quinine, thus altering its taste. In this experiment, quinine is added to the alcohol solution, but not to the water. Quinine is a very bitter tasting substance that usually produces a strong taste aversion in rats. Despite the aversive taste, however, the long-term alcohol-drinking rats consume large amounts of the quinine-

containing alcohol solution following a deprivation phase. In fact, alcohol intake and preference and the time course of the ADE of quinine-exposed animals are similar to those of control animals that have had the same experimental history and which have received unadulterated alcohol. In long-term alcohol-drinking rats, alcohol intake following a deprivation period is thus relatively resistant to modification by taste adulteration, that is, drinking behavior becomes compulsive and uncontrolled. In addition, pronounced changes in the diurnal rhythm of drinking activity are observed following alcohol deprivation in chronic drinking rats. In particular, most of the animals still show high-drinking activity during the inactive phase, and some animals even show no differences in drinking activity during the dark and light phases of the daily cycle. Such a level of drinking activity is far beyond the normal controlled behavior seen in the appropriate control animals, and points to alterations in circadian rhythmicity.

In summary, alcohol consumption behavior following long-term consumption and subsequent deprivation is characterized by changes in the alcohol-intake patterns of animals. The animals consume not only more alcohol, but also large amounts of highly concentrated alcohol solutions at inappropriate times during their daily cycle in an uncontrolled and compulsive manner, that is, during the light phase when the animals are normally inactive and drinking activity is low. Finally, the fact that the clinically effective antirelapse drugs acamprosate and naltrexone reduce or even abolish the ADE lends predictive value to this animal model for the development of novel and improved drugs for the treatment of craving and relapse.

Dependence-Induced Alcohol Drinking – A Procedure that Leads to Allostatic Dysregulation of the Reward System

George Koob and Michel Le Moal describe the development of addiction as an allostatic dysregulation of the brain reward system. They suggest that chronic alcohol intake induces counteradaptive processes within the reward system that fail to return within the normal homeostatic range resulting into an allostatic state of anhedonia. Thus, the allostatic state represents a chronic deviation of reward set point. This state is not only caused by dysregulation of reward circuits, but also by the activation of brain and hormonal stress responses.

In order to induce an allostatic dysregulation of reward function in animals, repeated alcohol vapor exposure is used. In rodents, chronic intermittent alcohol vapor exposure (14 h ON/10 h OFF) for 8 weeks leads to long-lasting neural and behavioral plasticity. This type of manipulation produces persistently increased alcohol intake in genetically nonselected rats. Similar effects are also

observed in alcohol-preferring rat strains. For example, if alcohol-preferring rats are trained to respond for a 10% alcohol solution in an operant situation, then are exposed to chronic intermittent alcohol vapor for 8 weeks, and subsequently tested for operant alcohol responding at multiple time points during acute alcohol withdrawal and protracted abstinence (1–15 days), persistent augmented alcohol responding will be observed. In conclusion, exposure to repeated cycles of intoxication and withdrawal, which mimics the course of the clinical condition, is most effective for inducing increased alcohol drinking. Examination of drinking during protracted abstinence allows for complete dissociation of the somatic and motivational aspects of alcohol dependence, as well as separation of their respective effects on dependence-induced increases in alcohol drinking. Similar to the human condition, a minimum duration of dependence is required for lasting upregulation of alcohol preference. Importantly, elevated alcohol intake in post-dependent rats is sensitive to the clinically effective compound, acamprosate, while alcohol intake of nondependent rats is unaffected by the same treatment. Furthermore, the post-dependent state is characterized by a persistently upregulated behavioral sensitivity to stress. Together, these findings indicate that neuroadaptive processes induced by a prolonged exposure to cycles of intoxication and withdrawal parallel those in alcohol-dependent patients and will therefore be helpful for preclinical medication development.

An Animal Model to Study Alcohol-Seeking Behavior

The most common procedure to study alcohol-seeking behavior – which can be considered as the motivational component of alcohol craving – is the reinstatement model. The origin of the reinstatement model can be traced to some findings of Pavlov and Skinner, but its application in the context of drug abuse research did not appear until 1970. The first report using this procedure, as it is now actually understood, was published in the classical paper by de Wit and Stewart in 1981 and, over the last 10 years, the number of studies referring to the use of this paradigm has grown exponentially. From a procedural point of view, it is clear that any assessment of reinstatement needs to first instate the self-administration behavior to an adequate level, followed by an alcohol-free period (i.e., extinction) after which the resumption of the extinguished behavior in response to a specific trigger will be tested. These three phases can be implemented in a single (within-session design) or, more often, several experimental sessions. It is usually an operant procedure, whose schedule of reinforcement is generally a low fixed ratio (i.e., FR1) that regulates alcohol delivery and, very often, the appearance of an initially neutral stimulus (i.e.,

light). After this self-administration period, reinstatement procedures usually include an extinction phase (i.e., allowing the subject to perform the operant response, without programmed consequences) rather than an abstinence process. This procedure imposes a reduction of the face validity of the model, since rarely do humans undergo extinction, although no systematic studies have been conducted to assess its possible consequences on the construct or predictive validity of these methods. Finally, the re-emergence of this behavior in response to a specific trigger is conducted under an alcohol-free condition. This allows for studying the recovery of the extinguished behavior without the interference produced by the psychoactive effects of the drug, and the increase in the number of operant responses (compared to that observed during extinction) is understood as an enhancement of the subject's alcohol-seeking behavior. However, this factor also distinguishes preclinical reinstatement procedures of human relapse episodes. In fact, in these methods, the operant response is reinstated but the subjects, *sensu strictu*, do not relapse because they actually do not resume alcohol consumption.

In humans, alcohol priming, negative mood states, and stress or drug-associated cues are able to produce an increase of self-reported craving. Similarly, reinstatement of alcohol-seeking behavior in rodents can be induced by a small quantity of alcohol. This phenomenon is consistent with the widely reported description of the first-drink phenomenon by which ingestion of a small amount of alcohol may induce a strong subjective state of craving in abstinent alcohol-dependent subjects. This priming effect can even occur in alcohol-dependent subjects who have been abstinent for years. Stress caused by intermittent mild electric shocks to the animals' feet as well as alcohol-associated olfactory cues can also reinstate previously extinguished responding for alcohol. Data derived from studies using the reinstatement model suggest that the neuronal substrates mediating alcohol-, stress-, and cue-induced reinstatement are not identical. For example, naltrexone reduces cue-induced reinstatement of alcohol-seeking behavior whereas stress-induced reinstatement is not affected by this drug but can be blocked by CRH1 receptor antagonists. Furthermore, foot-shock stress and response-contingent presentation of an alcohol-associated light cue, acting as a conditioned stimulus also augments reinstated responding. Thus, additive effects of these stimuli on responding are observed, which demonstrate that more than one neurobiological pathway is involved in provoking alcohol-seeking behavior.

The reinstatement model of alcohol-seeking behavior is now a well-established model in rats, and has recently been replicated in mice. However, some methodological transfer problems from rats to mice have to be considered: operant tasks have to be achieved by the individual during the course of a reinstatement experiment and usually

rats acquire alcohol-directed behavior more easily than mice. The first goal which has to be achieved by an individual in the reinstatement procedure is selective responding on a reinforced lever. Usually an easy task for a rat; for mice, due to higher motor activity, it is more difficult to achieve this task. Another confounding variable in some mice strains is that lever pressing is reinforcing *per se*. The same problem might also relate to nose-poking. Thus, whether a reinforcer follows a lever press/nose poke or not, it might not influence further behavior of the mouse. Despite the problems of high-motor activity and reinforcing effects of lever pressing/nose poking, mice usually acquire selective responding under a simple FR1 for the drug although on the control lever – the nonreinforced lever – a higher number of responses is seen than in rats. The next task which has to be achieved is extinction of lever responding which means that responding is without any further consequence and the individual does not receive the drug anymore. Rats usually show a short burst of responding and then responding gradually declines over days. Usually following 4–6 days rats show only some spontaneous responses; however, this occurs on a low rate. Extinction in mice seems to be more difficult and one needs more extinction days compared to rats; again much higher rates of spontaneous responding are seen and even if a satisfying degree of extinction is achieved, spontaneous recovery of responding often occurs. In the third task, reinstatement of alcohol-seeking behavior has to be elicited. Using the reinstatement paradigm, only a few studies with mice have been reported so far. However, in the future, this paradigm will be frequently used to study conditional knock-out mice in order to pin down precisely the genes and brain sites involved in alcohol-seeking behavior.

In conclusion, the reinstatement model can be used to study the neurobiological and molecular basis of alcohol-seeking behavior since there appears to be a good correspondence between the events that induce this behavior in laboratory animals and those that provoke craving in humans. Furthermore, naltrexone is known to reduce craving in alcohol-dependent patients and can also reduce or even block cue-induced reinstatement of alcohol-seeking behavior. Nevertheless, the usefulness of the reinstatement model in mimicking craving in humans has some limitations. First, the phenomenon of craving is complex. Thus although the operational definition of craving as incentive motivation to drink alcohol has the advantage of making the phenomenon of craving measurable, such a definition neglects the fact that craving also has a subjective dimension that is difficult, if at all possible, to assess in laboratory animals. Second, it appears that extinction of alcohol-seeking behavior usually plays only a minor role in alcohol-dependent patients trying to achieve and maintain abstinence. With the exception

of patients undergoing focused extinction therapy, alcoholics generally try to avoid exposure to external alcohol cues during abstinence. In most cases, alcoholics stay abstinent for a while but may experience craving and subsequent relapse if they are re-exposed to external cues (e.g., the smell of alcohol), particularly if they are in a vulnerable internal state. Consequently, the animal reinstatement procedure may not accurately reflect the situation of abstinent alcoholics experiencing craving.

Conclusions

In summary, the last decade has witnessed advances in the field of alcohol research with the development of new animal models mimicking core features of an addictive behavior. The validity of animal models is typically assessed using three evaluation criteria, including face, construct, and predictive validity. Reliability is also a critical issue in complex animal models. At the present time, the reinstatement and alcohol-deprivation paradigms are the models for which these issues have been addressed most systematically. Another animal model in which excessive drinking occurs following a history of dependence is used by several laboratories to study the consequences of allostatic dysregulation of the reward system and, thereby, the neurochemical substrates of the addicted brain. Considerable work remains to be done to establish whether measures obtained in these and other models are valid and reliable. The refinement of these animal models and the characterization of specific reliable phenotypes within these models is a challenging process that requires a multidisciplinary research approach, involving collaboration between experimental and clinical psychologists, clinicians and, of course, the patients themselves. Nevertheless, these models can already be used to study the neurobiological foundation of alcohol craving, relapse, loss of control, and alcohol intake despite the negative consequences.

Glossary

Adult antisocial behavior (AAB) – A behavioral syndrome in which a person meets the other diagnostic criteria of the *Diagnostic and Statistical Manual of Mental Disorders Fourth Edition* (DSM-IV) for antisocial personality disorder, but not the criterion requiring the presence of conduct disorder before age 15.

Anterior cingulate cortex (ACC) – A region of the medial surface of the cerebral cortex.

Antisocial personality disorder (ASPD) – DSM-IV defines this condition as “A pervasive pattern of disregard for, and violation of, the rights of others that begins in childhood or early adolescence and continues into adulthood.”

Antisocial substance dependence (ASD) – This term may name a categorical diagnosis, combining ASPD and substance dependence, or it may name the extreme end of an externalizing trait of behavioral disinhibition.

Attention deficit/hyperactivity disorder (ADHD) – A behavioral disorder characterized by excessive inattention and/or a combination of impulsivity and hyperactivity that begins in childhood.

Cholinergic receptors (CHRs) – A family of proteins that alters the activity of cells in response to acetylcholine or related chemicals.

Conduct disorder (CD) – According to DSM-IV, this condition of children and adolescents is “a repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms or rules are violated.”

Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (Text Revision) (DSM-IV TR) – A widely used manual of psychiatric diagnoses published by the American Psychiatric Association, Washington, DC, in 2000.

Functional magnetic resonance imaging (fMRI) – A powerful technique for producing pictures that identify regions of the brain involved in processing cognitive or motor tasks.

Genome-wide association studies (GWASs) – Studies aiming to find unique DNA structures that contribute to a particular trait or disorder by examining

DNA structure across the whole genome, comparing DNA in large groups of persons who do, versus those who do not, have the trait or disorder.

Lateral prefrontal cortex (LPFC) – Usually divided into dorsolateral (upper lateral) prefrontal cortex and ventrolateral (lower lateral) prefrontal cortex, it lies on the right and left surfaces of the front of the brain.

Magnetic resonance imaging (MRI) – A powerful technique that can produce detailed pictures of brain structure. The technique allows the comparison of brain structure in persons with, or without, a particular trait or disorder.

Multisystemic treatment (MST) – One of several family and community treatments that seek to strengthen multiple domains of functioning in the lives of antisocial youths by involving the entire community (i.e., school, family, church, neighborhood, peers, and courts) to modify interactions with the youth to promote and sustain prosocial behavior.

Nucleus accumbens (NAcc) – These paired deep-brain structures are way stations in the brain reward system that responds to reinforcers. Through the mechanism of changing dopamine release, NAcc is in a key position to recognize changing contingencies and to guide behavioral change.

Orbitofrontal cortex (OFC) – It lies at the inferior front of the brain just over the eyes. Different sections of OFC, working closely with ACC, have roles in stopping (inhibiting) some risky responses; in monitoring, learning, and remembering the value of reinforcers and punishers; and in assessing the future consequences of behavior.

Posterior medial frontal cortices (pMFCs) – Two regions of cortex that face one another, each forming a part of the middle wall of a hemisphere. Included in the right and left pMFC are the right and left dorsal ACCs. The pMFCs help to detect response conflict.

Substance use disorders (SUDs) – In DSM-IV, SUDs include substance abuse and substance dependence, two related diagnoses that both involve continued use of substances despite life problems from those substances.

Definition, Comorbidity, and Clinical Course

The term ‘antisocial substance dependence (ASD)’ may have two meanings. First, it names a categorical diagnosis. Categorical disorders are discrete; each person falls into one of two categories – they do or do not have the disorder. ASD also may imply the severe end of an externalizing dimensional trait that is called behavioral (or neurobehavioral) disinhibition. Dimensional traits are continuous; each person lies somewhere on a continuum of severity ranging from trait absent to trait very severe.

ASD as a Categorical Diagnosis

In this sense, ASD is the co-occurrence within an individual of serious antisocial behavior and serious substance use disorder. This term is not used in the standard psychiatric nomenclature, the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV).

ASD's antisocial component

DSM-IV does include the antisocial diagnoses ‘conduct disorder’ (CD) for children and adolescents, and ‘antisocial personality disorder’ (ASPD) for adults. Most persons with ASD would receive one of these diagnoses. To receive the ASPD diagnosis one must have had CD before age 15. According to a recent large national survey, ASPD affects about 5.5% of adult male Americans, and about 1.9% of female Americans. Fortunately, not all youths with CD develop ASPD in adulthood, but of the 4.7% of adults who reported having met the diagnostic criteria for CD in childhood or adolescence, about three-fourths did develop ASPD.

Studies indicate that antisocial problems developing early in childhood are more likely to persist into adult ASPD. Among persons with ASD, the conduct problems usually antedate the substance problems, sometimes appearing as early as ages 3–6 years. Compared with others, these children often are excessively impulsive, exploratory, excitable, curious, and distractible, with reduced cautiousness, fearfulness, shyness, and inhibition. Such early antisocial characteristics often antedate, and lead adolescents into, extensive illicit drug use. Persons developing such early-onset substance use disorders (SUDs) tend to have early antisocial problems as well, while those developing substance problems in their third or fourth decades of life tend to have less severe antisocial problems.

ASD's substance component

In addition to an antisocial diagnosis, most persons with ASD would also be diagnosed with an SUD. DSM-IV includes two SUDs: substance dependence and substance abuse; either can be fatal, but substance dependence usually is the more serious condition. Therefore, we focus here on

the comorbid association of antisocial problems with substance dependence. A recent national survey estimated the ever-in-your-life prevalence of substance dependence among adult Americans to be 12.5% for alcohol dependence and 2.6% for other substances (excluding nicotine, for which dependence is much more common).

Often, in fact, persons with ASD receive several diagnoses. One person, for example, might have DSM-IV diagnoses of ASPD, nicotine dependence, cannabis dependence, and methamphetamine dependence. However, despite such multiple, co-occurring DSM diagnoses, the combined antisocial and substance problems *per se* warrant clinical and research attention because of their comorbid prevalence (discussed next), and because they may share a common etiology (discussed below).

The comorbid prevalence of antisocial and substance use disorders strongly argues for considering them together. For example, alcohol dependence is about 8 times more prevalent among persons with ASPD than among the general population. For other drugs, such as stimulants, opioids, or marijuana, dependence is 17–23 times more common among those with ASPD, compared with persons in the general population. Clearly, these disorders co-occur far more frequently than would be expected by chance alone. This strong comorbidity of antisocial and substance problems holds true in both sexes, and in Asian as well as Western countries. It also holds among younger persons. A large survey of adolescents in the Great Smoky Mountain region found that (in comparison with other youths) boys were about 6 times, and girls about 30 times, more likely to have SUD if they had CD.

Additional comorbid disorders

In addition to their antisocial and substance use disorders, persons with ASD often have other comorbid disorders. Thirty to fifty percent of adolescents with substance dependence and CD also have attention-deficit/hyperactivity disorder (ADHD), and the reverse also is true. Compared with youths in the general population, those with CD are about 24 times more likely to have ADHD. Furthermore, many youths with ASD, having experienced significant abuse, neglect, or other trauma, suffer from posttraumatic stress disorder. Finally, major depression is common in adolescents with ASD.

ASD as a Dimensional Trait

Many clinicians and researchers productively consider ASD to be the severe end of an absent-to-very-severe dimensional continuum of combined impulsive, risk-taking antisocial, and drug-using behaviors. For example, one research group examined the number of adolescent CD symptoms reported by a large sample of

American adults; many had no CD symptoms, others had a few, and some had many. The range of those adolescent symptom counts associated very significantly with the number of different substances that, by adulthood, had caused problems for the subjects; more symptoms of adolescent CD predicted more drug involvement.

Many researchers have studied adult antisocial behavior (AAB), a syndrome consisting of the adult symptoms of ASPD, but with no history of childhood CD. A large national survey found that over 12% of adult Americans meet those criteria, and SUD is about as common in them as in ASPD. Since they do not have ASPD, they could not qualify for a categorical diagnosis of ASD, as described above. However, combined antisocial and substance problems would place many of them at the severe end of a dimensional trait of ASD.

Risk-taking, behavioral disinhibition, and ASD

Risk-taking is a behavior that unpredictably may result in either, or both, reinforcing or punishing outcomes. Risk-taking in competitive sports, high-altitude mountaineering, or stock day trading is not pathological and may be adaptive. However, when the possible punishing outcomes are very severe or endanger others, continued risk-taking is pathological, and tends to be associated with substance dependence.

Extensive substance use is itself a risk-taking behavior that often produces severe, punishing outcomes. Abused drugs do produce rewards by directly activating a brain reward system, but with uncertain street doses, those rewards are unpredictable. Drugs also unpredictably may result in severe punishments, such as overdoses, arrests, school expulsions, psychosis, seizures, cerebrovascular pathology, compulsive drug seeking, or withdrawal.

Antisocial behaviors can also result in either reinforcing or punishing outcomes, or both, for the perpetrator, often harming others as well. Risk-taking actually is a central characteristic of CD and ASPD, with many of the defining symptoms of those disorders being risk-taking behaviors: stealing, fire-setting, break-ins, truancy, reckless disregard for safety, etc. Patients describe such behaviors as exciting, but doing them requires considerable disregard for potential adverse consequences. For example, early-onset sexual intercourse, with possibly major adverse consequences, is much more common among adolescent girls with CD than among others. Antisocial persons' risk-taking disposition also makes them more likely to try available substances, and less likely to abstain when adverse effects arise, thus enhancing their vulnerability to SUD.

So risk-taking is one important component that ties together antisocial and substance problems. However, this three-cornered relationship is complex, because substances themselves may induce greater risk-taking. Even

when abstinent, adults and adolescents with antisocial and substance problems do take more risks than others in standardized laboratory tests, but intoxication with either alcohol or marijuana further increases risk-taking in such tests.

Summary

Persons who had antisocial, aggressive, and hyperactive behaviors in early childhood are quite likely to develop adolescent CD and adult antisocial problems, usually with serious SUD. Those, whose problems begin before age 10, especially if they later developed ASD, have an especially unfavorable prognosis. Indeed, many adolescents with CD will have persisting antisocial problems for decades. Mortality rates among such adolescents considerably exceed those of their age-mates. ASD, the combination of serious antisocial problems and substance dependence, comprises a profound, devastating, often persisting, life-threatening condition.

Etiology

Contributions of Genes

The strong comorbidity of SUDs and antisocial disorders in ASD apparently is no random accident. Several research groups have used CD symptom counts, symptom counts of other childhood disorders, and various psychological measures (including novelty seeking) to define a latent psychological trait that may underlie this comorbidity. They variously have called this an externalizing trait, behavioral disinhibition, or neurobehavioral disinhibition. Research shows that high neurobehavioral-disinhibition scores at ages 12–14 strongly predict SUD in early adulthood.

Persons with ASD, having many antisocial and substance problems, comprise the severe end of a behavioral disinhibition continuum, and genes contribute to this continuum. For example, early adoption studies showed that adoptees whose biological parents had antisocial and substance problems were at increased risk to develop similar problems. Moreover, alcohol problems in the biological families predicted increased nonalcohol drug use in the adoptees. These probably are genetic effects, since biological parents determine an adopted child's genetic make-up, but have little impact on the environment in which the child is raised.

Two research groups found that behavioral disinhibition was very strongly heritable (i.e., heavily influenced by genes); genes accounted for about 80% of the variance among individuals on this underlying trait. By contrast, studies that separately consider antisocial disorders or SUDs find that genes contribute only about half of the

variance for the individual disorders. Another group studied SUD, CD, and AAB in young adults using a gambling task and found that insensitivity to future consequences was related to the severity of the combined scores for the disorders, a disinhibitory dimension, but not to the severity of any one disorder. Similarly, a twin study found evidence for a single externalizing genetic influence (which could be multiple genes working together) on SUD, CD, and AAB.

After studying antisocial and substance disorders, Hicks and his colleagues concluded that, “parents pass on to the next generation . . . a general vulnerability to a spectrum of [these] disorders, with each disorder representing a different expression of this general vulnerability.” Dick and her associates agree, stating “that shared genetic factors influence a spectrum of externalizing disorders, including alcohol dependence, illicit drug dependence, conduct disorder, antisocial behavior, and disinhibitory personality traits.” However, although behavioral disinhibition appears to be highly heritable, researchers do suspect that several genes are involved, each contributing only a small effect.

Several genes have been suggested to play a role in antisocial and substance problems. Acetylcholine-related CHRM2 may contribute to an externalizing trait, and perhaps specifically to alcohol dependence. Other acetylcholine-related genes, CHRNa6 and CHRNb3, may be involved in nicotine dependence. In addition, GABRA2 and ADH4 are suggested as important in alcohol dependence. Newer genome-wide association studies (GWASs) are the most promising contemporary approaches for identifying genes influencing complex traits (such as ASD), traits influenced by the environment and by many genes, each with a small individual effect. GWASs require that several thousand individuals, some with the disorder and some community controls, provide both genetic samples and information on their behaviors (e.g., their antisocial and substance using behaviors). Several such studies currently are in progress, and it is widely hoped that complex statistical procedures will reveal relationships between specific genetic variants and the broadly externalizing behaviors of ASD, an approach already successful with more isolated disorders related to nicotine and alcohol use.

However, practical applications of ASD genetics remain for the future. Complex traits are aptly named, and identifying numerous genes, each with a small effect on the disorder, will not lead immediately to genetic or pharmaceutical interventions. Rather, GWASs findings will gradually shed light on the biological basis of these disorders, including chemical mechanisms and neural pathways. Only then will converging evidence suggest new interventions for the genetic factors contributing to these disorders.

Contributions of Environment

Environment also contributes to ASD. Among children adopted away at birth, in addition to genetic influences from biological parents, environmental factors present in adoptive families, most notably divorce and psychiatric disturbance, apparently contribute to increased drug abuse. In addition, adopted children raised in an antisocial environment are at greater risk for antisocial behaviors and SUD. Similarly, children with highly antisocial fathers tend to fare better when raised by a single mother, rather than by both parents. Furthermore, childhood maltreatment (abuse and neglect) apparently exacerbates adolescent ASD.

Gene–Environment Correlation

In addition to independent risks for ASD from genetic and environmental factors, a gene–environment correlation for ASD produces a double-whammy of risk factors. Some children are at high biological risk for ASD because they inherited deleterious gene variants from parents with ASD. Then, during the toddler years, the parents, often antisocial and substance dependent themselves, fail to effectively reward prosocial behavior or to punish non-compliant, aggressive behavior. The family models antisocial and substance-using behaviors, providing an environment that further enhances risks for the genetically at-risk child.

Neuroscience

The shared genetic influences on antisocial and SUDs, discussed above, presumably are mediated in the brain, which clearly is central to ASD’s behavioral abnormalities. Other articles in this encyclopedia extensively address neural mechanisms in drug seeking, drug reward, and drug withdrawal. However, our review suggests that a genetically influenced externalizing trait called behavioral (or neurobehavioral) disinhibition underlies the excessive risk-taking that leads persons with ASD to recklessly engage in sometimes-rewarding, but often punishing, antisocial and drug-using behaviors. Thus, we focus here on neural mechanisms that may contribute to a failure of restraint in persons with ASD.

One consistent brain finding in ASD concerns abnormal electroencephalographic (EEG) responses to infrequent oddball stimuli. The normal EEG response to such stimuli mainly occurs over the frontal cortex as a P300 wave. P300 is suppressed in adults with antisocial and substance problems, and even in their children not yet exposed to substances. Among nearly 1000 community adolescents, externalizing scores, constructed from symptom counts for CD, ASPD, and SUD, better predicted P300 suppression

than did symptom counts for any of the disorders considered alone. This indicates a strong relationship between the P300 brain response and the externalizing trait that underlies both the antisocial and substance problems of ASD.

Frontal lobe injuries produce a frontal disinhibition syndrome, with impairments of judgment, insight, and foresight. The behavior of persons with ASD often resembles that syndrome. Indeed, in a few case reports, youths with CD-like syndromes actually did suffer early frontal brain injuries. Brain imaging techniques, such as positron emission tomography, and especially magnetic resonance imaging (MRI) and functional magnetic resonance imaging (fMRI), now provide extraordinary four-dimensional images of the structure and neural activity of human brain. These techniques allow researchers to ask whether there are structural differences, or differences in neural activity, between the brains of living human beings who do, or do not, have ASD.

Growing evidence suggests that without brain injury even substance dependent or antisocial adults have subtle structural abnormalities in frontal lobes and their connections, perhaps contributing to flawed decision making, increased risk-taking, and ASD. Even youngsters with CD reportedly have reduced structural volumes of insula, amygdala, temporal lobes, hippocampus, and ventromedial cortex. Brain structure may affect brain function. For example, researchers recently measured the neurobehavioral disinhibition of young adolescents. Then, in an fMRI machine, the youths did a task that required occasionally inhibiting a movement of the eyes. Those youths with higher neurobehavioral disinhibition scores had significantly less frontal-lobe activation as they tried to inhibit the movement; their frontal lobes functioned differently.

Neural Equipment for Risk Decisions

Each person's world changes constantly, and a behavior that safely gained things of value yesterday may not do so today. Therefore, the brain must continually monitor ones' success at gaining reinforcers and avoiding punishers. A network of brain regions constantly monitors, anticipates, and weighs response conflicts and risky potential gains and losses (Figure 1). Persons with ASD excessively do risky antisocial and drug-using behaviors, pursuing reinforcers despite the danger of very harmful punishers. We now review evidence that substance-involved adults considering risky decisions show hypoactivity in the brain's risk-decision network. Our review above suggests that genes and life experience in the environment may influence this hypoactivity. In addition, the drugs consumed by persons with ASD may persistently, adversely affect brain function.

The posterior medial frontal cortices (pMFCs) comprise parts of the risk-decision network. These two

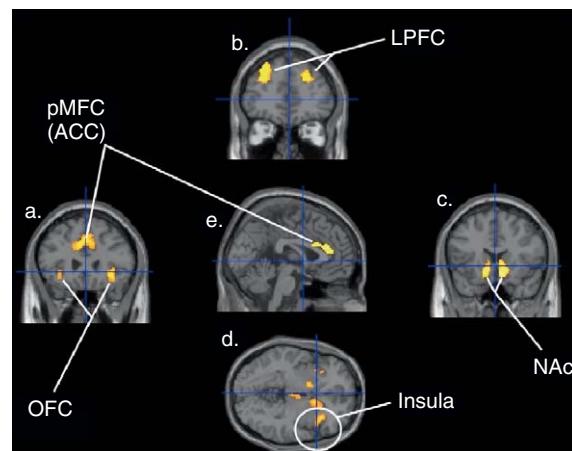

Figure 1 Functional magnetic resonance images showing group-average activation sites among adolescent boys as they worked on a cognitive risk-taking task. (a–c) coronal slices (as though viewed looking forward through the back of the head). (d) Axial slice (as though viewed looking down through the top of the head, forehead at right). (e) Sagittal slice through brain midline (as though viewed from right side of head). Abbreviations: ACC, anterior cingulate cortex; LPFC, lateral prefrontal cortex (shown is the dorsal, or upper, portion of LPFC); NAc, nucleus accumbens; OFC, orbitofrontal cortex (regions shown are in Brodmann Areas 47, considered part of OFC by most authors); pMFC, posterior medial frontal cortex, including ACC (which is activated here). See text for description of sites' functions.

regions of cortex face each other, each forming part of the middle wall of a hemisphere. Included in the right and left pMFCs are the right and left dorsal anterior cingulate cortices (ACCs). The pMFCs are critical for detecting response conflict (e.g., choosing whether to do, or not do, behaviors that could produce either rewards or punishments). The pMFCs also monitor behavioral outcomes (reinforcement and punishment), and based on that monitoring, the pMFCs signal other brain regions to adjust behavior to maximize reinforcement. People with ASD often persist with antisocial or drug-using behaviors that had been reinforced, but which later mostly earned punishment; they fail to adjust behavior normally. Among now-abstinent adults with substance dependence, the pMFCs are hypoactive during risk-taking tasks. Children and adolescents with antisocial problems and psychopathic traits show neural hypoactivity in the nearby ventromedial prefrontal cortex while doing a task requiring rapid strategy changes to earn rewards. These critical outcome-monitoring and behavior-adjusting regions apparently fail to operate normally among persons with antisocial and substance problems.

Orbitofrontal cortex (OFC), another part of the risk-decision network, lies at the inferior front of the brain just over the eyes. Different sections of OFC, working closely with ACC, have roles in stopping (inhibiting) some risky responses; in monitoring, learning, and remembering the

value of reinforcers and punishers; and in assessing the future consequences of behavior. OFC definitely malfunctions in substance-dependent persons, among whom several studies report structural gray-matter volume reductions in OFC, while functional studies find neural hypoactivity there.

Insula, an infolded, buried region of prefrontal cortex, is another part of the risk-decision network. In risky decision making it apparently evaluates recent, and estimates future, losses or punishments from risky behaviors. Neural activity of the insula correlates with the ambiguity, uncertainty, and complexity of risky choices, and the insula also is thought to adjust its assessment of risk when contingencies change. Boys with CD reportedly lack gray-matter volume in the insula, and the extent of that reduction correlates with their aggressive behavior and lack of empathy. Some researchers even suggest that the intensity of neural activity of the insula is an endophenotype (an internal biological marker) for a risk-taking personality, which is central to ASD.

NAcc, paired deep-brain structures, also participate in the risk-decision network. Way stations in the brain reward system that responds to reinforcers, the NAcc help drive repetition of whatever behaviors have gained reinforcement. All abused drugs activate that system, and that behavior-driving effect of the reward system is thought to underlie the compulsive, driven nature of substance dependence; drugs commandeer the reward system that normally drives people to repeat behaviors that gain valuable reinforcers, such as food, water, social contact, or sexual opportunity. The drugs' activation of the reward system similarly drives repetition of drug-using behaviors. When a new reinforcer is presented, NAcc activates. However, after repeated experience with the reinforcer, NAcc begins to activate in anticipation of the reinforcer, presumably responding to stimuli associated with the reinforcer (e.g., a sound announcing the imminent delivery of food). Moreover, NAcc responds more strongly to unexpected reinforcers, and deactivates when a reinforcer is expected but not delivered. Thus, through its principal mechanism of changing dopamine release, NAcc is in a key position to recognize changing contingencies and to guide behavioral change. However, among detoxified alcohol-dependent persons dopamine release in NAcc is profoundly attenuated, suggesting that for these people NAcc's ability to guide adaptive behavior change is impaired.

Lateral prefrontal cortex (LPFC, usually divided into dorsolateral prefrontal cortex and ventrolateral prefrontal cortex) lies on the right and left sides of the front of the brain. Subdivisions of the LPFC are involved in critical executive functions: inhibiting some behaviors; formulating conscious plans and intentions; regulating choices

among different actions, based on current environmental circumstances; directing attention to the most salient current stimuli; monitoring the contents of working memory to use memories in choosing behaviors; and using information stored in other brain regions to make active judgments. As currently drug-free, substance-dependent persons work on a risk-taking task, the right dorsolateral PFC, so crucial to planned behavior, is hypoactive. Curiously, however, the left dorsolateral PFC reportedly is overactive.

An Integrated Network

The above structures and others, probably including thalamus, caudate nucleus, putamen, cerebellum, and some cortex of the superior temporal gyrus, function as an integrated network to make choices about doing, or not doing, risky behaviors. In some regions of this network, persons with ASD have less gray matter than do normal controls. Moreover, among such persons several of these regions show functional hypoactivity on fMRI during decision making. These findings support the view that reduced neural activity in this network may underlie the excessive antisocial and drug-use risk-taking of persons with ASD.

Prevention and Treatment

Early Prevention-Intervention Strategies

ASD typically begins in childhood or adolescence, so early interventions have been widely studied. Such interventions fall into three major groups. First, parent management training is aimed at modifying the interactions between parent and child that may support antisocial and drug-using behaviors. Second, social-cognitive and problem-solving skills training aim to improve problem-solving skills, perceptions, self-statements, and self-attributions. In particular, these cognitive interventions help adolescents consider precursors, correlates, and consequences of their antisocial and drug-using behaviors. Of Dutch youths treated with these procedures for CD-like disorders as pre-teens, fewer (compared to a treatment-as-usual group) were found at a 5-year follow-up to be using drugs, and delinquency rates were similar to those of community controls. Third, for children at high risk, school-based interventions show considerable promise. A recent study followed children who, in first- or second-grade, had received an intervention rewarding teams of children for avoiding disruptive behaviors. When followed in early adulthood, students who had received the intervention (compared to those without it), especially boys who were very aggressive when beginning school, had significantly lower rates of ASPD and violent crime.

Psychosocial Treatments

Once CD and SUD develop in adolescence, family and community treatments, such as multisystemic therapy (MST), seek to strengthen multiple domains of functioning in the lives of the youth. These therapies aim to enlist the entire community (i.e., school, family, church, court, neighborhood, and peers) to modify interactions with the youth to promote and sustain prosocial behavior. Such interventions appear to be effective, although such short-term treatments may not adequately address the long-term needs of these youths and their families. For example, among juvenile offenders with SUD, a 4-year follow-up after MST (compared with treatment-as-usual) found in the MST group reduced aggressive crimes, no difference in property crimes, and a worse outcome on biological tests for substances.

For drug-dependent adults, many of whom have ASD, many studies document the benefit of several psychosocial treatments. However, an extensive review of that literature is beyond the scope of this article.

Medications

Many medications have been shown to improve outcome among nicotine, alcohol, and opioid-dependent persons. Strong evidence indicates that concurrent psychosocial treatments improve responses to such medications. Unfortunately, no medications have been shown consistently to improve antisocial disorders. Furthermore, although multiple medications may benefit other psychiatric disorders commonly comorbid with ASD, such as depression, anxiety disorders, or attention-deficit/hyperactivity disorder, such treatments do not appear to alter the course of the ASD itself.

Treatment or Punishment

The antisocial behavior of persons with ASD often involves them in the criminal justice system. Many serve prison sentences without effective treatment and without the on-site family and social supports that help to treat these disorders. However, some collaborations of the criminal justice and treatment systems show great promise. For example, specialized drug courts can deploy their coercive authority, giving offenders a choice: successfully participate in effective treatment or go immediately to jail. Although more research is needed, that imposed change in the reward–punishment equation appears to motivate more pro-therapeutic and prosocial decision making.

Summary

Antisocial and substance problems co-occur much more often than would be expected by chance. Genes strongly

influence the development of these disorders, with the same or closely linked genes contributing to both the antisocial and substance problems. Those genetic abnormalities presumably contribute to the brain-structure abnormalities found in children with CD, even before the children would have had much drug exposure. In addition, many of these youths are raised by antisocial and substance-involved parents in a vulnerability-enhancing environment. Abuse and neglect may further exacerbate their problems. Then, during adolescence, most youths with CD develop serious substance problems, apparently related to the risk-taking behavioral disinhibition that underlies both the antisocial and substance problems. The abused drugs may further adversely affect brain function. By adulthood, persons with ASD have significant neural hypofunction in several regions of a network that regulates risk-taking behavior, and that presumably contributes to the persistent high-risk antisocial and substance-using behaviors that characterize ASD.

The substance use and antisocial behavior of ASD appear to be different manifestations of a primary neurogenetic disorder that produces a trait of behavioral disinhibition, which in turn may be exacerbated by life experiences and by ingested substances. Environment apparently can make it worse (e.g., by gang involvement) or better (e.g., by treatment). Treatment clearly is effective in the short run. However, ASD treatments usually last, at most, a few months, and the underlying brain disorder still can be detected even during treatment. After treatment ends, the persisting brain disorder and its associated behavioral disinhibition presumably contribute to the observed high rates of relapse. Our review suggests that effective ASD treatment should not be episodic, with each brief episode aiming at a cure. Rather, ASD treatment, like effective diabetes treatment, should aim at lifelong management of this chronic disorder.

Disclosure of Support: Potential Conflicts of Interest

Preparation of this article was supported by Grants DA-009842 and DA-011015 from the National Institute on Drug Abuse, and by a donation from the Kane Family Foundation. Dr. Crowley receives travel support from the American Psychiatric Association to participate in the Association's revision of DSM-IV. Following submission of this article, Dr. Gelhorn, formerly with the University of Colorado Denver, took employment with United BioSource Corporation, a firm that provides contract support for pharmaceutical research projects.

Glossary

Addiction – A chronic, relapsing brain disease that is characterized by compulsive drug seeking and use, despite harmful consequences. It is a brain disease that results from the long-lasting changes in brain neurochemistry and function that occur with repeated drug exposures in vulnerable individuals (because of genetics, development, or adverse environments). These brain changes are long lasting and persist for months after drug discontinuation, which accounts for the chronic nature of addiction. Abuse and addiction to alcohol, nicotine, and illegal substances cost Americans upward of half a trillion dollars a year, considering their combined medical, economic, criminal, and social impact. Every year, abuse of illicit drugs and alcohol contributes to the death of more than 100 000 Americans, while tobacco is linked to an estimated 440 000 deaths per year.

Dopamine (DA) – All drugs of abuse directly or indirectly target the brain's reward system by flooding the circuit with DA, which is a neurotransmitter present in regions of the brain that regulate movement, emotion, cognition, motivation, reward and prediction of reward, and learning (conditioning, habits). The overstimulation of this system, which rewards our natural behaviors, is associated with the euphoric effects sought by people who abuse drugs increasing the likelihood that they will repeat the behavior. It also associates the environment where the drug was taken with the drug itself (conditioning) so that when the individual is in the same environment DA will increase in the limbic brain in expectation of receiving the reward.

Mesocorticolimbic – A circuit of extended brain network that spans the midbrain (predominantly the ventral tegmental area) and the limbic system (the nucleus accumbens (NAcc), amygdala, hippocampus, hypothalamus, and the medial prefrontal cortex). The functional integration within this vast brain system, which relies heavily on dopaminergic transmission, contributes to or mediates complex behavioral outputs, such as response to emotional and rewarding stimuli, motivation, learning, memory, and higher cognitive function.

Positron emission tomography (PET) – The imaging technique that takes advantage of short-lived positron emitters used to label various compounds that are used

to measure the concentration of receptors, transporters, and enzymes in the human brain as well as to measure brain glucose metabolism and cerebral blood flow and to measure the distribution and movement of a drug.

Striatum – Dopaminergic cells, which are predominantly located in the ventral tegmental area (VTA) and the substantia nigra (SN) in mesencephalon send projections to various cortical (most dense in prefrontal cortex) and subcortical regions. The main projection is to the striatum, which receives innervation from SN (predominantly dorsal striatum) and the VTA (predominantly to the ventral striatum where the NAcc is located). All of the drugs of abuse increase DA in the NAcc (their mechanism by which they do it being distinct for the various classes of drugs) and this effect is believed to underlie their reinforcing effects.

Imaging the Relationship between Acute Dopamine Increases in the Human Brain and Drug Reinforcement

One of the major roles of dopamine (DA) is to optimize memory, learning, motivation, and attentional processes along the mesocorticolimbic axis. Addictions involve profound disruptions in these cognitive domains, and it is not surprising that some form of DA dysregulation can be found in substance use disorders. Indeed, the vast majority of addictive drugs has the ability to rapidly increase extracellular DA levels in nucleus accumbens (NAcc), a key structure of the limbic system. These DA surges resemble but greatly surpass the physiological increases that are triggered by the phasic DA cell firing that conveys information about saliency, reward, and reward expectation.

Human brain imaging studies have been mostly consistent with the notion that drug-induced increases in DA in the dorsal and ventral striatum (the location of the NAcc) are closely linked to the subjective experience of reward or euphoria. However, as drug use continues, the repeated firing of DA cells begins to upset the balanced neurochemistry required to support plastic changes in associative learning circuits, facilitating the consolidation of maladaptive memory traces that are connected to the drug. These can then trigger the firing of DA cells upon

exposure to any number of contextual stimuli that happen to be associated with the drug (in expectation of the reward). In addition, due to DA's role in motivation, its increased association with the drug-cues, or with the drug itself, is also likely to modulate the drive to secure the reward.

This better understanding of DA's multiple roles in the reinforcement process has resulted in a more coherent model of drug addiction, according to which drugs are reinforcing not only because they are pleasurable but also because, by increasing DA, they are processed as salient stimuli that will inherently motivate the procurement of more drug (whether the drug is consciously perceived as pleasurable or not). This model continues to evolve, largely thanks to the increasing use of sophisticated brain imaging techniques that allow us to (1) measure neurochemical and metabolic processes in the living human brain; (2) investigate the nature of the changes in DA induced by drugs of abuse and their behavioral impact; and (3) study the long-term plastic changes in brain DA activity and its functional consequences in drug-addicted subjects.

The use of positron emission tomography (PET) with DA, D2 receptor radioligands (e.g., [¹¹C]raclopride, [¹⁸F]N-methylspiroperidol, and the more recent [¹¹C]-(+)-4-propyl-9-hydroxynaphthoxazine) have allowed the study of the involvement of DA in drug reward and addiction in the human brain. This includes studies that investigate the relationships between the ability of various drugs to modulate DA and their reinforcing (i.e., euphorogenic, high-inducing, and drug-liking) effects, both in nondependent and in drug-dependent individuals. Using [¹¹C]raclopride, these studies have shown that stimulant drugs (such as methylphenidate, amphetamine, and cocaine), nicotine and alcohol, increased DA in striatum in the human brain, whereas opiates did not. Failure to see an effect with opiates could reflect the limited sensitivity of the PET method since opiates elicit relatively small DA responses in rats, but it could also reflect a minor role of DA in the subjective experience of heroin in opioid addicts. This is in contrast to other drugs for which the DA increases have been associated with their reinforcing effects. For example, both the intravenous (i.v.) administration of methylphenidate (0.5 mg kg^{-1}), which like cocaine, increases DA by blocking DA transporters (DAT), as well as that of amphetamine (0.3 mg kg^{-1}), which like methamphetamine, increases DA by releasing it from the terminal through DAT, can increase extracellular DA concentration in the striatum and that such increases are associated with self-reports of 'high' and 'euphoria.' In contrast, orally administered methylphenidate ($0.75\text{--}1 \text{ mg kg}^{-1}$), which can also increase DA, is not typically perceived as reinforcing. The difference between the i.v. and oral administration of methylphenidate with respect

to their reinforcing effects most likely reflects the fact that the i.v. route leads to DA changes that are much faster than those observed after oral administration. Thus, the failure of oral methylphenidate – or amphetamine – to induce a 'high' is likely due to slower pharmacokinetics (slower brain uptake). This is because the speed with which drugs of abuse enter the brain is a key parameter that affects their reinforcing effects; the faster their brain uptake, the more intense are their reinforcing effects. Similarly, DA increases in ventral striatum induced by smoking, which has very fast rate of brain uptake, are also associated with its reinforcing effects. More precise details on DA's actions in the human brain and their relationship to rewards will continue to evolve as new radioligands with improved selectivity and sensitivity are developed. For example, recent experiments with [¹¹C]-(+)-4-propyl-9-hydroxynaphthoxazine (PHNO), a novel D2/3 agonist radioligand in humans appears to be more sensitive to the DA-releasing effect of amphetamine than the D2/3 antagonist [¹¹C]raclopride (Figure 1). The collected evidence, albeit not conclusive, appears to point to an important contribution of D3 receptor binding to the differential patterns of displacement observed with this novel ligand. The DA D3 receptor is of particular interest because it has been implicated in the establishment of addictive behaviors and is a target for medication development in addiction.

The close correlation between the fast uptake of a drug into the brain, the rapid changes in extracellular DA in the striatum, and its reinforcing properties suggests the involvement of phasic DA firing. Phasic release at frequencies of $>30 \text{ Hz}$ cause abrupt fluctuations in DA levels that contribute to highlighting the saliency of a stimulus. In contrast, tonic DA cell firing, with frequencies of $\sim 5 \text{ Hz}$, serves to maintain the baseline steady-state DA levels that set the threshold of the DA system's responsiveness. This has led to the notion that drugs of abuse manage to induce changes in DA concentration that mimic, but greatly exceed those produced by physiologic phasic DA cell firing. However, the outcome of such DA increases – even when supraphysiologic – will be contingent upon other factors, such as expectation of a particular outcome and context of administration. This dependency of a drug's effects on its context of administration is likely to reflect prefrontocortical regulation of DA cell activity and DA release in the NAcc.

In contrast, oral administration of stimulant drugs, which is the therapeutic route, is more likely to induce slow DA changes, more akin to those provoked by tonic DA cell firing. However, since stimulant drugs block DATs, which are the main mechanism for DA removal, they have the potential to increase the reinforcing value of other reinforcers (natural or drug rewards), even when administered orally by amplifying weak DA signals.

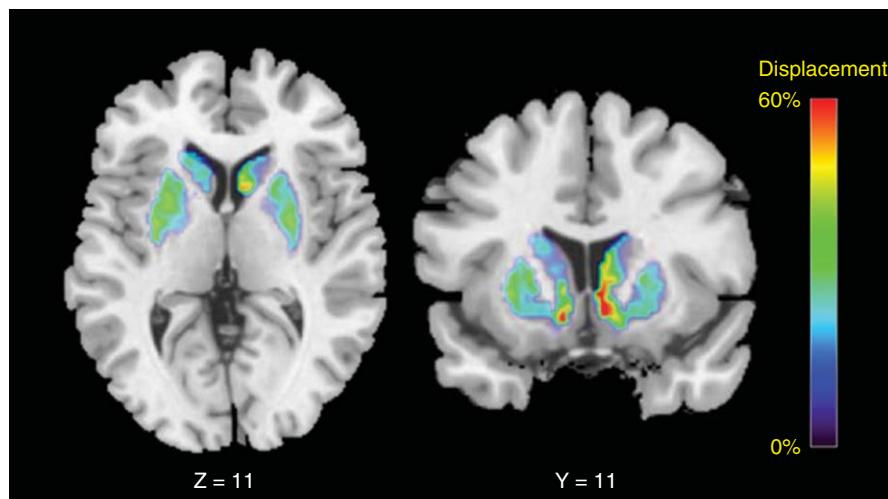

Figure 1 Colored areas show percent decrease in $[^{11}\text{C}]$ - $(+)$ -PHNO binding potentials (BPs) in *d*-amphetamine scans as compared to placebo scans. Image represents mean image of nine individual subtraction images calculated as $(\text{BPmap placebo-BPmap } d\text{-amphetamine/BPmap placebo}) \times 100$. Reproduced with permission from Willeit M, Ginovart N, Graff A, Rusjan P, et al. (2008) First human evidence of *d*-amphetamine induced displacement of a D2/3 agonist radioligand: A $[^{11}\text{C}]$ - $(+)$ -PHNO Positron emission tomography study. *Neuropsychopharmacology* 33(2): 279–289.

Similarly, nicotine, which facilitates DA cell firing, can also enhance the reinforcing value of stimuli with which it is paired. Thus, the combination of nicotine with natural rewards becomes inextricably linked to its reinforcing effects. Since nicotine is smoked throughout the day, blending with an individual's everyday activities, it makes smoking a particularly entrenched behavior, since a virtually unlimited number of everyday activities can become conditioned to nicotine and thus trigger drug craving in the smoker. This is in sharp contrast to other drugs, which are typically abused in very specific and therefore, more limited settings (i.e., bar, dealer's house, and parties).

The usefulness of the PET technique to explore the importance of pharmacokinetics on the reinforcing effects of drugs of abuse stems in part from the ability to label the drugs of abuse with the positron-emitting isotope ^{11}C , which can be substituted for a regular C without affecting the pharmacological properties of the drug. This allows not only for the measurement of its *in vivo* kinetics in the human brain, but also for a detailed mapping of the drug's potential target sites in the brain and periphery. Using this strategy it was possible to measure the pharmacokinetics in brain of cocaine, methamphetamine, toluene, nicotine, and salvinorin. In addition, it is worth mentioning the use of PET to study the availability of drugs in the fetus of nonhuman primates, as illustrated by a PET study done in pregnant nonhuman primates which showed that $[^{11}\text{C}]$ cocaine readily crosses the placenta and accumulates in the fetal liver and to a lesser extent in the brain.

Long-Term Effects of Drugs of Abuse on DA in the Human Brain: Involvement in Addiction

It is important to underscore the fact that even though drug-induced surges in synaptic DA occur in both addicted and nonaddicted individuals, only a minority of exposed subjects – the actual fraction being a function of the type of drug used – ever develop a compulsive drive to continue taking the drug. This is the reason that DA increases alone are insufficient to explain the start of an addiction trajectory. Chronic drug administration is a prerequisite for the development of a drug addiction, which suggests that addictions hinge – in vulnerable individuals – on the ‘repeated’ perturbation of the DA system. Over time, these perturbations are thought to induce neuroadaptations in reward/saliency, motivation/drive, inhibitory control/executive function, memory/conditioning, and mood/stress circuits, all of which are known to be modulated by dopaminergic pathways.

In fact, there is growing evidence that supports this notion. Chronic exposure to stimulants, nicotine, or opiates can induce persistent adaptive changes in the structure of dendrites and dendritic spines on neurons in key brain circuits with roles in motivation, reward, judgment, and inhibitory control of behavior. This observation becomes particularly significant when we consider that the induction of long-term potentiation (LTP) is often associated with measurable increases in the size of dendritic spines and their associated structures.

Drug-induced DA perturbations are likely to have both direct and indirect effects on the maladaptive rewiring of neural circuits. DA (as well as other neurotransmitter systems) is a versatile modulator of synaptic plasticity in its own right. In addition, chronic adaptations in DA receptor signaling may trigger, for example, compensatory glutamate receptor responses with the potential to affect synaptic plasticity. It is interesting to note in this context that, while DA receptors can be found throughout the neuron, there is growing evidence of their increased concentration in dendritic spines, which also feature the highest density of glutamatergic synapses. Thus, the various combinations of postsynaptic DA receptor types are strategically located to influence the synaptic properties of spines through the accurate decodification of tonic and phasic trains of DA signals, while also modulating glutamatergic neurotransmission.

When combined, these observations draw a direct path connecting the effects of drugs of abuse with the adaptive alterations, not only in reward centers but also in many other circuits, through the strengthening, formation, and elimination of synapses.

Effects on Reward and Motivation Circuits

The availability of several radiotracers has allowed researchers to monitor both transient as well as persistent

neurochemical changes in the DA network of the human brain (**Table 1**). It has been shown, using [¹⁸F]N-methylspiroperidol, [¹¹C]raclopride, or [¹¹C]-(+)-4-propyl-9-hydroxynaphthoxazine that subjects addicted to a wide range of drugs (e.g., cocaine, heroin, alcohol, methamphetamine, and nicotine) exhibit significant reductions in D2 DA receptor availability in the striatum (including ventral striatum) that persist for months after protracted detoxification.

It has also been observed that the striatal increases in DA levels induced by i.v. methylphenidate or i.v. amphetamine (and assessed with [¹¹C]raclopride) in cocaine abusers and alcoholics are at least half of what is seen in control subjects. Since DA increases induced by methylphenidate are dependent on DA release – a function of DA cell firing – it is reasonable to hypothesize that the difference likely reflects decreased dopaminergic cell activity in these drug-abusing populations.

While evaluating the results of PET studies based on the competition of [¹¹C]raclopride by endogenous DA, it is critical to remember that the results merely reflect the fraction of D2 DA receptors that is vacant and thus capable of binding the tracer. As a consequence, any reduction in D2 DA receptor availability measured with this technique could reflect either ‘decreases’ in levels of D2 DA receptors and/or ‘increases’ in DA release (competing for binding with [¹¹C]raclopride for the D2 DA

Table 1 Summary of PET findings comparing various targets involved in DA neurotransmission between substance abusers and control subjects for which statistically significant differences between the groups were identified

Target investigated	Drug used	Finding
D2 DA receptors	Cocaine	↓ Acute withdrawal ↓ Detoxified
	Alcohol	↓ 1–68-week abstinence ↓ Detoxified
	Methamphetamine	↓ Detoxified
	Heroin	↓ Active user
	Nicotine (via cigarette smoking)	↓ Active user
	Cannabis	0 Detoxified 0 Early remission
DA transporters	Cocaine	↑ 4 weeks abstinence 0 Detoxified
	Alcohol	↓ Acute withdrawal 0 Detoxified
	Methamphetamine	↓ Detoxified
	Cigarettes	↓ Active user
Vesicular monoamine transporters-2 Metabolism (MAO A and B) Synthesis (dopa decarboxylase)	Methamphetamine	↓ Detoxified
	Cigarettes	↓ Active user
	Cigarettes	↓ Detoxified
	Cocaine	↓ Active user
	Alcohol	↓ Detoxified
DA release	Alcohol	0 Detoxified
	Cocaine	↑ Active user
	Alcohol	↓ Detoxified ↓ Detoxified

receptors) in striatum (including NAcc). However, the fact that cocaine abusers as well as alcoholics show blunted reductions in specific binding (indicative of decrease DA release) when administered i.v. MP indicates that these individuals had both a reduction in the levels of D2 DA receptors as well as a decrease in DA release in striatum. Each deficiency would contribute to the overall decreased sensitivity in addicted subjects to natural reinforcers.

On the other hand, drugs are much more potent at stimulating DA-regulated reward circuits and at triggering persistent circuit changes than natural reinforcers. Therefore, drugs would still have an advantage in individuals attempting to activate their depressed reward circuits. This decreased sensitivity would also result in a reduced interest for environmental stimuli, possibly predisposing subjects for seeking drug stimulation as a means of temporarily activating an underresponsive reward network. As time progresses, the chronic nature of this behavior may sustain the transition from taking drugs in order to feel 'high' to taking them just to feel 'normal.'

Executive Function and Inhibitory Control

The long-term imbalances in dopaminergic function can eventually trigger profound metabolic and functional consequences. The use of the PET radiotracer $[^{18}\text{F}]$ fluoro-deoxyglucose (FDG) that measures regional

brain glucose metabolism, allowed researchers to document decreased activity in orbitofrontal cortex (OFC), cingulate gyrus (CG), and dorsolateral prefrontal cortex (DLPFC) in addicted subjects (e.g., alcoholics, cocaine abusers, marijuana abusers, and methamphetamine abusers). Moreover, there are significant correlations between reduced metabolic activity in OFC, CG, and DLPFC and decreased D2 DA receptor availability in the striatum of cocaine- and methamphetamine-addicted subjects (**Figure 2**) and of alcoholics. Since the OFC, CG, and DLPFC play critical roles in inhibitory control and emotional regulation, it has been postulated that their abnormal modulation by DA, characteristic of addiction, could underlie the subjects' loss of control over drug intake and their poor emotional self-regulation. Indeed, in alcoholics, reductions in D2 DA receptor availability in ventral striatum appear to be associated with alcohol-craving severity and with greater cue-induced activation of the medial prefrontal cortex and anterior CG, as assessed with fMRI. In addition, because damage to the OFC results in perseverative behaviors – and, in humans, impairments in OFC and CG are associated with obsessive-compulsive behaviors – it has also been postulated that DA impairment of these regions could underlie the compulsive drug intake that characterizes addiction.

However, the implication of inhibitory control areas should be considered with caution, because weakened

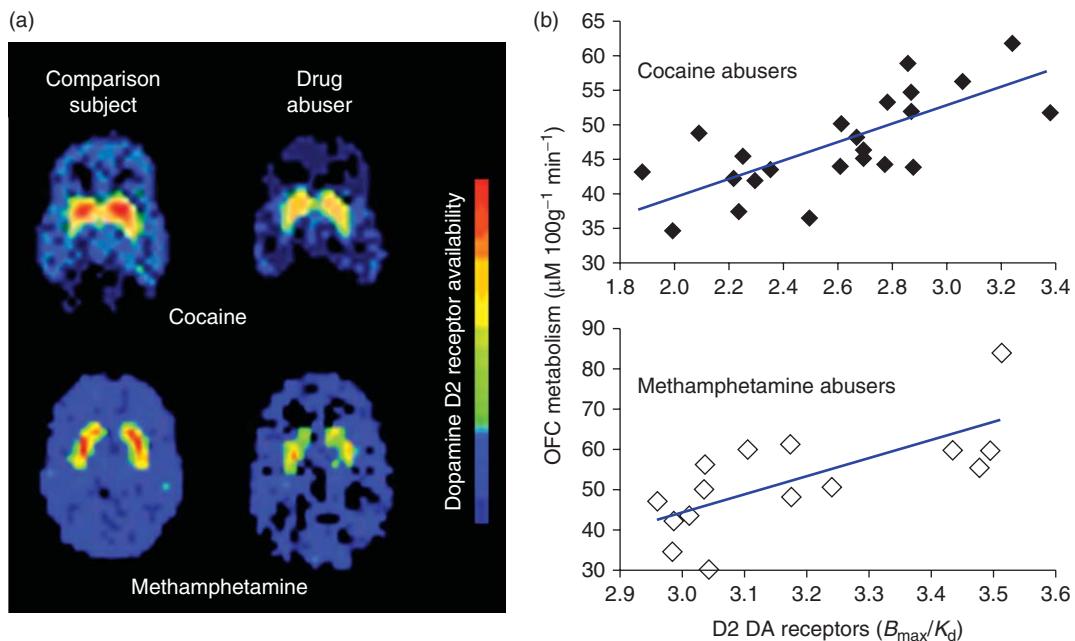

Figure 2 (a) Comparison of dopamine D2 receptor images at the level of the striatum of cocaine and methamphetamine abusers and non-drug-abusing control subjects. (b) Correlation of DA receptor availability (B_{\max}/K_d) in the striatum with measures of metabolic activity in the orbitofrontal cortex (OFC) in cocaine (closed diamonds) and methamphetamine (open diamonds) abusers. Reproduced with permission from Volkow ND, Chang L, Wang GJ, et al. (2001) Low level of brain dopamine D2 receptors in methamphetamine abusers: Association with metabolism in the orbitofrontal cortex. *American Journal of Psychiatry* 158(12): 2015–2021; and Reproduced with permission from Volkow ND, Fowler JS, Wang GJ, et al. (1993) Decreased dopamine D2 receptor availability is associated with reduced frontal metabolism in cocaine abusers. *Synapse* 14(2): 169–177.

prefrontal regions could also increase the drive to engage in risky behaviors in general, which could ‘secondarily’ put individuals at risk for drug abuse. Alternatively, low D2 DA receptors during fetal developmental periods may also influence prefrontal activity in adulthood.

Effects on Conditioning Circuits

It is well known that the hippocampus (declarative memory), amygdala (conditioning), and dorsal striatum (habits) play critical roles in learning and memory. All these areas have been shown to undergo significant adaptations in preclinical models of drug abuse, leading to a growing recognition of the relevance and likely involvement of memory and learning mechanisms in drug addiction. It is highly relevant then, that DA (interdependently with 5-hydroxytryptamine (5-HT)) can modulate the activity of, and affect adaptive changes in the circuits that support learning/memory, conditioning, and habit formation. Moreover, the effects of drugs of abuse on memory systems suggest a likely mechanism – conditioned-incentive learning – through which neutral stimuli can acquire reinforcing properties and motivational salience.

A central question in relapse research is: Why do drug-addicted subjects experience such an intense desire for the drug when exposed to places, people, or things associated with drug taking behaviors? A better understanding of the mechanisms involved could have profound clinical implications, for exposure to conditioned cues (stimuli that had become strongly linked to the drug experience) is a known, powerful trigger of relapse. Due to its involvement in the prediction of reward, DA has been proposed to underlie the conditioned responses that trigger craving. Animal studies support this hypothesis: when neutral stimuli are paired with a drug, animals will – with repeated associations – acquire the ability to increase DA in NAcc and dorsal striatum when exposed to the now conditioned cue. Predictably, these neurochemical responses have been found to be associated with drug-seeking behaviors.

Human PET studies using [¹¹C]raclopride have recently confirmed this hypothesis by showing that in cocaine abusers, drug cues (video images of subjects taking cocaine) significantly increased DA in dorsal striatum, and that these increases were also associated with cocaine craving in a cue-dependent fashion. If we consider the fact that the dorsal striatum is implicated in habit learning, this association is likely to reflect the strengthening of habits as addiction develops. This suggests that the DA-triggered conditioned responses that produce, first habits and then compulsive drug consumption, may reflect a fundamental neurobiological perturbation in addiction. In addition, it is likely that these conditioned responses involve adaptations in corticostriatal glutamatergic pathways that regulate DA release.

Do DA increases induce cravings by themselves or do they represent a secondary response to the cue? A recent study investigated this important question directly in cocaine-addicted individuals, by imaging the effects of oral administration of methylphenidate (which increases DA) in the presence or absence of a drug cue. The results of the study revealed a clear dissociation between oral methylphenidate-induced DA increases and cue-associated cravings, suggesting that cue-induced DA increases are not the primary effectors but rather reflect downstream stimulation of DA cells (corticostriatal glutamatergic pathways that regulate DA release). This observation sheds light on the relevance of the ‘rate’ of DA firing in addiction circuits, for the failure of methylphenidate-induced DA increases to induce craving in this paradigm could be explained by the slow nature of the DA increases. On the other hand, fast DA changes as triggered by phasic DA cell firing – as a secondary response to the activation of descending pathways – may underlie the successful induction of cravings during exposure to a cue. It is worth highlighting one study that found a negative correlation between the DA increases induced by i.v. amphetamine in cocaine abusers and their choice of cocaine over money when tested on a separate paradigm. That is, the subjects that showed the lower DA increases, when given amphetamine, were the ones more likely to select cocaine over a monetary reinforcer. Because in their studies they also reported reduced DA increases in cocaine abusers when compared with controls, this could indicate that cocaine abusers with the most severe decreases in brain dopaminergic activity are the ones more likely to choose cocaine over other reinforcers (such as money).

DA and Vulnerability to Drug Abuse

Understanding why some individuals are more vulnerable to becoming addicted to drugs than others remains one of the most challenging questions for drug-abuse researchers. Only a largely unpredictable minority of drug abusers progress to drug addiction (approximately 10% of those exposed), a fact that hints at a complex interaction between genetic and environmental risk and protective factors. Twin data, for example, suggest that about half of the overall vulnerability toward addiction is heritable. However, the neurobiological mechanisms underlying the role of genes in vulnerability or protection are not understood. Imaging studies are starting to shed light on these mechanisms as illustrated by the following examples.

Recent studies found that allelic variations in the D2 DA gene contribute to significantly higher scores in novelty seeking among methamphetamine-addicted patients and among children who were reared in a punitive environment. There is also preliminary evidence

suggesting that specific DA receptor gene variants (particularly in the D2 and D4 subtypes) modulate smoking progression (initiation and continuation) in adolescence. Finally, there is also good evidence that the availability of D2 DA receptors in the striatum can modulate the subjective responses of healthy nondrug-abusing controls to the stimulant drug methylphenidate. In that experiment, subjects describing the experience as pleasant displayed significantly lower levels of receptors than those describing methylphenidate as unpleasant (**Figure 3**). This suggests that the relationship between DA levels and reinforcing responses follows an inverted U-shaped curve: too little being suboptimal for reinforcement while too much may become aversive.

Could this result mean that high D2 DA receptor levels are protective against drug self-administration? Interestingly, there is a substantial amount of evidence that supports this hypothesis. On the preclinical side, higher levels of D2 DA receptors in NAcc significantly reduce alcohol or cocaine intake in animals previously trained to self-administer alcohol or cocaine, respectively; and, switching cynomolgus macaques from individual to group-housing conditions, exposes a robust (inverse) correlation between individual changes in striatal DA D2 receptor levels and the tendency to self-administer cocaine. Evidence in favor of this relationship has also emerged from human studies. First, there is evidence of depressed

DA activity in specific brain regions of adults with attention-deficit hyperactivity disorder (ADHD) compared to controls. Deficiencies were observed at the level of both D2 DA receptors and DA release in the caudate and in the ventral striatum. Importantly, and consistent with this model, the depressed DA phenotype was associated with higher scores on self-reports of liking when methylphenidate was administered intravenously. It is not surprising then, that individuals with ADHD have a high risk for substance-abuse disorders. Second, it has been observed that subjects who, despite having a dense family history for alcoholism, were not alcoholics had significantly higher D2 DA receptors in striatum than individuals without such family histories. Interestingly, the higher the D2 DA receptors in these subjects, the higher their metabolic activity in OFC and CG. Thus, it can be postulated that high levels of D2 DA receptors may protect against alcoholism by modulating frontal circuits involved in salience attribution and inhibitory control. In this respect, it is worth noting that in the rodent model low levels of D2 DA receptors are associated with impulsive behaviors, which in turn predict compulsive administration of cocaine. Inasmuch as the prefrontal cortex is involved in modulating impulsivity, this may be another mechanism by which low D2 DA levels may increase an individual's vulnerability to drug abuse and addictions and/or by which high D2 DA receptor level may protect against drug abuse.

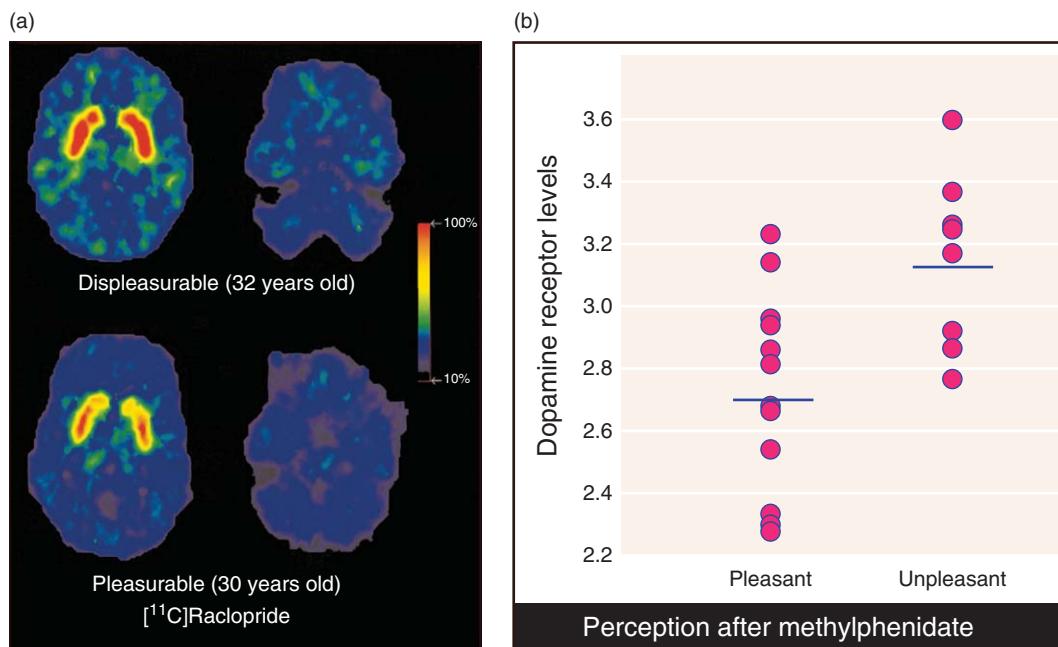

Figure 3 Striatal D2DA is predictive of methylphenidate liking in humans (a) Distribution volume images of $[^{11}\text{C}]$ raclopride at the levels of the striatum (left) and cerebellum (right) in a healthy male subject who reported the effects of methylphenidate as pleasant and in a healthy male subject who reported them as unpleasant. (b) D2DA receptor levels (B_{max}/K_d) in 21 healthy male subjects who reported the effects of methylphenidate as pleasant or unpleasant. Reproduced with permission from Volkow ND, Wang GJ, Fowler JS, et al. (1999) Prediction of reinforcing responses to psychostimulants in humans by brain dopamine D2 receptor levels. *American Journal of Psychiatry* 156(9): 1440–1443.

There are many other variables that are likely or known to significantly modulate the risk of abuse, addiction, and/or relapse. For example, sexual dimorphisms have been observed repeatedly in addictive disorders and recently proposed to be strongly mediated by epigenetic mechanisms. Preclinical evidence suggests that such differences may be due in part to striatal DA system differences and/or differences in the activity of prefrontal regions. Currently, the data do not permit a clear-cut conclusion as to whether men or women display greater DA responses when exposed to drugs. It is also likely that the patterns will be sensitive to experimental conditions, such as context, age, and stage of menstrual cycle.

Another relevant component in drug addiction is the connection that exists between the stress response and addiction vulnerabilities. For, in addition to drug-related cues, stress is a major contributing factor to the increased risk of relapse in an addictive disorder. Indeed, there are substantial overlaps between the circuits in charge of processing stress signals and drug cues and those responsible for processing reward information. Since chronic stress is often accompanied by some degree of sleep disturbances or full-fledged sleep deprivation (SD), it is also pertinent to mention in this context, the recent finding that a single night of SD was associated with a significant reduction in specific binding of [¹¹C]raclopride in the striatum, which was interpreted as a reflection of DA increases. Thus, DA increases with SD may be one of the mechanisms linking sleep deprivation and relapse to drug taking.

When combined, these and other observations provide critical insight into the contribution of the striatal DA system to addiction vulnerability, to the observed sexually dimorphic patterns of substance abuse, and the emergence of frequent psychiatric comorbid conditions.

Treatment Implications

Imaging studies have corroborated the role of DA in the reinforcing effects of drugs of abuse in humans and have dramatically extended the traditional views of DA involvement in drug addiction. These findings suggest multipronged strategies for the treatment of drug addiction designed to (1) decrease the reward value of the drug of choice and increase the reward value of nondrug reinforcers; (2) weaken conditioned drug behaviors, and the motivational drive to take the drug; (3) strengthen frontal inhibitory and executive control; and (4) improve mood and decrease reactivity to stressors. Additional circuits that play a role in various aspects of addiction and that provide potential targets for therapeutic interventions are interoceptive circuits (perception of needs and desires), which are mediated in part by the insula and the brain stress circuits associated with the extended amygdala.

Glossary

Anhedonia – Inability to gain pleasure from normally pleasurable experiences – a clinical feature of depression.

Brain-stimulation reward (BSR) – The outcome in operant intracranial self-stimulation (ICSS) procedures that serves as the reinforcing stimulus to maintain the ICSS behavior.

Dysphoria – A state of feeling unwell or unhappy, opposite to euphoria; a clinical feature of depression.

Dysphoria-like – A treatment-induced (e.g., withdrawal-induced) hedonic state resembling the human hedonic experience of dysphoria.

Euphoria – A feeling of well-being or elation, opposite to dysphoria.

Euphoria-like – A treatment-induced (e.g., drug-induced) hedonic state resembling the human hedonic experience of euphoria/pleasure/reward.

Intracranial self-stimulation (ICSS) – An operant behavioral response such as a nose-poke, lever-press, or turn of a wheel, the successful completion of which results in electrical stimulation of reward pathways.

Brain-stimulation reward is measured by an animal's willingness to perform a particular response (e.g., pressing a lever, turning a wheel manipulandum, nose-poking) in order to receive a response-contingent electrical stimulation of a particular region of the brain. The behavioral response is often referred to as intracranial self-stimulation (ICSS), with the outcome of said behavioral response being brain-stimulation reward (BSR). A broad range of abused substances including cocaine, amphetamines, nicotine, opioid narcotics, cannabinoids, alcohol, benzodiazepines, barbiturates, phencyclidine (PCP/Angel Dust), and even inhaled solvents such as toluene and benzene, can facilitate ICSS behavior and lower thresholds of electrical stimulation required to maintain responding (see **Table 1**). Conversely, in dependent subjects an elevation of thresholds is observed during withdrawal from many of these same substances, and this reward-deficit state is commonly used as a model of the depression-like symptoms experienced by human addicts undergoing withdrawal.

Most often studied in rodents, BSR can be elicited from many parts of the brain, from cortical (e.g., medial

prefrontal cortex) all the way down to brainstem structures (e.g., cerebellum, nucleus of the solitary tract). However, in studying the effects of abused substances on BSR, the majority of studies have focused on electrical stimulation of either the medial forebrain bundle (MFB) as it courses through the lateral hypothalamus, or the ventral tegmental area (VTA) which serves as the mid-brain origin of mesolimbic dopamine neurons critical to reward.

Why Use ICSS to Study Addiction?

Addiction is a chronic, relapsing disorder characterized by loss of control over the ability to limit one's intake of a drug and a high probability of relapse during periods of successful abstinence. Initiation of recreational (nonprescription) drug use is typically motivated by a desire to experience pleasurable effects (e.g., euphoria), or in some cases for self-medication of existing states of pain, anxiety, or depression. With continued drug use, the body and in particular the brain adapt to drug-induced disruptions in normal function, and dependence on the drug may develop – which is expressed as a withdrawal syndrome when drug use is discontinued. Most significant among the varied symptoms of withdrawal across classes of abused drugs are negative emotional states, including profound depression-like symptoms such as dysphoria and anhedonia. The greatest utility of animal models of BSR lies in their ability to readily measure both elements of the hedonic continuum experienced by addicts: the euphoria elicited by acute drug intoxication, and the dysphoria/anhedonia experienced during bouts of abstinence. Because animals, unlike the human, cannot directly tell us that they are experiencing euphoria or dysphoria, we will refer to the effects of acute drug intoxication and drug withdrawal on BSR thresholds as euphoria-like and dysphoria-like, respectively.

ICSS paradigms are but one of several commonly used procedures to assess the rewarding effects of acute intoxication and aversive consequences of withdrawal in dependent subjects, and to study the underlying neurobiological substrates. Other useful paradigms include drug self-administration, drug discrimination, and place-conditioning procedures. The advantages and limitations of ICSS for studying acute drug reward, dependence, and withdrawal, and for assessment of abuse liability are considered briefly below relative to these other techniques.

Table 1 Euphoria-like effects of acute intoxication and dysphoria-like effects of withdrawal from various abused substances as measured by shifts in brain-stimulation reward thresholds

		<i>Dysphoria-like effect of withdrawal?</i>

ICSS Compared to Other Operant Techniques: Self-Administration and Drug Discrimination

In self-administration, an animal completes an operant response such as a lever press to administer a drug, either intravenously or in some cases orally. Therefore the animal's behavior directly leads to consumption of the drug itself – which by inference suggests that the drug produces rewarding effects. ICSS, in contrast to self-administration, provides not a direct measure of the drug's potential to act as a reinforcer, but instead measures its ability to enhance the reinforcing efficacy of rewarding electrical stimulation. Thus, face validity for modeling human drug-taking behavior is greatest for self-administration, but the ICSS procedure nonetheless possesses excellent predictive validity for the assessment of a drug's potential abuse liability and its euphoria-like effects, with virtually all substances that are self-administered by the human demonstrating facilitatory effects on BSR (see **Table 1**). Indeed, in some cases (e.g., nicotine, alcohol, phencyclidine/PCP) it has been possible to establish reliable drug-induced reductions in BSR thresholds in rodents without special manipulations required to establish self-administration (e.g., adulteration of alcohol solutions with sweeteners to initiate self-administration followed by gradual fading out of the sweetener; food-restriction or addition of explicit drug-predictive cues to initiate nicotine self-administration), or for abused substances such as inhaled solvents, where self-administration techniques are technically difficult.

Drug discrimination involves training an animal to recognize the interoceptive stimulus properties of a particular drug, which the animal demonstrates by pressing one lever for food reward when intoxicated with the drug, and another lever when injected with placebo or with a different drug. This has utility in assessment of abuse liability of novel compounds when they are substituted for the training drug with known abuse liability. If a novel compound shares discriminative stimulus effects of a known abused substance, this overlap implies potential abuse liability for the novel compound as well. However, drug discrimination, unlike ICSS, provides no direct measure of a drug's euphoria-like effects, as the discriminative state includes interoceptive components beyond just the euphoria-like properties of the drug, also including physiological, somatic, and other behavioral states. For example, the subjective state produced by lysergic acid diethylamide (LSD) is readily discriminated by animals, but they will not self-administer LSD, nor does it facilitate ICSS behavior as other abused drugs do.

In addition, relative to self-administration and drug discrimination, ICSS has the distinct advantage of requiring no exposure to an abused drug during the acquisition of stable operant responding. Therefore, the euphoria-like effects of a drug, and experimental manipulations to

elucidate the underlying neural substrates thereof, can be assessed on the very first exposure to the drug in ICSS procedures, eliminating possible complicating influences such as the development of tolerance, sensitization, and/or dependence during training.

With regard to dependence and withdrawal, the motivational significance of avoiding or terminating withdrawal certainly is most directly demonstrated in self-administration paradigms where animals actually increase their drug intake in order to terminate the withdrawal state. Withdrawal can also be studied in drug-discrimination paradigms, as the interoceptive state of withdrawal from some drugs is readily discriminable, and the withdrawal interoceptive state of many drugs can be generalized to the discriminative stimulus effects of anxiogenic agents such as pentylenetetrazol, providing an indirect assessment of potential anxiogenic effects of withdrawal. However, withdrawal from most abused substances involves a constellation of somatic, physiological, and affective/emotional signs that vary according to the class of drug. Neither increased self-administration during withdrawal or recognition of the interoceptive stimulus characteristics of withdrawal can identify the specific withdrawal symptom(s) that support the operant behavior. The dysphoria-like effects of withdrawal may indeed be one relevant component that supports increased self-administration during withdrawal, or the ability to discriminate the withdrawal interoceptive state, but only ICSS provides a selective assessment of a reduced functioning or deficit state of the reward system during drug withdrawal – as measured by an increase in BSR thresholds. Moreover, in examining the neural substrates of withdrawal from acute dependence on a drug (i.e., withdrawal from a single acute administration in otherwise drug-naïve animals), ICSS again enjoys an advantage over self-administration and drug discrimination in requiring no prior exposure to the drug during training and establishment of stable baseline performance.

ICSS Compared to Place Conditioning

In conditioned place-preference procedures the potential reinforcing, presumed euphoria-like, effects of drugs are assessed through a demonstrated preference for an environment that was previously paired with the subjective experience of drug intoxication, relative to another environment paired with the absence of drug (i.e., placebo treatment). In contrast, the aversive consequences of drug withdrawal can be assessed through avoidance of a withdrawal-paired environment relative to a neutral environment where no withdrawal has been experienced – so-called conditioned place aversion.

Relative to operant paradigms such as self-administration, drug discrimination, and ICSS, place conditioning

can assess the potential euphoria-like effects of drug intoxication, or aversive consequences of withdrawal, while the animal is drug-free during the test session where preference or aversion for the conditioned environment is expressed. Place conditioning also requires substantially less training than operant paradigms. However, the place-preference paradigm is limited relative to the operant paradigms in that it cannot be used in within-subjects designs of treatment effects on drug-induced reward (once preference has been assessed, it cannot be re-assessed without some extinction of the conditioned association between drug and the paired environment). While repeated testing is feasible in self-administration and drug-discrimination studies – for example, when testing different experimental manipulations (e.g., different doses of a test agent, different types of antagonists to block a drug effect, etc.) – in both procedures re-establishing baseline performance between days of experimental treatment requires further exposure to the abused substance. In contrast, baseline performance in ICSS studies can be re-established between test sessions without further drug exposure.

Conditioned place preference also is hampered by the fact that it provides only a conditioned, not direct, measure of possible euphoria-like or aversive effects. Therefore, treatments that alter learning and memory processes can modulate the strength of the memory for the conditioned environment without necessarily directly altering the underlying hedonic effects of drug intoxication or withdrawal. Conditioning procedures can be successfully integrated into operant techniques, including the ICSS procedure, such that both direct (unconditioned) and conditioned alterations in hedonic processing (both euphoria-like and dysphoria-like) can be studied.

Conditioned place aversion is one of the most widely used measures of the aversive stimulus effects of precipitated withdrawal from drugs such as opioid narcotics, nicotine, and cannabis, where competitive antagonists are readily available and can facilitate precise temporal contiguity of withdrawal and confinement to the conditioning environment. However, establishing the required temporal contiguity between the withdrawal state and the conditioning environment can be problematic for drugs such as alcohol, cocaine, and amphetamines where the lack of available competitive antagonists necessitates the examination of spontaneous withdrawal. Spontaneous withdrawal takes place over an extended time course, and association of a novel context with just a portion of the withdrawal period may not engender a strong conditioned association. Finally, while the dysphoria-like effects of withdrawal indeed may contribute to a conditioned place aversion, other aspects of withdrawal malaise can also readily elicit avoidance of the conditioned environment. Therefore, although ICSS experiments are more time-intensive than those utilizing place conditioning,

this is offset substantially by the utility of ICSS for within-subjects designs. In addition, ICSS provides a selective measure of dysphoria-like effects – not a non-specific index of withdrawal malaise – can be used to study both spontaneous and precipitated withdrawal, and can be used to assess both direct and conditioned alterations in hedonic processing.

Commonly Employed ICSS Techniques for Studying Abused Substances

Many early studies of BSR employed ICSS techniques based on simple fixed-ratio schedules of reinforcement, often a continuous reinforcement schedule in which each successfully completed response, most often a lever-press, resulted in delivery of a brief (typically 100–500-ms) delivery of biphasic square- or sine-wave stimulation. Under such schedules of reinforcement, the absolute response rate for stimulation at a fixed current intensity, stimulation frequency (e.g., 60 Hz), and duration of stimulation has been used as an index of the reward-facilitating effects of abused substances with some degree of success. However, most abused substances can exert nonspecific effects such as attentional deficits, behavioral stimulation, sedation, or behaviors that compete with high rates of operant responding, and these effects usually increase as the dose of the abused substance is increased, thereby confounding dose-dependent reward-facilitation with nonspecific alterations in operant performance. For example, early studies of morphine effects on BSR often failed to find significant facilitatory effects on the first few administrations using rate-dependent measures, likely due to the rate-suppressing motoric effects of morphine that predominate until tolerance develops. However, procedures that can separate reward threshold from absolute response rate (see below) detect changes in BSR threshold on first morphine exposure.

Some researchers have proposed alternative response requirements to lever-pressing (not a natural component of a rodent's behavioral repertoire) that are more readily elicited in rodents (e.g., licking a surface, nose-poking into a small aperture, locomotion from one location to another, turning of a wheel manipulandum), but even these simpler responses are susceptible to performance-altering effects at higher drug doses. Therefore, irrespective of the physical-response requirement, researchers have applied a number of alternative approaches to mere assessment of absolute response rate at fixed stimulation parameters, including autotitration schedules, progressive ratio schedules, partial reinforcement schedules, differential reinforcement of low rates of responding, discrete trial current-intensity-threshold procedures, and curve-shift procedures. Rather than reviewing all of their relative advantages and limitations

in exhaustive detail here, several of the most frequently employed techniques are described.

Curve-Shift-Analysis Procedures

By selectively manipulating one stimulation parameter while holding the others constant, rates of responding are observed to increase in direct proportion to current intensity, stimulus frequency, or train duration up to a certain point, at which an asymptote in the rate function is reached. Several measures derived from these rate functions can be used to separate effects on reward from effects on performance. Taking rate–frequency functions as a prominent example utilized in studying drug- and withdrawal-induced alterations in BSR thresholds, the critical measures include the slope of the rate–frequency curve, the asymptotic maximal response level, the M50 (frequency at which 50% of maximal responding is achieved), and Theta-0 (theoretical frequency at which responding is first initiated). Factors that affect only reinforcement magnitude (e.g., lowering or increasing stimulation frequency), but not the effort required to complete the response, will generally produce parallel shifts in the rate curves without altering the slope of the function or the asymptotic maximal response rate. Under conditions where parallel shifts are observed, both M50 and Theta-0 serve as reliable indices of relative magnitude of BSR, and both measures are used extensively to estimate BSR thresholds. In contrast, manipulations that affect the ability of the animal to complete the response (e.g., increased force required to depress a lever) will lower the slope of the function and decrease the asymptotic maximal response rate. When a drug produces such a nonparallel shift in the rate–frequency curve, Theta-0 is more resilient than M50 to nonspecific performance effects because M50 is dependent on slope; therefore, Theta-0 provides the best estimate of BSR threshold when a drug affects slope and maximal response rate.

Two-Lever Autotitration Procedure

In this procedure, each response on one lever in an operant chamber results in delivery of a suprathreshold level of electrical stimulation that reliably maintains responding, but after completion of a defined number of responses on that same lever, the current intensity or the frequency of stimulation is automatically stepped down. Thus, as animals continue to respond, the reward magnitude is progressively lowered. A second lever in the chamber serves as a reset lever, and each response on that lever will reset the current intensity or stimulation frequency to the starting level, and the titration point (current intensity or stimulation frequency at which the reset lever is pressed) serves as a measure of BSR threshold. Although response rates generally remain quite high

in this procedure, it is possible to manipulate the response rate independent of titration point – which can serve as a reasonably resilient index of BSR threshold even when drugs affect response rate on the reward lever.

Psychophysical Discrete Trial Procedure

Kornetsky and colleagues have championed a psychophysical, discrete trial method to estimate the threshold for BSR. The major advantage of the procedure is that it requires a single discrete response by the subject in each trial to receive the electrical stimulation, and the total response requirement of a typical 30–45-min session can be 60 responses or fewer. In this procedure, train duration and frequency of stimulation are held constant, and each trial begins with a noncontingent electrical stimulation at a given current intensity, after which the animal has a defined interval, typically 7.5 s, to complete a response requirement of one-fourth rotation of a wheel manipulandum in order to receive a response-contingent stimulation of identical current intensity. If the response does not occur within the specified interval, the second stimulation is omitted on that trial. Each operant response completed during a variable inter-trial interval (e.g., 5–20 s, average of 10–15 s) resets the inter-trial interval and delays the onset of the next trial. In this fashion, animals are trained to elicit only the minimal response required to earn the response-contingent stimulation in each given trial where they detect the initial noncontingent stimulation. Beginning at a current intensity that is suprathreshold for a given subject, intensity is lowered and raised in two series of ascending and descending trials, with changes in stimulus intensity dependent on whether the animal successfully responded on more than 50% of the trials at the prior intensity (3–5 trials are typically conducted at each current intensity step). The midpoint between the lowest current step that supported 50% or greater successful responding and the highest current intensity that failed to support that level of responding is determined for each ascending and descending series, and the average of the midpoint for all four series is taken as the threshold current intensity. Response latency serves as an independent measure of possible nonspecific performance effects of a drug in this procedure.

The discrete trial component of the procedure ensures that responding is truly contingent upon the intensity of the priming stimulation provided to start each trial, and the extremely low response requirements ensure that all but the most severe of nonspecific performance-altering effects will have a minimal influence on threshold. For example, suppression of operant responding during antagonist-precipitated withdrawal from morphine serves as a sensitive behavioral index of opioid withdrawal, but an animal will successfully complete a discrete trial current-intensity ICSS session at doses of the antagonist that

would dramatically reduce operant response rates under high-demand schedules of reinforcement.

Measuring the Effects of Acute Drug Intoxication and Neuroadaptive Responses in Reward Circuitry Using ICSS

As shown in **Table 1**, the majority of substances that are abused by humans and self-administered by animals also will facilitate BSR, with the most notable exception being pure psychedelic/hallucinogenic compounds such as LSD, which appear not to be rewarding to animals in either self-administration or ICSS paradigms. The vast majority of ICSS studies examining euphoria-like effects of acute drug intoxication and dysphoria-like effects of withdrawal have employed rats, but models with mice have begun to emerge for cocaine, amphetamine, morphine, and nicotine. These should prove useful through leveraging of the vast array of mutant mouse lines for examination of molecular/genetic substrates, but to date the studies with rats and mice have yielded qualitatively similar results, and consequently the discussion below does not distinguish among them.

Euphoria-Like Effects of Acute Drug Intoxication

The euphoria-like effects of most abused substances as measured in ICSS procedures appear to be mediated by reward circuitry in the extended amygdala, with the mesolimbic dopamine system sitting at its core. BSR thresholds are reduced by the activation of this system at the level of its midbrain site of origin (VTA) and/or its forebrain terminal regions (e.g., nucleus accumbens, medial prefrontal cortex) via actions on nicotinic receptors (nicotine), opioid receptors (opioid narcotics), dopaminergic axon terminals (e.g., cocaine, D-amphetamine), or glutamatergic N-methyl-D-aspartate (NMDA) receptors (phencyclidine/PCP/Angel Dust, MK-801). Combinations of these drugs can facilitate BSR in a synergistic fashion, with administration of ineffective or minimally effective doses of each compound producing a potent, combined euphoria-like effect (e.g., cocaine–ethanol, cocaine–caffeine, morphine–amphetamine, morphine–MK-801, and caffeine–MK-801), thereby providing further evidence that most drugs of abuse produce their euphoria-like effects through action on common neural circuitry.

Stimulants

D-amphetamine dose-dependently elicits euphoria-like effects in progressive ratio, autotitration, rate–frequency and rate–current intensity curve-shift, and psychophysical discrete-trial threshold-determination techniques,

with both MFB and VTA as sites of stimulation. Significant effects are observed in a dose range of 0.5–5 mg kg⁻¹, with maximal threshold reductions of about 40% below baseline reached at 3–4 mg kg⁻¹. D-amphetamine administered directly into the nucleus accumbens – a primary forebrain terminal projection site of mesolimbic dopamine fibers from the VTA – mimics the euphoria-like effects of systemically administered D-amphetamine, and dopaminergic antagonists will oppose the euphoria-like effects of D-amphetamine.

Although methamphetamine has not been as extensively evaluated as D-amphetamine for effects on BSR thresholds, one study demonstrated 50% reductions from baseline threshold in a rate–frequency curve-shift procedure, with MFB as the stimulation site. The optimal dose of 0.65 mg kg⁻¹ was lower than optimal doses of D-amphetamine – consistent with methamphetamine’s greater potency in other measures of drug reward such as self-administration and conditioned place preference.

Cocaine also dose-dependently lowers BSR thresholds measured in rate–frequency, rate–duration, or rate–current intensity curve-shift analyses, as well as psychophysical discrete-trial current-intensity-threshold procedures, irrespective of whether the stimulation site is the VTA or MFB. In addition, while it has been difficult to demonstrate euphoria-like effects of D-amphetamine or morphine on electrical stimulation of the medial prefrontal cortex, the effects of cocaine appear reliable and reproducible with this stimulation site. Peak effects observed after administration of 16–30 mg kg⁻¹ doses of cocaine result in threshold reductions of up to 60% below baseline, making the euphoria-like effects of cocaine in ICSS procedures the largest documented to date among all abused substances tested. Dopaminergic antagonists reverse the euphoria-like effects of cocaine.

Nicotine dose-dependently reduces BSR thresholds for stimulation of the VTA or MFB in the dose range of 0.1–0.8 mg kg⁻¹, with peak effects in rate–frequency curve-shift or psychophysical discrete-trial procedures of about 30–40% reductions from the baseline threshold. Slightly lower doses are effective in facilitating BSR thresholds when the VTA is the site of stimulation than when MFB is the stimulation site. The euphoria-like effects of nicotine appear to rely upon the activation of nicotinic receptors in the VTA, which in turn facilitates mesolimbic dopamine activity, and dopaminergic antagonists will reverse threshold-lowering effects of nicotine.

Caffeine produces stimulant effects by acting as an antagonist of the inhibitory neurotransmitter adenosine at A1- and A2a-receptors in the brain. Caffeine-induced reductions in BSR thresholds are weak at best when administered on its own (maximal effect at 3–5.6 mg kg⁻¹ usually <10% reductions from baseline), and higher doses (10 mg kg⁻¹ and above) produce dose-dependent reductions in response rate and elevations in threshold.

However, the combined administration of ineffective doses of caffeine and MK-801, a noncompetitive NMDA antagonist that mimics PCP effects (see below), produce significant reductions in BSR thresholds. This finding is consistent with observations that selective antagonists of the A2a-receptor do not alter reward thresholds on their own, but can potently reverse the dysphoria-like effects of withdrawal from chronic cocaine. Therefore, caffeine and other adenosine antagonists, while weakly euphoria-like on their own, may potentiate the positive hedonic efficacy of acute drug intoxication and reduce the negative hedonic consequences of drug withdrawal.

Opioid narcotics

Numerous ICSS studies have documented the euphoria-like effects of opioid agonists such as morphine, heroin, and 6-acetylmorphine, among others (see **Table 1**). Activation of either μ - or δ -opioid receptors in the shell region of the nucleus accumbens, or in the VTA, results in reliable reductions in BSR threshold. However, κ -opioid receptor activation results in dysphoria-like effects, indicating that significant κ -receptor activation by nonspecific opioid agonists that can interact with multiple receptor types may oppose the euphoria-like effects of μ - and δ -receptor activation.

Morphine in the dose range of 2–10 mg kg⁻¹ elicits dose-dependent reductions in threshold for electrical stimulation of the VTA or MFB using autotitration, rate–frequency curve-shift, or psychophysical discrete-trial procedures. Peak effects are observed at doses of 4–8 mg kg⁻¹ (30–40% reduction from baseline threshold). Both heroin (diacetylmorphine) and 6-acetylmorphine are roughly 40 times as potent as morphine itself in reducing BSR thresholds. The partial opioid agonist buprenorphine, approved for use in the treatment of opioid addiction, has inconsistent effects on its own at doses of 20–80 μ g kg⁻¹ in a psychophysical discrete-trial procedure (significant threshold reduction in one study, no effect in another). However, it has been shown that buprenorphine can potently reverse the dysphoria-like effects of spontaneous withdrawal from the full opioid agonist fentanyl, and marked buprenorphine-induced reductions in BSR threshold of 25–30% below baseline persist after the dysphoria-like effects of fentanyl withdrawal have dissipated. This suggests that opioid withdrawal may unmask euphoria-like potential of partial opioid agonists. This latter observation has significant implications for buprenorphine treatment of addiction, as administration of the compound during periods where peak withdrawal dysphoria is present may result in increased risk of abuse of buprenorphine itself.

General central nervous system (CNS) depressants

Using their classic discrete-trial current-intensity method, Kornetsky and colleagues demonstrated that BSR thresholds for electrical stimulation of the MFB were significantly reduced by alcohol that was self-administered by the animals immediately prior to the ICSS session to a blood alcohol concentration of 0.03–0.05 g%. Lewis and June found that passively administered alcohol also could lower BSR thresholds during the rising phase in the blood alcohol concentration curve (15–20% reductions from baseline threshold in the first 20 min postinjection), but not after concentrations had peaked, suggesting a potential rapid acute tolerance to the euphoria-like effects of alcohol.

Among other classes of general CNS depressants, benzodiazepines and barbiturates have been found to facilitate rates of responding for electrical stimulation of the MFB at lower doses, and suppress rates at higher doses as would be expected of a sedative drug. To date only benzodiazepines such as chlordiazepoxide (Librium) and diazepam (Valium) have been assessed in ICSS threshold procedures, and both drugs reduce BSR thresholds in autotitration or rate–current intensity and rate–frequency curve-shift paradigms. Maximal reductions of about 15–20% below baseline are observed at 2.5–5 mg kg⁻¹ doses of diazepam and 5–15 mg kg⁻¹ doses of chlordiazepoxide. Barbiturates and newer-generation anxiolytic agents such as midazolam (Versed) and alprazolam (Xanax) have yet to be systematically evaluated for effects on BSR threshold.

While the maximum reductions in threshold produced by diazepam, chlordiazepoxide, and alcohol are relatively modest, a recent study provided intriguing evidence that another group of CNS-depressant agents may produce more profound euphoria-like effects. Autotitration ICSS thresholds determined in sealed vapor-inhalation chambers during active delivery of abused inhalant solvents such as toluene, cyclohexane, acetone, and benzene revealed concentration-dependent reductions in BSR thresholds, with up to 50% reductions in threshold produced by benzene (maximal effect of 20–30% with all other agents investigated).

Psychedelics

Drugs such as LSD and dimethyl-tryptamine (DMT), which exert profound psychedelic effects through action on serotonergic systems but do not stimulate mesolimbic reward circuitry, appear to lack euphoria-like effects in ICSS threshold-determination paradigms. This finding is consistent with the fact that these compounds also are not self-administered by animals. However, reductions in BSR thresholds are produced by several mixed-class drugs that have psychedelic properties but additionally stimulate either directly or indirectly mesolimbic reward

circuitry, suggesting that psychedelic properties *per se* do not preclude an agent from exerting euphoria-like effects in ICSS paradigms. For example, methylenedioxymethamphetamine (MDMA/Ecstasy) lowers BSR thresholds in rate–frequency curve-shift and discrete-trial current-intensity ICSS paradigms, with peak effects observed at $2\text{--}4 \text{ mg kg}^{-1}$. The maximum threshold reduction produced by MDMA is comparable to that seen after administration of 1 mg kg^{-1} of D-amphetamine or 15 mg kg^{-1} of cocaine (30–40% reduction from baseline), suggesting similar euphoria-like efficacy.

Phencyclidine (PCP/Angel Dust) and the related compound ketamine were developed initially as dissociative anesthetic agents, but ultimately became limited in their clinical use in the human because of their psychedelic effects at moderate doses and psychomimetic effects at higher doses. Systemic administration of $2.5\text{--}10 \text{ mg kg}^{-1}$ doses of PCP lowers BSR thresholds for electrical stimulation of the MFB by about 20–25% as measured by parallel leftward shifts in rate–frequency curves. Microinjection of $5\text{--}20 \mu\text{g}$ doses directly into the shell region of the nucleus accumbens produces similar effects, implicating glutamatergic inputs to this component of mesolimbic reward circuitry as a substrate for the reward-facilitating effects of PCP. To date, ketamine has been examined only in a rate-dependent ICSS paradigm, where it was found to increase responding for stimulation of the MFB after systemic administration of 3.0 mg kg^{-1} , followed by response suppression at higher sedative doses ($30\text{--}100 \text{ mg kg}^{-1}$). Although PCP acts both as a noncompetitive antagonist of NMDA receptors and a blocker of monoamine (dopamine, serotonin, norepinephrine) reuptake, the reward-facilitating actions of PCP after systemic or intra-accumbens administration are mimicked by MK-801 – which like PCP is a noncompetitive antagonist at NMDA receptors, but unlike PCP is devoid of activity at monoamine reuptake transporters. This indicates that PCP effects at NMDA receptors in the nucleus accumbens are sufficient to produce reward facilitation.

Gardner and colleagues have consistently reported that δ -9-tetrahydrocannabinol (THC), the principal active ingredient in cannabis, reduces reward thresholds by 15–25% at doses of $1\text{--}1.5 \text{ mg kg}^{-1}$, as measured by the Theta-0 index in rate–frequency curve-shift paradigms, or in autotitration procedures. However, this group demonstrated that the effects are variable across strains of rats, with some strains showing no euphoria-like effects. Moreover, other groups have failed to detect THC-induced reductions in reward threshold using M50 as the threshold index in rate–frequency curve-shift analyses, or in psychophysical discrete-trial procedures. To date, systemic administration of synthetic cannabinoid receptor agonists most often have been shown to exert no effect, or in some cases modestly increase, BSR thresholds in curve-shift paradigms. Thus, while THC is self-

administered directly into the VTA and shell of the nucleus accumbens in a cannabinoid-receptor-dependent fashion, the available data from the BSR literature indicates that cannabinoid-receptor stimulation by systemically administered agonists is not consistently euphoria-like, suggesting that additional actions outside this circuit may diminish euphoria-like efficacy.

Neuroadaptive Responses in Reward Circuitry I: Chronic Dependence and Withdrawal

Initiation of drug use is typically motivated by pleasure seeking (e.g., euphoria-inducing effects, increased sociability) or for self-medication of preexisting pain, stress, mood, or anxiety disorders. However, as the body and particularly the nervous system adapts to the disruptions in homeostatic balance produced by drug intoxication, states of acute and/or chronic dependence will emerge, and avoidance or termination of the aversive consequences of withdrawal come to play an increasing role in the transition to and maintenance of addiction. Of particular motivational relevance are negative emotional signs of withdrawal such as anxiety and depression/dysphoria, which for the addict stand in stark contrast to the positive emotional state experienced during drug intoxication. Animal models of these negative emotional consequences of withdrawal from acute and chronic dependence are critical to the study of their underlying neurobiological mechanisms, and one of the most widely employed models is the dysphoria-like effects of withdrawal measured in ICSS paradigms.

Stimulants

Depression-like symptoms during withdrawal from abused substances were first reported in rodents in the mid-1970s by Barrett and colleagues following chronic treatment with D-amphetamine. Since then the reliability and robustness of the effect has been established in a number of studies under varying regimens of drug treatment, including repeated daily injections for as little as 4 days, and continuous infusion via osmotic minipumps for 7–14 days. Multiple threshold-detection techniques, including rate–intensity curve-shift, rate–frequency curve-shift, and psychophysical discrete-trial methods, have proven to be sensitive indices of the dysphoria-like effects of spontaneous D-amphetamine withdrawal. Peak threshold elevations of 175% and duration of effect as long as 18 days have been reported following more chronic exposure regimens, with lesser duration and peak magnitude observed under shorter-term D-amphetamine-exposure schedules.

Both curve-shift and psychophysical discrete-trial threshold-detection methods have been used to document elevations in BSR thresholds during withdrawal from chronic exposure to cocaine via repeated injections

(40–120 mg kg⁻¹ day⁻¹), or in animals allowed to continuously self-administer cocaine for 12–48-h periods. Maximum threshold elevations of 200% of baseline are seen from 1- to 6-h postcocaine administration, with a maximum duration of 72 h documented to date.

Both spontaneous and antagonist-precipitated withdrawal from chronic nicotine infusion via osmotic minipumps (7 days or longer, 3.2 mg kg⁻¹ day⁻¹ or higher) results in elevations in BSR thresholds of about 140% above baseline at peak intensity, as measured by the psychophysical discrete-trial procedure. The most frequently used administration regimen, 3.2 mg kg⁻¹ day⁻¹, results in plasma nicotine levels comparable to those observed in 30 cigarettes/day smokers. Some studies have reported the duration of spontaneous nicotine withdrawal as long as 104 h after cessation of infusion. Administration of nicotinic receptor antagonists directly into the VTA, but not into forebrain structures implicated in drug reward such as the nucleus accumbens, central nucleus of the amygdala, or bed nucleus of the stria terminalis, will precipitate withdrawal-induced dysphoria-like effects after chronic nicotine infusion.

Opioid narcotics

Naloxone-precipitated withdrawal from chronic administration of morphine via osmotic minipumps or slow-release pellets is well-established to elicit significant dysphoria-like effects, with peak magnitude of 170% above baseline threshold in psychophysical discrete-trial paradigms, and still significant but slightly lower peak elevations (140%) in an autotitration threshold-detection task. It has been suggested that high rates of self-stimulation in autotitration and curve-shift paradigms may in some cases act as a hedonic buffer against dysphoria-like effects, allowing for discrete-trial procedures with much less frequent electrical stimulation to detect larger threshold shifts during withdrawal.

Spontaneous withdrawal from morphine reduces the rate of responding in ICSS autotitration paradigms for 24–48 h after cessation of morphine delivery without significant alteration in threshold; spontaneous withdrawal from the partial agonist buprenorphine does not significantly alter thresholds in a discrete-trial paradigm. Recently, however, spontaneous withdrawal from the full μ -opioid-receptor agonist fentanyl was shown to result in dramatic elevations in BSR threshold in psychophysical discrete-trial procedures. This effect is dependent on dose of fentanyl administered per day, with 0.3, 0.6, and 1.2 mg kg⁻¹ day⁻¹ resulting in threshold elevations of 140%, 170%, and 180% above baseline threshold, respectively. The duration of threshold elevation is also dose-dependent (0.3 mg kg⁻¹ day⁻¹: 12 h; 0.6 mg kg⁻¹ day⁻¹: 36 h; 1.2 mg kg⁻¹ day⁻¹: 48 h). Precipitated withdrawal from chronic fentanyl exposure (1.2 mg kg⁻¹ day⁻¹) results in peak threshold elevations of

200% above baseline, comparable to the peak effects observed during cocaine withdrawal. It is notable that peak intensity of precipitated withdrawal during infusion of 0.6 mg kg⁻¹ day⁻¹ fentanyl is reached within 20 h of onset of infusion, and remains stable thereafter, whereas precipitation of somatic withdrawal signs is modest at 20 h, and rises gradually to a maximal level after 120 h of continuous infusion. This difference suggests that neuroadaptation in brain-reward circuitry may be more rapid than adaptation in other systems mediating somatic manifestations of opioid withdrawal.

General CNS depressants

To date, among all the CNS depressants shown to exert facilitatory effects on BSR during acute bouts of intoxication (alcohol, benzodiazepines, inhaled solvents), only withdrawal from chronic alcohol has been systematically examined for its dysphoria-like effects. Passive exposure to alcohol via vapor inhalation for 2 weeks at levels that resulted in average blood alcohol concentrations of 0.23 g% at the time of withdrawal resulted in time-dependent BSR-threshold elevations as measured by psychophysical discrete-trial current-intensity thresholds. Peak magnitude threshold elevation of 140% above baseline was observed from 6 to 12 h after cessation of alcohol exposure, and thresholds remained significantly elevated for 48 h. Similar results using this same ICSS threshold-detection procedure were recently obtained in animals that were actively consuming alcohol through forced consumption of a liquid diet containing 10% ethyl alcohol.

Psychedelics

Dependence on pure psychedelic compounds such as LSD is extremely rare, because even just a few doses produce almost complete tolerance to their psychedelic effects. However, spontaneous withdrawal from continuous infusion of 15–20 mg kg⁻¹ day⁻¹ via osmotic minipump of the mixed-class psychedelic compound PCP results in lasting increases in BSR threshold for up to 30 days after pump removal, as measured in a discrete-trial current-intensity-threshold paradigm. Thus, while peak magnitude of threshold elevations (125–140% of baseline threshold) during PCP withdrawal was substantially less than that observed during spontaneous withdrawal from cocaine, amphetamine, or the opioid narcotic fentanyl, the duration of the reward-deficit state post-PCP was considerably longer. The dysphoria-like effects of withdrawal following chronic exposure to other mixed-class psychedelic compounds such as MDMA and THC have yet to be evaluated in ICSS paradigms (but see below for evidence of BSR threshold elevations during withdrawal from acute dependence on THC).

Neuroadaptive Responses in Reward Circuitry II: Acute Dependence and Withdrawal

Dysphoria-like effects of withdrawal from single treatments with abused substances as measured in ICSS paradigms to date have been reported for morphine, alcohol, d-amphetamine, THC, and PCP. Greatest attention thus far has been given to withdrawal from acute intoxication with morphine. When an acute bolus dose of morphine ($3\text{--}10 \text{ mg kg}^{-1}$) is followed 4–8 h later by an antagonist such as naloxone or naltrexone, antagonist-precipitated elevations in BSR thresholds (peak effect of 115–125% of baseline threshold) are evident in several ICSS paradigms, including progressive ratio breakpoint, an autotitration threshold procedure, and the psychophysical discrete-trial current-intensity-threshold procedure. Although spontaneous withdrawal has yet to be demonstrated following a single acute morphine treatment at doses up to 10 mg kg^{-1} , repeated daily treatment with 5.6 mg kg^{-1} morphine results in a progressive increase in dysphoria-like effects of precipitated withdrawal (threshold elevations of 140–150% above baseline threshold), and under these conditions spontaneous withdrawal (115% of baseline threshold) has been observed 20 h after as few as two daily treatments.

Spontaneous withdrawal from a single 2.0-g kg^{-1} dose of alcohol also transiently elevate BSR thresholds in a discrete-trial procedure from 6–9 h post-ethanol administration, and repeated treatment at weekly intervals results in a further increase in both peak magnitude (up to 140% of baseline), and duration (up to 48 h) of threshold elevations. Spontaneous withdrawal from 4.0 mg kg^{-1} d-amphetamine, $5\text{--}10 \text{ mg kg}^{-1}$ PCP, and 1 mg kg^{-1} THC also produce transient elevations in BSR thresholds (about 120% of baseline) from 8 to 24 h postinjection in either the psychophysical discrete-trial current-intensity (amphetamine or PCP) or rate-frequency curve-shift (THC) threshold procedures.

A single study to date reported a lack of precipitated withdrawal by the benzodiazepine antagonist flumazenil when administered 4–24 h after diazepam ($3\text{--}10 \text{ mg kg}^{-1}$) or chlordiazepoxide ($30\text{--}100 \text{ mg kg}^{-1}$), but this effect has only been examined with progressive ratio breakpoint analysis to date. It has been suggested by Easterling and colleagues, the study authors, that high rates of responding for BSR may act as a hedonic buffer of sorts against milder withdrawal-induced reward deficits. Consistent with this suggestion, the magnitude of change in BSR threshold observed with precipitated morphine withdrawal is greater in the discrete-trial procedure, which has extremely low response requirements, than in the autotitration and progressive ratio procedures where high rates of ICSS behavior are maintained even during precipitated withdrawal. Therefore, further evaluation of possible dysphoria-like effects of withdrawal from acute

benzodiazepine administration should be conducted using a procedure with low response requirements before drawing any final conclusions. Among other substances with known euphoria-like effects in ICSS procedures, withdrawal from acute cocaine, nicotine, and inhaled solvents have yet to be examined.

Neuroadaptive Responses in Reward Circuitry III: Tolerance and Sensitization

Tolerance to euphoria-like effects

Among studies seeking evidence of tolerance (i.e., decreased responsiveness to the euphoria-like effects of acute drug intoxication upon repeated administration), only a few have provided positive evidence, whereas others have indicated no tolerance with similar treatment regimens. For example, one study reported tolerance to the threshold-lowering effects of 5 mg kg^{-1} morphine in an autotitration ICSS procedure after 5 days of treatment with this dose. However, another study using similar treatment regimens of morphine (repeated daily or twice-daily injections with $4\text{--}6 \text{ mg kg}^{-1}$) failed to produce any evidence of tolerance to the euphoria-like effects even after chronic (up to 30 days+) treatment, although rapid tolerance did develop to the rate-suppressing effects of morphine. Repeated intermittent injections with a number of other drugs (nicotine, caffeine, THC, etc.) have produced evidence of differential tolerance to rate-suppressing, but not euphoria-like, effects.

One study reporting tolerance to the euphoria-like effects of cocaine administered $120 \text{ mg kg}^{-1} \text{ day}^{-1}$ for 3 days (four divided doses of 30 mg kg^{-1}). However, a number of other studies employing $40\text{--}75 \text{ mg kg}^{-1}$ daily doses of cocaine failed to produce evidence of tolerance, suggesting perhaps that extremely high doses of passively administered cocaine are necessary before tolerance is induced. Koob, Markou and colleagues have similarly demonstrated apparent dose-dependent tolerance with self-administered cocaine. In their study, rats allowed to self-administer 10–20 injections of cocaine ($0.25 \text{ mg per injection}$) for several weeks showed reliable reductions in discrete-trial current-intensity BSR thresholds 15 min after the conclusion of most self-administration sessions throughout the testing period, whereas rats allowed to self-administer 80 injections per session showed no facilitation of BSR thresholds after several weeks of testing, suggestive of dose-dependent tolerance.

In addition to repeated intermittent injection regimens or self-administration procedures, a number of studies examined chronic, continuous infusion of nicotine, d-amphetamine, PCP, or the opioid narcotic fentanyl using osmotic minipumps. It must be noted that the primary objective of these studies was to study dysphoria-like effects of withdrawal after cessation of chronic delivery, not tolerance to the euphoria-like effects, and therefore

treatment regimens rarely were optimized for observing tolerance. That said, tolerance to the rate-suppressing effects were evident on the first day or two of continuous infusion, even though tolerance to threshold-lowering effects were not observed at any time during the course of chronic infusion.

Sensitization of euphoria-like effects

Sensitization of drug-induced behavioral effects with repeated intermittent drug administration has been characterized most thoroughly as increased responsiveness to the locomotor stimulating effects of agents such as cocaine, D-amphetamine, morphine, PCP, etc. Positive evidence of sensitization to the effects of abused substances on responding for BSR has been observed primarily by one group of investigators employing measures requiring high rates of responding, while several other groups have failed to demonstrate sensitization of BSR threshold-lowering effects of drugs. For example, Kokkinidis and colleagues have observed sensitization of the rate-increasing effects of 1–2 mg kg⁻¹ D-amphetamine administered daily for 10–20 days in ICSS studies using the VTA, substantia nigra, or nucleus accumbens as the stimulation site. Evidence of sensitization included progressive potentiation of the rate of responding elicited by the daily-treatment dose, and a significant increase in responding for low (0.3–0.5 mg kg⁻¹) challenge doses of D-amphetamine that do not alter ICSS responding in drug-naïve animals. Notably, this research group has demonstrated that the emergence of sensitization to a threshold challenge dose of D-amphetamine (0.5 mg kg⁻¹) was more pronounced when daily ICSS testing occurred immediately after each daily injection of D-amphetamine (2 mg kg⁻¹) than when ICSS testing occurred prior to daily treatment. This temporal contiguity effect suggests a critical role for contextual conditioning factors in development of the sensitized ICSS response – a factor long known to play a facilitatory role in the development of locomotor sensitization to drugs such as cocaine, amphetamines, and morphine. In contrast, the vast majority of studies employing threshold procedures to more clearly separate euphoria-like effects from rate-altering effects have yielded negative evidence of sensitization of threshold-lowering effects of nicotine, cocaine, D-amphetamine, PCP, or morphine. Taken together, the results to date provide ample evidence of sensitization to the rate-altering, but not the threshold-altering or euphoria-like, effects of abused substances in ICSS paradigms.

Concluding Thoughts

As described in the preceding sections, reductions in BSR thresholds during acute drug intoxication and withdrawal-related increases in BSR thresholds are among the

most reliable and reproducible of findings across multiple drug classes. However, evidence of tolerance and/or sensitization to the euphoria-like effects of abused drugs in ICSS have proven difficult to demonstrate on a consistent basis. Studies with both tolerance- and sensitization-inducing regimens of drug treatment have provided numerous positive results in rate-dependent measures of ICSS behavior, but rarely yield positive evidence when BSR thresholds are assessed separate from pure rate of responding. The few positive findings of tolerance to the threshold-lowering effects of morphine and cocaine suggest that there may be parameters (e.g., very high doses of cocaine) that may support these adaptive responses to euphoria-like effects measured in ICSS procedures. Perhaps thorough parametric analysis of tolerance and sensitization using shifts in drug dose-effect functions rather than probing the effects of single test doses will provide a clearer picture of the permissive conditions.

The broad range of conditions that fail to support the development of tolerance or sensitization to the euphoria-like effects of abused substances stands in stark contrast to the ability to demonstrate dysphoria-like effects of withdrawal, another index of neuroadaptation in reward circuitry, across a vast array of parameters and abused substances. In this regard, it is notable that some studies on tolerance and sensitization of BSR thresholds measured ICSS behavior at times when withdrawal from the preceding drug injection may have been present, and this factor should be systemically examined in future studies for its possible confounding influence. Moreover, some work by the Wise and Carlezon research groups suggests that repeated electrical stimulation of brain-reward circuitry during ICSS training and testing may by itself induce neuroadaptation that confounds ready demonstration of tolerance or sensitization to drug-induced alterations in BSR thresholds. If this is true, then ICSS may not be an optimal paradigm with which to assess development of tolerance and sensitization phenomena. Nonetheless, its utility in measuring the direct, unconditioned, euphoria-like effects of acute drug intoxication and dysphoria-like effects of withdrawal from both acute and chronic drug exposure cannot be questioned.

Glossary

Alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors (AMPAR) – One subclass of glutamate receptors.

Dopamine (DA) – A neuromodulator implicated in regulation of learning and memory, motivated behavior, and other neural functions.

GluR – A protein subunit (GluR1-4) of the AMPAR.

Long-term depression (LTD) – In some cases a persisting decrease in AMPAR function after repeated stimulation of glutamate release.

Long-term potentiation (LTP) – In many cases a persisting increase in AMPAR function after repeated stimulation of glutamate release.

LVGCC – L-type voltage-gated calcium channels which in some cases provide calcium needed for LTD or LTP induction.

Metabotropic glutamate receptors (mGluRs) – Receptors activated by glutamate that do not link directly to a Na^+ - or Ca^{2+} -permeable ion channel.

Nucleus accumbens (NAcc) – A brain region critical for regulating many motivated behaviors.

N-methyl-D-aspartate receptors (NMDARs) – One subclass of glutamate receptors.

NR2B – A subunit of the NMDAR.

SK – The calcium-activated SK potassium channel

Ventral tegmental area (VTA) – A major source of dopamine in the brain.

The mesolimbic dopamine system, formed in part by the ventral tegmental area (VTA) and nucleus accumbens (NAcc), is an integral part of the brain's natural reward circuit. The VTA is a major source of dopamine (DA) for the brain circuit involved in encoding of reinforcement and learning, and the NAcc is a critical node that integrates limbic and motivational input (including DA signals from the VTA) to influence behavioral output. Thus, these brain regions, in concert with other areas such as the prefrontal cortex, thalamus, and amygdala, are considered to play a critical role in the control of motivated and goal-directed behaviors, including the development and expression of addiction. In addition, recent studies suggest that addiction is a form of maladaptive learning, where neural links can be formed between the action of taking the drug and the drug-related reward or withdrawal-related negative states. For this reason, this article, in part, addresses the consequences of passive versus

active exposure to drugs. Repeated passive exposure to a given drug can enhance or sensitize the locomotor-activating effects of that drug, called behavioral sensitization. Since locomotor sensitization can be very long-lasting and can enhance subsequent drug self-administration, sensitization has been considered a model of enhanced drug seeking during abstinence. Drug-related sensitization has been observed in humans, and can contribute to enhancement of psychoses with repeated psychostimulant exposure. However, although pharmacological effects through passive drug exposure can produce enduring plastic changes, human drug intake is typically active and voluntary, and associative learning between drug taking and reinforcing or negative consequences may be a critical component in the development of addiction.

Overall, this article seeks to address the interesting possibility that drugs of abuse produce persistent changes in neuronal function that may drive drug seeking after periods of abstinence, especially prolonged abstinence. The ability of drugs to alter neuronal function was originally investigated predominantly through biochemical methods such as Western blot, which allow one to determine changes in protein levels or phosphorylation state of a given receptor or channel subunit. More recently, large-scale screening for changes in protein levels (using proteomics) or mRNA levels (using DNA microarrays) have shown great promise for indicating potential changes in receptor or channel function. Importantly, *ex vivo* electrophysiological techniques in brain slice have allowed direct examination of functional changes in excitatory synaptic strength or ion channel activity after drug exposure. Electrophysiological studies are particularly critical because they provide detailed information about the functional state of a given receptor or channel, which can occur without concurrent alterations in total protein or mRNA.

Thus, we examine evidence that abused substances can cause long-term changes (after 1 day or more of withdrawal) in glutamate receptor and ion channel function in the VTA and NAcc. Furthermore, we focus here on cocaine and alcohol, although interesting studies have also been performed in relation to other abused drugs such as morphine, nicotine, and amphetamine.

Ionotropic Glutamate Receptors

Ionotropic glutamate receptors can be broken into two distinct classes: alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors (AMPARs), which

generate fast depolarization to contribute to neuronal firing, and N-methyl-D-aspartate receptors (NMDARs), which are voltage activated and allow passage of cations including calcium. Thus, NMDAR currents both depolarize the neuron and supply calcium, which is critical for induction of synaptic plasticity in many systems. Also, NMDAR-dependent (and NMDAR-independent) synaptic plasticity often involves enduring changes in AMPAR function, although plasticity can also occur in the probability of glutamate release, intrinsic ion channel activity, or other aspects of neuronal physiology.

AMPARs are typically composed of four subunit proteins (GluR1-4), which can form hetero- or homomeric complexes. In both the VTA and NAcc, AMPARs are thought to exist as heteromeric complexes containing both GluR2/3 and GluR1 subunits in the basal state, before any changes in synaptic strength occur, and reflect a state where synaptic strength is low. In several cases, changes in AMPAR function during glutamatergic plasticity are associated with altered trafficking of particular AMPAR subunits to the plasma membrane or the post-synaptic density. Importantly, there are several powerful techniques which allow delineation of changes in AMPAR subunit composition during plasticity, including sensitivity to subunit-selective inhibitors and analysis of the rectification index. The latter measure is widely used, since a decrease in the rectification index, due to a reduced AMPAR current measured at +40 mV versus -70 mV, indicates an increased plasma membrane occurrence of GluR2-lacking receptors, primarily through increases in GluR1. This is important because only GluR2-lacking AMPARs can pass calcium, which may facilitate calcium-dependent plasticity.

Synaptic Plasticity in the VTA Following Cocaine Exposure

DA neurons of the VTA are crucial for many aspects of goal-directed behavior. Midbrain DA neurons exhibit two patterns of firing activity: a pacemaker firing responsible for tonic DA levels in target regions, and burst firing,

likely responsible for phasic DA changes in midbrain target regions. Burst firing in particular may indicate salience of important stimuli, which can serve to initiate goal-directed behavior as well as act as a teaching signal. Thus, phasic activation of VTA DA neurons is thought to promote behavior, especially in relation to conditioned stimuli. Importantly, modeling studies have shown that changes in AMPAR number or function can alter firing of VTA DA neurons, perhaps by indirectly facilitating NMDAR activity and burst firing. In this regard, excitatory synapses onto VTA DA neurons are highly plastic, exhibiting NMDAR-dependent long-term potentiation (LTP), long-term depression (LTD), as well as short-term plasticity. Thus, it is hypothesized that glutamatergic plasticity could modify AMPAR function in response to the environmental context and demands on the organism, and could significantly alter generation of firing in VTA DA neurons during goal-directed behavior. Indeed, learning in relation to behavioral sensitization to cocaine as well as cocaine and morphine-induced conditioned place preference can both be blocked by VTA NMDAR antagonists.

Interestingly, Ungless *et al.* were the first to report that, 24 h after a single exposure to cocaine, the ratio of AMPAR-mediated current to NMDAR-mediated current (termed the AMPAR–NMDAR ratio) is significantly elevated at excitatory synapses in the VTA relative to saline-injected controls (Table 1). The increase in the AMPAR–NMDAR ratio after cocaine exposure occludes further LTP induction, suggesting that these synapses are already in an LTP-like state. Importantly, LTP of VTA glutamatergic synapses is observed after a single exposure to many other drugs of abuse, demonstrating a convergence of cellular effect within the VTA by many abused drugs. The mechanism underlying LTP of excitatory synapses onto VTA DA neurons appears to be mediated by the insertion of GluR2-lacking AMPARs. This insertion of GluR2-lacking AMPAR subunits is thought to be transient, so that the GluR1 subunits are eventually replaced by newly locally synthesized GluR2/3 after many hours. Further, the insertion of GluR2-lacking AMPARs can be reversed

Table 1 Estimated consequence of repeated cocaine or alcohol on VTA and NAcc function

	Cocaine VTA	Cocaine NAcc	Alcohol VTA	Alcohol NAcc
Early withdrawal (6–24 h)	↑	↓	↓	↑
Protracted withdrawal (weeks)	↑ ^a	↑ ^b	↑	↑
Neuro-adaptation important for relapse/reinstatement?	n.d.	Yes	n.d.	Yes

^aVoluntary intake only.

^bIn some cases can be reversed by cocaine re-exposure.

We should note that multiple neuro-adaptations can occur simultaneously with opposite effects on excitability, especially during early withdrawal, making the integrated effect more difficult to determine, n.d. not determined.

by activation of the metabotropic glutamate receptor 1 (mGluR1), which induces replacement of GluR2-lacking receptors with GluR2-containing receptors. This is hypothesized to readjust synaptic strength back to basal levels and therefore prevent behavioral changes that could contribute to development of addiction.

Thus, LTP changes in VTA DA neurons after a single cocaine exposure are transient, exhibiting potentiated AMPAR currents 5 but not 10 days after cocaine exposure. The same time course for potentiated VTA AMPAR currents is also observed following repeated cocaine injection, suggesting that increased cocaine exposure does not *per se* increase the duration of the VTA AMPAR enhancement. Also interesting is that a single cocaine injection produces changes in opiate conditioned place preference and aversion with a similar time course (altered conditioning 5 but not 10 days after cocaine exposure), and these effects of cocaine were prevented by inhibition of NMDARs in the VTA during cocaine exposure. Since LTP often requires NMDARs, this is strong evidence that AMPAR LTP in the VTA after cocaine exposure could enhance Pavlovian conditioning and perhaps other reward-related learning.

Importantly, because pathologic drug use and seeking in humans is believed to involve associative learning mechanisms, it is critical to examine plasticity changes under conditions where animals voluntarily self-administer cocaine. Indeed, a recent study examined plasticity changes in the VTA in rats during abstinence from self-administered cocaine. Unlike previous experiments where animals passively received experimenter-administered cocaine, enhanced glutamate function in VTA DA neurons from cocaine self-administering rats remained significantly elevated for up to 3 months of abstinence (Table 1). Importantly, control experiments in this same study showed that rats given yoked cocaine infusions (noncontingent delivery of cocaine in a similar pattern and dosage as cocaine self-administering rats), or that self-administered food or sucrose, exhibited short-term but not LTP-like changes in VTA DA neurons. This study illustrates the importance of the role of associative learning and memory mechanisms in the generation of long-term plasticity after drug exposure. Finally, although there are some mixed results in biochemistry experiments, the majority of studies show an increase in GluR1 expression level after withdrawal from cocaine self-administration (Table 1). Changes in the VTA NMDAR levels have also been observed during cocaine withdrawal, although electrophysiological studies have not been performed to corroborate these results. Taken together, these data suggest that a number of behavioral conditions can produce short-term plasticity in the VTA (passive cocaine exposure, self-administration of natural reinforcers), but the combined outcome of cocaine's pharmacological effect

with the animal's volition to take cocaine can produce a long-lasting potentiation of glutamate transmission onto VTA DA neurons.

Nucleus Accumbens Glutamate Receptors Following Cocaine Exposure

The NAcc is another integral part of the brain's reinforcement circuit, and many studies concur that synaptic plasticity in the NAcc can be altered by cocaine exposure. LTP of glutamatergic transmission onto medium spiny neurons, the main output neurons of the NAcc, was first observed following passive, experimenter-administered cocaine injections (Table 1). However, unlike the VTA where LTP is elicited after a single cocaine exposure, NAcc synaptic plasticity was observed only after 5 daily cocaine injections. After repeated cocaine exposure, mice show both cocaine-induced behavioral sensitization and LTP *ex vivo* in NAcc shell but not core. Further, cocaine injection 24 h before recording converts the cocaine-associated LTP back to the basal state of LTD. Thus, the history of cocaine exposure can readily change the direction of synaptic plasticity in the NAcc. In addition, unlike the VTA, AMPAR potentiation in the NAcc following experimenter-administer cocaine was not attributed to changes in AMPAR subunits, since analyses of rectification index revealed no rectification before or after cocaine exposure. This is also consistent with the result that blocking constitutive recycling of GluR2-containing AMPAR prevented NAcc LTD and reduced expression of cocaine-induced sensitization, perhaps indicating a role for NAcc LTD in the enhanced locomotor activation by acute cocaine after sensitization.

Paralleling studies in the VTA, NAcc plasticity induced following cocaine self-administration revealed differences between passive and voluntary cocaine self-administration. In cocaine self-administering rats, LTD in the core and shell of the NAcc was inhibited after 1 day of abstinence. However, after 21 days of abstinence, LTD induction remained occluded in the NAcc core, but could be readily induced in the NAcc shell. This result suggests that voluntary cocaine self-administration induces long-lasting glutamatergic neuroadaptations exclusively in the NAcc core, a region associated with control of behavior by drug-related stimuli and relapse. In support of this finding, a number of studies have observed increased NAcc GluR1 levels after cocaine self-administration (Table 1). Importantly, a recent study demonstrated an increase in GluR1 subunits in the NAcc core, but not the NAcc shell, during abstinence from cocaine self-administration. Increased NAcc core GluR1 levels are associated with an increase in rectification in AMPAR currents, as would be expected from plasma membrane insertion of GluR1-containing AMPARs. Importantly, to demonstrate

that addition of GluR1-containing AMPARs plays a significant role in cocaine relapse, this study showed that intra-NAcc injection of antagonists that block only GluR1-containing AMPARs significantly reduces cocaine reinstatement.

In addition to altered AMPAR function, recent work has shown the importance of changes in the Homer proteins, scaffolding proteins that bind directly to mGluRs and indirectly to NMDARs, as critical neuroadaptations that can drive cocaine seeking. Repeated cocaine and abstinence is associated with reduced NAcc protein levels of Homer1b/c and Homer2a/b isoforms and group I mGluRs (mGluR1 and mGluR5) (**Table 1**). Activation of group I mGluRs with the NAcc can increase NAcc glutamate levels and produce locomotor activation. However, mGluR enhancement of NAcc glutamate levels and locomotor activation is blunted after 3 weeks but not 24 h of withdrawal from repeated cocaine injection, in agreement with reduced mGluR and Homer protein levels. No reductions in mGluR or Homer levels are observed after 3 weeks of withdrawal from cocaine in any other brain region, including the VTA. Also, under some models of cocaine exposure, the time course of changes in NAcc mGluR and Homer differ, but whether this is due to active versus passive cocaine exposure or other methodological details is unclear.

Alcohol and Glutamate Receptors

Alcohol is both highly addictive and legal to obtain, and alcohol abuse is considered the third leading preventable cause of human death; thus, alcoholism extracts enormous social and economic costs relative to other drugs of abuse. For this reason, neuroplastic changes that contribute to the pathological, compulsive alcohol seeking and relapse are of particular interest, especially because alcohol seeking and intake occurs even in the face of detrimental consequences, and represents a significant clinical hurdle when attempting to overcome alcohol use disorders.

A number of studies concur that, early in withdrawal from alcohol, there is increased NMDAR function in several brain regions, including the NAcc (**Table 1**). The exact changes in particular NMDAR subunit levels vary among brain regions, and may depend on whether alcohol intake is continuous or intermittent. Some studies have also observed increased NMDAR function without changes in subunit levels, for example, through changes in subcellular localization. In the NAcc, increases in both NR1 and NR2B have been observed during early withdrawal from alcohol, as well as increased levels of mGluR1 and Homer 2b (see below). One study also observed that long-term alcohol strongly upregulates the NAcc NR1-2 isoform, which lacks the C1 cassette of NR1 and thus is inefficient in

trafficking or anchoring NMDARs to the proper PSD sites. In any case, a general hypothesis is that increased NMDAR function during withdrawal from alcohol will enhance neuronal excitability and drive withdrawal symptoms and resumption of alcohol consumption. Since negative affects can strongly promote alcohol seeking, antagonism of NMDARs is an attractive clinical intervention to reduce early withdrawal symptoms.

In the VTA, increased NMDAR subunit levels are observed after chronic forced alcohol intake. In addition, a recent study found increased VTA AMPAR function after alcohol self-administration. Although enhanced glutamate receptor function would be predicted to increase VTA excitability during withdrawal, decreased activity of VTA neurons and decreased DA release in terminal regions is observed during early withdrawal (**Table 1**), and this hypoactivity is reversed by systemic inhibition of NMDARs. Thus, NMDAR activity in a region other than the VTA may predominate in terms of control of VTA activity during early withdrawal from alcohol as well as other drugs of abuse. Also, one study found reduced NMDAR excitation of VTA firing *ex vivo* during withdrawal from alcohol. Importantly, reduced DA levels in VTA target regions likely contribute to alcohol seeking, since self-administration of alcohol during withdrawal continues until NAcc DA levels are normalized. We should also note that VTA DA neurons may exhibit hypoactivity during withdrawal from alcohol, but it is also possible that enhanced NMDAR and AMPAR function after chronic alcohol could facilitate VTA neuron activity while the animal is consuming alcohol, especially since alcohol exposure can facilitate firing of VTA neurons.

During longer withdrawal from alcohol, the NAcc shows a different pattern from cocaine in terms of glutamate receptor levels, with increases in NR2B, mGluR1, and Homer2b (instead of the decreases associated with cocaine) (**Table 1**). These changes are observed after 2 weeks withdrawal from 3 months alcohol drinking, with an increase only in Homer2b after 2 months withdrawal. Also, changes in all three proteins are observed after shorter-term passive exposure or binge drinking, and thus the time course of glutamate receptor changes may depend on the duration and route of alcohol exposure. Interestingly, viral overexpression of Homer2b in the NAcc increases alcohol preference and alcohol-related place preference, suggesting that mimicking the drinking-induced increase in Homer2b is sufficient to enhance alcohol preference and reinforcement. Furthermore, NAcc Homer2b overexpression increases alcohol-induced NAcc glutamate and DA release, a phenotype that has been associated with increased alcohol preference and has been linked to mGluR1/5 regulation of glutamate release. Thus, enhanced NAcc Homer2b levels, acting through mGluRs, could facilitate the

reinforcing effects of alcohol after long-term intake and thus promote alcohol seeking.

Altered Intrinsic Excitability after Alcohol or Cocaine

In order for glutamate receptor activation to generate action potential firing, the synaptically generated excitatory postsynaptic currents (EPSCs) must travel along dendrites to reach the area where action potentials are generated, which is in the spike-initiation zone of the axon hillock in many neurons, and in a primary dendrite in the VTA. Although passive cable properties defined by the dendritic geometry can greatly filter EPSCs, numerous ion channels can amplify or degrade passing EPSCs. Thus, alterations in ion channel function could greatly alter EPSC translation into action potentials, as well as modulate the ion flux within synapses which impacts generation of LTD or LTP. Of particular interest is the possibility that persistent changes in ion channel regulation of NAcc or VTA firing could dramatically alter the ability of relapse-inducing stimuli to drive firing of these brain regions and to facilitate cravings and relapse during abstinence.

L-type voltage-gated calcium channels (LVGCCs) are particularly interesting, since LVGCC misregulation could represent a common mechanism underlying early withdrawal from many abused drugs, including alcohol. Chronic alcohol upregulates LVGCC levels in several brain regions, although mixed results have been observed in the few studies from the striatum. Furthermore, systemic administration of LVGCC antagonists decreases alcohol withdrawal symptoms as well as the depression in DA levels associated with withdrawal from alcohol and other drugs. There is also considerable evidence from human preclinical trials suggesting that LVGCC antagonists may ameliorate withdrawal, tolerance, and cravings in human alcoholics and addicts. Also, in the striatum, LVGCCs are necessary for induction of LTD, and NAcc LTD is necessary for the expression of behavioral sensitization to cocaine. Thus, like NMDARs, antagonism of LVGCCs may represent a clinical intervention to reduce early withdrawal symptoms, although the brain regions in which LVGCC alterations mediate withdrawal symptoms have not been identified.

Changes in NAcc ion channel activity after repeated cocaine injection and 3 days withdrawal are well studied. During withdrawal, there is increased potassium channel activity, decreased N- and R-type VGCC activity, and decreased sodium channel activity, which overall depress NAcc neuron excitability (**Table 1**). Decreased calcium channel activity might also depress induction of glutamatergic plasticity, neurotransmitter release, and perhaps calcium-dependent activation of kinases or other regulatory molecules. Interestingly, some cocaine-associated changes in channel function may be secondary to altered

tonic activity of intracellular signaling molecules. Increased tonic protein phosphatase activity and increased tonic PKA activity could underlie the reduced VGCC and sodium channel function, respectively. Psychostimulant-related changes in intrinsic excitability have also been identified in the prefrontal cortex and subiculum.

VTA DA neuron firing after alcohol exposure is also well studied, with a reduction in firing during the first 1–6 days of withdrawal from alcohol (**Table 1**). We should note that the possible role of ion channel changes in this decreased VTA neuron excitability is poorly understood, with even mixed results regarding whether VTA firing is reduced following alcohol exposure in the *ex vivo* brain slice preparation. Nonetheless, also of interest are changes in channel function that persist beyond the early withdrawal period. A recent study found that calcium-activated SK potassium channel (SK) function is significantly reduced in VTA DA neurons after 7 days withdrawal, with a small reduction also in the I_h current (which was also observed after one day of withdrawal in a different study). Although baseline pacemaker firing is not altered after alcohol exposure, NMDA receptor activation increases firing rate in control animals but leads to burst firing in alcohol animals. This is in agreement with *in vivo* and *ex vivo* studies showing that SK inhibition facilitates glutamate-induced bursting in midbrain neurons. Since bursting is associated with increased DA release in VTA terminal regions, loss of SK could enhance DA release in response to alcohol-related stimuli and thus facilitate alcohol seeking.

Most critical are neuroadaptations present after even longer periods of abstinence from alcohol, since these could anchor the increased propensity for relapse in human alcoholics apparent after even months or years of abstinence. An early study showed that protracted abstinence from long-term alcohol intake was associated with a reduced afterhyperpolarization in the dentate gyrus; the SK makes a strong, although not unique, contribution to the afterhyperpolarization. Thus, these electrophysiological data, as well as work from biochemistry and gene chip studies, identify changes in SK as well as other ion channels and neurotransmitter receptors as critical neuroadaptations in the NAcc and other brain regions that may facilitate alcohol seeking during protracted abstinence from alcohol.

Conclusions and Future Directions

Although there are tantalizing clues toward the effect of chronic drug exposure on glutamate receptor and ion channel function, many questions remain. Few studies have examined excitability changes beyond the period of early withdrawal, although recent studies of glutamate receptor and ion channel function have begun to address this question after cocaine, alcohol, or heroin exposure.

Identifying long-term changes is particularly critical since neuroadaptations persisting after weeks or months of abstinence may mediate long-term susceptibility to cravings and relapse. Importantly, these long-term neuroadaptations may also correlate with structural changes in spine density or dendritic architecture that can occur in the NAcc after passive or active cocaine administration. It is also clear that self-administration and passive administration can differentially alter gene expression and protein function, perhaps due to learned cues that come to be associated with the act of voluntary self-administration and that can reinforce further alcohol or drug seeking in a conditioned, involuntary manner. Fortunately, the field possesses a battery of powerful techniques including traditional Western blot protein analyses, larger-scale genomic and proteomic methods, local knockdown or overexpression of particular signaling molecules during behavior, and *ex vivo* brain slice electrophysiology from animals that have learned to self-administer cocaine or alcohol. Although laborious and technically challenging in adult animals, we argue that *ex vivo* electrophysiology is especially critical for uncovering and defining which neuroadaptations might persist during abstinence, in part because potent functional changes can occur without altered total protein or mRNA levels. In addition, exact delineation of the molecular alterations apparent after abstinence could allow one to utilize very precise antagonists to reverse that molecular change (e.g., reversing the plasma membrane trafficking of particular AMPAR subunits), and perhaps provide a novel therapeutic intervention for addiction and alcoholism.

Glossary

Ahedonia – An inability to experience pleasure from normally pleasurable activities.

Dysthymia – A chronic mood disorder with symptoms similar to, although less severe than, major depressive disorder.

Dysphoric – Having an unpleasant mood state which may include sadness, irritability, and anxiety.

Major depressive disorder (MDD) – A chronic, severe mood disorder.

Selective serotonin reuptake inhibitors (SSRIs) – This class of drug includes fluoxetine, paroxetine, sertraline, citalopram, and escitalopram, and is commonly used to treat depression and anxiety.

disorder, depression occurring as part of a bipolar illness, dysthymia, depression directly secondary to a general medical condition, and the variety of syndromes falling under the category of “depressive disorder not otherwise specified.” There is also depression secondary to the effects of a substance, which can be exceedingly difficult to separate from true comorbidity.

In North America, depression affects 8–10% of the population in a given 1-year period, with lifetime rates between 15% and 20%. Rates are higher (up to 25% lifetime incidence) in women. Onset can be anywhere from childhood to the end of life. Risk factors include family history of depression, medical illness or chronic pain, high levels of life stressors, social isolation, and low socioeconomic status.

Substance Use Disorders

Between 3% and 10% of Americans over age 12 use illicit substances (not including alcohol or nicotine) yearly, with higher use among men and rate of use being inversely proportional to education, level of employment, and socioeconomic status. Over half of those using illicit substances are younger than 30 (which may be one reason substance use precedes depression in a majority of patients with both illnesses). The most commonly abused drugs are prescription drugs, including anxiolytics and opiates, followed by marijuana.

Almost half of Americans over age 12 describe themselves as current alcohol drinkers, and a similar number have engaged in heavy drinking (more than five drinks on one occasion). Binge drinking most commonly occurs in the late teens and early 20s, and is more common among men. Approximately 30% of Americans over age 12 consider themselves to be regular smokers, and well over half report that they have tried to quit smoking and failed at least once.

Suicide

Approximately 1 million people per year commit suicide, with women being more likely to attempt but men being more likely to complete. The two biggest risk factors for suicide are depression and substance use, making patients with comorbid depression and substance use an especially high-risk combination. Up to 40% of people attempting or completing suicide are intoxicated at the time of the attempt; these numbers are higher in younger people.

Epidemiology

Depression

There are several distinct syndromes which fall under of the category ‘depression;’ these include major depressive

Lifetime risk of suicide in patients with alcohol dependence is tenfold that of the general population, and both chronic alcohol use and acute intoxication are associated with a higher risk of suicide attempts and completions. Opiate dependence is also linked to increased risk of suicide attempts and completions, particularly in patients who have also had accidental overdoses. Higher-than-average suicide risk has also been shown in patients dependent on cocaine, amphetamines, and many other substances.

Comorbidity

Patients with depression have an approximately 33% lifetime prevalence of problematic alcohol use. Patients with higher alcohol intake after a stressful event are more likely to develop depression than those with lower intake. In addition, patients with depression are less likely to attain sobriety and more likely to relapse if they do.

Abuse or dependence on opiates, including heroin, opium, and prescription narcotics, is also correlated with depression. As is the case with alcohol, patients with both depression and opiate dependence are less likely to attain sobriety and more likely to relapse than nondepressed opiate-dependent patients.

Stimulant abuse, including cocaine and amphetamines, is highly correlated with depression, both during and after the period of dependence. Several studies have also shown a correlation between cigarette smoking and a higher incidence and severity of depressive symptoms; it is unclear whether this is cause or effect.

There is also significant correlation between early-onset heavy or problematic marijuana use and later development of depression and suicide attempts; this correlation persists after controlling for possible confounding variables. Patients who develop depression have not been consistently shown to be at increased risk for marijuana use or dependence, calling the self-medication theory into question; there are, however, some smaller studies which do support an antidepressant effect of cannabis. There is clearly a correlation between lifetime cannabis dependence and lifetime incidence of major depressive disorder (MDD); it is still not clear how much of this is due to confounding variables. It is also not clear if recent cannabis use has a significant effect on, or is affected by, depression. One study suggests that depressed patients who use marijuana are less likely to experience euphoria during use and are more likely to experience anxiety, depression, and dysphoria than nondepressed users.

Ecstasy, or methyl-d-methamphetamine (MDMA), is a semisynthetic amphetamine which inhibits serotonin reuptake and induces release of norepinephrine and dopamine. Some studies have shown that people with depressive disorders are more likely to use MDMA, and use it more frequently than nondepressed people, possibly

as a means of self-treatment; other studies suggest that those who use MDMA infrequently have the same incidence of depression as the general population. Depression precedes MDMA use more often than the other way around, although acute withdrawal from MDMA often includes dysphoria, and there is some evidence that heavy MDMA use can lead to longer-lasting depressive symptoms.

Few studies exist on comorbidity of depression and benzodiazepine dependence. Many patients with depression are prescribed benzodiazepines, either as a mood stabilizer, an augmenting antidepressant, or a treatment for comorbid anxiety. Benzodiazepine overdose is a common form of suicide attempt, although generally benzodiazepines are only lethal if combined with alcohol or other gamma aminobutyric acid (GABA)ergic drugs.

There are also few studies on the relationship between barbiturates and depression; most of those that have been done examine the effect on mood when barbiturates are used to treat epilepsy or as part of a course of electroconvulsive therapy, rather than on depression in barbiturate-dependent patients. This may be in part due to the relatively uncommon occurrence of barbiturate dependence. The studies that do exist present conflicting data; some studies have shown that epileptic patients treated with barbiturates are more likely to be depressed, whereas others show that when depressed epileptic patients are treated with barbiturates, their depression improves.

Symptoms

Depression

The core depressive symptoms are depressed mood and loss of interest in activities that were formerly pleasurable (anhedonia). Other significant symptoms include changes in sleep (hypersomnia or insomnia), changes in appetite (either increased or decreased), poor concentration, low energy or fatigue, feeling guilty, feeling worthless, feeling hopeless, psychomotor slowing, and suicidal thoughts. Many of these symptoms also occur with substance intoxication or withdrawal, which makes it very difficult to distinguish between a depression secondary to substance use and a depression comorbid with substance use. Some of these symptoms are mitigated by substance intoxication, leading to the theory that some patients may begin or continue using substances in an effort to self-medicate their depression. This self-medication is described most commonly in middle-aged women, and after chronic use the medications themselves will induce depressive symptoms during either intoxication, withdrawal, or both.

Substance Use Disorders

Intoxication

Many substances have acute effects which may relieve depressive symptoms. Cocaine, amphetamines, and other stimulants, as well as MDMA, have a euphoric high, while opiates, alcohol, and anxiolytics may relieve comorbid anxiety, temporarily improve sleep, or allow for an escape from depression. For obvious reasons, few drugs of abuse consistently cause depressive symptoms during intoxication, although several, including stimulants and hallucinogens, may at times cause dysphoria, irritability, or panic in certain individuals.

Acute withdrawal

The acute withdrawal from most substances induces effects directly opposite of those induced by the high. Most drugs which involve a euphoric, elevated, or activated high can mimic depression during the acute withdrawal period. Depression, often severe, is a hallmark of acute cocaine withdrawal. There is some evidence that this withdrawal period is worse with crack use than with intranasal or intravenous use. Symptoms during this period may include severely depressed mood, suicidality, hypersomnia, hyperphagia, fatigue, and inability to concentrate – all symptoms of depression. Acute withdrawal from amphetamines and other stimulants is similar. Depressed mood may also occur with acute withdrawal from nicotine, hallucinogens, MDMA, alcohol, and opiates. Patients often relapse as a result of this dysphoric mood.

Protracted withdrawal

Some drugs cause long-lasting, or even permanent, brain changes which may result in depressive symptoms lasting for years after sobriety is achieved. Long-term cocaine users can develop chronic anhedonia, which may persist even after years of sobriety; this is thought to be related to permanent changes in dopamine neurotransmission from downregulated postsynaptic D2 dopamine receptors. In animal studies, high doses of MDMA have been shown to destroy serotonergic axons, which may explain why heavy MDMA use can lead to a depressive syndrome lasting years after the last use. Inhalants and solvents cause nonspecific brain damage, which can at times include a depressive syndrome.

Chronic use

Current chronic use of many substances may cause depressive symptoms; this is due both to the direct neurochemical effects and to the lifestyle and social consequences of chronic use. Patients who are currently abusing or dependent upon alcohol often have depressed mood, anhedonia, insomnia, poor appetite, difficulty concentrating, feelings of guilt about their drinking, feelings

of hopelessness and worthlessness, and suicidality – basically the entire complement of depressive symptoms. This is also true of patients who are currently using opiates or anxiolytics, and is true of those using stimulants when they are between highs. Current smokers have also reported higher levels of depressive symptoms and anxiety than do nonsmokers or former smokers.

Neurobiology and Genetics

Neurobiology

The three neurochemicals thought to be most strongly related to depression are serotonin, norepinephrine, and dopamine. When drugs of abuse act directly on these circuits, as with cocaine, for example, it is easy to see how comorbidity (and also substance-induced depression) can occur. However, many drugs of abuse do not act primarily or directly on these circuits – nicotine acts on nicotinic and cholinergic circuits, alcohol acts widely, opiates and cannabinoids act on their own specific receptors, and anxiolytics tend to act on the GABA system. While the neurobiology of these three amines certainly contributes to understanding the comorbidity of substance-use disorders and depression, it is not fully explanatory. Important findings in MDD have included that GABA brain activity is significantly downregulated in depression as well as most forms of drug abuse. The role of cholinergics, cannabinoids, and opiates in mood regulation has also become evident in the last 20 years.

Depressive disorder rates in stimulant-dependent individuals are substantially higher than community rates. The comorbidity of these disorders may reflect shared neurochemical alterations in the function of serotonin, dopamine, and peptide systems, such as corticotropin-releasing factor and neuropeptide Y. These alterations are observed in humans and in animal models of depression and stimulant dependence, particularly in limbic brain structures. Since this shared neurobiology does not seem to result from significant shared heritability or genetic linkage, it is thought that stimulants induce changes in neurobiology that are similar to those found in depression; these changes might provide a future therapeutic target. Stimulant-dependent patients with a depressive disorder may be a specific subpopulation for antidepressant trials, and they might reduce their stimulant abuse when treated with antidepressants. Concomitant dependence on alcohol or opioids may influence this response; antidepressants appear to be more effective for depression in combined stimulant and opioid dependence than in combined stimulant and alcohol dependence.

Many patients experience depressive symptoms while quitting smoking; this may be partially due to a substance in tobacco which acts as an MAO inhibitor rather than the

nicotine itself; smoking may serve to treat a primary depression, and the withdrawal of the MAO inhibitor then precipitates a relapse. Developing serious major depression within 6 months after stopping smoking is significantly more likely in patients with a history of MDD than in those without an MDD history.

Depressed patients have neurobiological abnormalities which persist even after treatment with antidepressants has been completed and remission achieved. One such abnormality is a decrease in cortical GABA; it is currently not clear if the low GABA levels precede the depression or are caused by it. Use of antidepressants leads to changes in the GABA system, and GABAergic drugs have been shown to have some mood-stabilizing and antidepressant effects.

Genetics

Genetic predispositions have been demonstrated for both depression and substance use disorders. Having a family history of either depression or substance-use disorders raises the individual's risk for both. The major forms of substance dependence, including cocaine, alcohol, nicotine, and opiate dependence, are all heritable to some degree – 50–60% by estimates obtained from large family, twin, and adoption studies. In the case of comorbidity, it may be that a single gene predisposes to both depression and substance-use disorders, or that a gene which predisposes to depression is linked to a gene which predisposes to substance use disorders.

The S and L types of the serotonin transporter have been shown to be related to depression, with homozygous S individuals being more prone to depression than heterozygotes, who in turn are more prone to depression than homozygous L individuals. The S allele has also been linked to higher rates of nicotine dependence in some studies, although other studies contradict this.

Some studies have suggested that alcohol dependence and mood disorders co-occur more frequently than would be expected by chance alone, while other studies suggest that they vary independently. Studies involving the mu opiate receptor polymorphism have shown one mu receptor form which predicts alcohol dependence responsive to naltrexone therapy; non-alcohol-dependent female relatives of these subjects had higher-than-average rates of depression. A study done in non-alcohol-dependent men showed that the men with a positive family history of alcohol dependence felt a lower subjective level of intoxication for a given blood alcohol level than did men who had no family history of alcohol dependence; this subjective insensitivity is itself a risk factor for alcohol dependence. Linkage studies have identified several potential loci which may influence the risk of alcohol dependence; many of these are in the alcohol dehydrogenase gene cluster on the long arm of chromosome 4.

Candidate genes include genes related to alcohol metabolizing enzymes, the mu opioid receptor, the GABA_A receptor, and the muscarinic acetylcholine receptor. There are also controversial studies which suggest a serotonin transporter subtype coded for on chromosome 17 may be a candidate. The A1 allele of the D2 dopamine receptor is another controversial candidate.

A large female twin study showed that a family history of depression was predictive of cigarette smoking; this association is thought to be due to genetic factors which may predispose an individual both to smoking and to depression. Heritability of nicotine dependence is estimated to be 60% or higher. Linkage studies have shown candidate loci for genes related to nicotine dependence on at least 12 chromosomes; one candidate gene is dopa decarboxylase, and others code for cholinergic receptors, parts of the cytochrome P450 system (with those who metabolize nicotine more slowly less likely to be addicted; linked genes in this area may have important implications for treatment) and the A1 allele of the D2 dopamine receptor.

A large Australian study done with same-sex twins discordant for cannabis dependence or for early onset heavy cannabis use found that cannabis-dependent twins were two to three times more likely to have suicidal ideation or a suicide attempt. Those who began marijuana use prior to age 17 had a 3.5 times higher risk of suicide attempt, but were not at increased risk of MDD or suicidal ideation. Fraternal, but not identical, twins had an increased risk of MDD if they were cannabis-dependent as compared to their non-cannabis-dependent twin. Fraternal twins were also more likely to become cannabis dependent if they developed MDD or suicidal ideation; this did not hold true for identical twins.

Twin studies done on the heritability of cocaine abuse and dependence have found heritabilities as high as 65–80%. Several candidate loci have been identified. Candidate loci for opioid dependence have been found on chromosome 17.

Treatment

Antidepressants

Successful treatment of underlying depression modestly improves outcomes for treatment of alcohol abuse and dependence, in contrast to previous theories that addiction must be treated first. Clinical and preclinical research since the 1980s has demonstrated an inverse relationship between serotonergic activity and alcohol use; however, SSRIs are not consistently effective as treatment for alcohol abuse or dependence in heterogeneous groups. They do show promise in specific groups of alcoholics, including specific genetic groups, early- or late-onset alcoholics, and alcoholics with comorbid anxiety or depression.

There is evidence to suggest there may be distinct subtypes of alcoholism which may be distinguishable by the type and complexity of the serotonergic dysfunction. Response to serotonin uptake inhibitors varies greatly by individual, with drinking reductions ranging from 10% to 70% in some studies. A major challenge is treatment matching to predict which patients will respond to which treatment.

In contrast to alcohol dependence, treatment with antidepressants in opiate-dependent patients does not have good evidence for improving outcomes of either depression or opiate dependence; however, attaining sobriety (whether by pharmacologic or behavioral means) typically leads to a significant decrease in depressive symptoms. It is possible that this indicates an opiate-induced depression rather than a true comorbidity, at least in a majority of patients. An important caveat here is that both methadone and buprenorphine stabilization and maintenance clearly reduce depressive symptoms. The distinction in chronic effects of dysphoria and depression between these treatments and abuse of short-acting opiates such as heroin or most prescription opiates is that short-acting opiates lead to intermittent withdrawal, then relief and sometimes euphoria with a sufficiently large dose of opiate in chronic abusers with significant opiate tolerance. This intermittent pattern of symptoms in the abuser of short-acting opiates seems critical to induction of depression. Further studies are needed to fully address this question.

Several studies have indicated that treating cocaine dependence and depression simultaneously may be more successful than sequential treatment. Preclinical studies have suggested that serotonin plays an important role in the dopamine reward pathway activated by cocaine use, suggesting a possible role for SSRIs in the treatment of cocaine dependence; however, most clinical studies have failed to show an effect. SSRIs may be less useful in this population than other agents, particularly desipramine and bupropion.

Bupropion is also commonly used for patients with comorbid depression and nicotine dependence, although this may not be the ideal choice for patients who are already on antidepressants or who have high levels of anxiety.

Table 1 summarizes recent data for antidepressant medications used in the treatment of comorbid substance-use disorders and depression.

Other Medications

Aside from antidepressants, the two major categories of pharmaceutical treatments for patients with comorbid depression and substance-use disorders are medications (which are FDA-indicated for treatment of substance use

disorders) and medications (which are used off-label for the treatment of one or both illnesses).

Patients treated for opiate dependence with methadone or buprenorphine maintenance therapy typically show improvement with regard to depressive symptoms, at least initially; it is unclear how much of this is a pharmacologic effect and how much may be related to improvement of life circumstances with treatment. There are few data supporting improvements in depressive symptoms with naltrexone, disulfiram, or acamprosate.

Nicotine replacement therapy does not appear to mitigate the depression associated with smoking cessation, although it does improve the dysphoria and anxiety experienced during the first several weeks of abstinence. Varenicline showed early promise, but concerns have now arisen about possible worsening of depression and suicidality.

Anti-epileptic drugs have been used off-label (except in the case of those approved for use in bipolar depression) in patients with comorbid depression and substance use with varying degrees of success. These drugs have the benefit of reducing the risk of seizures during acute withdrawal from anxiolytics or alcohol, and those which act as mood stabilizers may help improve irritability as well as depressive symptoms. Valproic acid has been studied in patients with comorbid substance abuse and bipolar disorder; it shows the most promise in patients whose drug of choice is alcohol, as it relieves symptoms of alcohol withdrawal and may help prevent relapse to drinking.

Table 2 summarizes recent data for medications used in the treatment of comorbid substance use disorders and bipolar disorder.

Behavioral Treatments

Pharmacologic treatment is generally just one part of the overall plan in patients with either depression or substance-abuse disorders; this is also the case for patients with comorbidity. There are several behavioral treatments which have excellent data to support their use in depression, including cognitive behavioral therapy (CBT), insight-oriented therapy, 12-step facilitation, motivational enhancement therapy (MET), group therapy, behavioral activation, and, in severe cases, residential treatment. All of these modalities have also been used for patients with substance-use disorders, with varying degrees of success. Self-help groups such as Alcoholics Anonymous, Narcotics Anonymous, and similar groups have limited systematic data but many testimonials of helping patients maintain sobriety. These groups may also help improve depressive symptoms by improving social connectedness, although there are currently few studies on the topic. Motivational interviewing and contingency management strategies also have good data to

Mood stabilizers	Valproate	↓ bipolar symptoms	↓ relapse to alcohol and cocaine	GABA agonist	Malcolm 2001
	Gabapentin	↓ bipolar symptoms	↓ relapse to cocaine	GABA agonist	Sokolski 1999 González 2007
Depression	Lamotrigine	↓ depression and psychosis	↓ cocaine craving	Glutamate antagonist	Brown 2003
	Bupropion	↓ depression	↓ smoking	DA and NE reuptake blocker	Hurt 1997 Hughes 1999
Augmenters	Venlafaxine	↓ depression	↓ cocaine use	5HT & NE reuptake blocker	McDowell 2000
	Baclofen	↓ depression	↓ cocaine use	GABA agonist	Ling 1998
	Tiagabine	↓ depression	↓ cocaine use	GABA agonist	González 2003 Somoza 2007
ADHD/ adolescents	Topiramate	↓ bipolar	↓ alcohol use ↓ cocaine use	GABA agonist	Johnson 2003 Kampman IP
	Naltrexone	↓ depression	↓ alcohol use	Opiate antagonist	Salloum 1998
	Buprenorphine	↓ depression	↓ opiate use	Partial mu opiate agonist	Kosten 1990
	Lofexidine		↓ opiate craving	NE agonist	Sinha 2003
	Pemoline	↓ ADHD	↓ cocaine use	DA agonist	Riggs 2001
	Fluoxetine	↓ depression	↓ cocaine use	SSRI	Deas 2001
	Paroxetine	↓ depression	↓ cocaine use	SSRI	Lohman 2002

support their use in patients with substance-use disorders, but may not specifically target the depression.

Summary

The comorbidity of depression and substance abuse has dire consequences such as much higher rates of suicide than the community rates or than either disorder alone and is not due to a simple causation of one disorder leading to the other. The interaction of these disorders is based on shared genetics, neurobiology, environmental precipitants, and social supports. Their treatments can often be overlapping and patients have the best outcomes when both disorders are treated simultaneously. Treatments include medications such as bupropion, SSRIs, and tricyclic antidepressants, as well as medications focused on the substance abuse itself such as methadone and buprenorphine for depressed opiate-dependent patients. Behavioral interventions can be critical and a wide range of options is available for treating the substance abuse and the depression.

Glossary

Behavioral sensitization – A progressive increase in a behavioral response following repeated administration of a drug at a constant dose.

Conditioned stimulus – A previously neutral stimulus that through association with an unconditioned stimulus elicits a response similar to that of the unconditioned stimulus.

Negative reinforcement – An increase in the probability of a response when the response is followed by removal of a stimulus.

Positive reinforcement – An increase in the probability of a response when the response is followed by presentation of a stimulus.

Common Themes

In the subsequent discussion around specific models, there are some common themes that are relevant to the use and interpretation of all animal models of drug addiction. As a result, a more general introduction to these themes is warranted. It should be noted that the purpose of raising these themes is not to say that they are problematic or specific to the animal models, since their impact may be just as significant on the drug addict; in fact, some aspects are likely to be crucial to understanding addictive behavior in man. Instead, the aim is to highlight the potential importance and impact of such variables on both the animal models and clinical manifestations of drug addiction.

The first of these is the impact that learning and conditioning can have on models of drug addiction. By its very nature and definition, drug addiction is intimately tied to both positive and negative reinforcement. The definition of a positive reinforcer as a stimulus that strengthens the behavior that precedes it parallels the clinical observation that the use of drugs of abuse (the positive reinforcer) increases the probability of subsequent drug use. Similarly, the removal of a stimulus that strengthens the behavior that precedes it, known as a negative reinforcer, can describe at its most basic level, the avoidance of a negative affective state such as that induced by drug abstinence. While these parallels between the definition of reinforcement and the basic tenets of drug addiction are admittedly simplistic, they serve to highlight the key role of reinforcement in drug addiction. One key aspect of such primary reinforcers is that through conditioning they routinely become associated with conditioned stimuli (CSs) that previously held neither significant motivational value nor possessed any ability to influence behavior relevant to drug addiction. However, following the formation of conditioned associations, CSs acquire key roles in drug-taking and -seeking behavior, to the extent that some behaviors can be completely absent when the stimuli are removed. For some models, this aspect is used to our advantage and is indeed a core principle of the assay, while for others it is a potential variable that should be considered. Therefore, an understanding, or at the very least an appreciation, of the role of conditioning in animal models of drug addiction is critical if these models are to be used and interpreted correctly.

A second point to consider, again common to many models, is how one can dissociate between effects specific

General Principles

Drug Addiction

While specific definitions of drug addiction (or substance dependence) vary, there is general agreement regarding the factors that are typical of the addicted or dependent individual. Definitions typically require the act of compulsive or obsessive drug seeking, a progressive increase in the amount of drug taken over time, and the occurrence of a negative affective state following withdrawal of the drug. These three components can also be viewed as describing aspects of craving, loss of control over drug intake, and physical dependence, respectively. While it is not possible to study or model drug addiction in any single animal model, by breaking down the complex disorder of drug addiction into its more basic components, it becomes possible to model specific aspects of addictive behavior. For example, one can develop animal models to study aspects of drug taking or drug seeking, while separately investigating the development of physical dependence and the occurrence of negative affect during withdrawal from chronic drug administration. As with all complex disorders of the brain, the value of animal models of drug addiction really lies in understanding the psychological and neurobiological mechanisms, which underlie specific aspects of the disorder, and the subsequent application of such learning to the clinical situation.

to drugs and those that have more general application to other nondrug reinforcers, such as food, water, and sex. Many of the models described below can be applied effectively to study the positive-reinforcing effects of food, or the ability of food-paired stimuli to influence behavior such as the seeking of positive reinforcement. To understand the specificity of mechanistic investigations to drug reinforcement, researchers will often run parallel studies with nondrug reinforcement. However, the lack of specificity to drugs does not preclude outcomes from being relevant to the study of drug addiction. While the specific actions and effects of drugs may be different to those of many natural reinforcers, the underlying psychological processes and neurobiology of these effects may share many commonalities. As such, an understanding of these common mechanisms may be an important first step to understanding the specific nature of drugs of abuse as highly addictive stimuli. Taking such an approach allows the drug addiction researcher to tap into the wealth of knowledge obtained in complementary fields of positive and negative reinforcement.

Finally, while breaking drug addiction down into its component parts may enable study of the disorder in a manageable way; it is important to remember that each of the models described here still relies on the assessment and analysis of behavior, which, by its very nature, is the complex output reflecting a number of underlying psychological and neurobiological processes. A decrease in the number of responses emitted by an animal to obtain a drug could in theory result from effects of the drug on motor output, muscle relaxation, attention, learning, memory, or motivation. In reality, it probably reflects a combination of these domains. The aim is not to say that such models are impossible to interpret, but rather to highlight that the dependent variables studied in animal models of behavior are not always what they seem. The use of appropriate controls and a broader appreciation of complimentary research fields can help tie down effects to particular domains.

Positive Reinforcement Models

Of the animal models of behavior developed to study drug abuse, the most frequently used have focused on the assessment of positive reinforcement. Drugs of abuse typically act as positive reinforcers, meaning that the administration of these drugs increases the probability of the behavioral output, which resulted in drug delivery. It is easy to see the parallel between this description of positive reinforcement and the clinical manifestation of drug abuse. The ability of drugs of abuse to act as reinforcing stimuli can be studied in animals using both the drug self-administration model and the conditioned place preference (CPP) model. In addition, the ability of drugs to

modulate the neuronal pathways that underlie reinforcement can be studied using the intracranial self-stimulation (ICSS) model.

Drug Self-Administration

The drug self-administration model is founded on the principle that an animal will learn the contingency between the performance of an operant response, such as a lever press or nose poke, and the administration of the drug (**Figure 1**). By virtue of the drug's ability to act as a reinforcer, the probability of the operant response being repeated is therefore increased and the behavior maintained. Drug self-administration has been demonstrated in animals for the majority of drugs that have high abuse potential in humans. Typically, drugs are administered via the intravenous route to allow rapid delivery of the drug to the brain and a closer temporal contingency between response and the drug effect. However, self-administration has also been demonstrated via other routes, principally oral, mimicking, for example, alcohol self-administration in humans. To increase the understanding of the neurobiological substrates of drug self-administration, studies have also been performed demonstrating self-administration of drugs directly into discrete brain regions.

The self-administration model is itself a valuable tool in understanding the mechanisms that underlie the ability of an addictive drug to act as a positive reinforcer. However, by manipulating experimental variables, it is also possible to use this model to understand more regarding the nature of the reinforcing properties of drugs of abuse. For example, by altering the schedule of reinforcement, it is possible to build up a picture of the reinforcing profile of the drug. Animals are typically trained to respond under a fixed-ratio (FR) schedule of reinforcement, where a fixed number of responses are required to obtain a single administration of drug. One limitation of such schedules is that response rates are frequently influenced by factors such as satiation and pharmacokinetics, whereby response rates actually decrease with higher unit doses of drugs, reflecting a potential titration of drug intake by the animal (**Figure 2**). Interestingly, a similar effect has been reported in humans where, for example, smokers switching to cigarettes containing lower levels of nicotine have been shown to partially compensate by increasing the number of cigarettes smoked or altering their smoking behavior to increase nicotine intake. As a result, the rate of responding is not necessarily considered a good predictor of reinforcing value and may not differentiate between drugs with a high and low propensity for abuse. One method frequently employed to address the question of relative reinforcing efficacy is the use of progressive-ratio (PR) schedules of reinforcement (**Figure 3**). Under PR schedules, response requirements

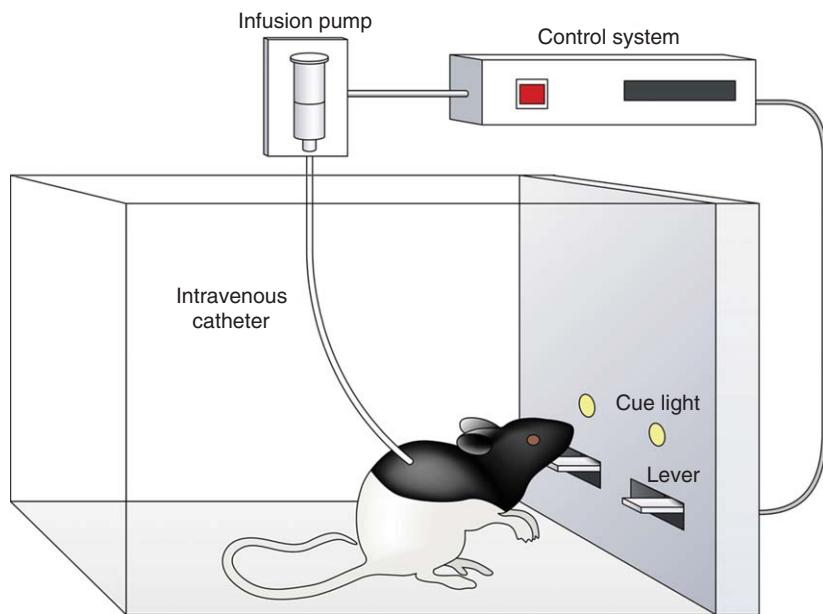

Figure 1 Schematic of the intravenous self-administration procedure in an operant chamber. The rat, with an indwelling intravenous catheter externalized to a port, is connected to an infusion pump containing the test solution. Typically, two levers are presented, and responding on one of these (termed the 'active' lever) results in the delivery of drug. Responding on the alternative 'inactive lever' has no consequence and this is frequently viewed as a measure of response generalization or motor disruption. Cue lights are often included and can be used to signal drug availability or delivery, increasing the speed with which the operant contingency is acquired, and permitting the study of the effects of drug associated conditioned stimuli.

for successive drug administrations gradually increase until the animal fails to continue responding. The point at which responding ceases or drops below a predetermined level, termed the 'break point,' can then be used as an estimate of reinforcing strength. It should be noted that this methodology has its limitations, principally regarding comparisons across drug classes and also regarding the effects of stimulant and sedative drugs on motor output.

Second-order schedules of reinforcement warrant discussion as an example of the potential value that the self-administration model brings to understanding the importance of CSs in reinforced operant responding. Second-order schedules of reinforcement are those in which responding is not only maintained by the drug, but also by response-contingent drug-associated CSs. The principles of such schedules are that the CS, by virtue of its association with the primary reinforcer, attains reinforcing value of its own (termed a conditioned reinforcer) and is therefore capable of supporting an operant response. Typically, responding for the drug is maintained on a high-demand schedule, during which performance of a lower-demand schedule produces multiple presentations of the CS. For example, responding under a FR 15 (FR 10:S) schedule produces presentation of the CS following each set of 10 responses and administration of the drug after 150 responses (15 sets of 10). This schedule provides two distinct advantages. First, the ability of the CS to act as a reinforcer can be examined in

the absence of the drug during the first drug-free interval. This is particularly a key aspect since it is well established that many drugs of abuse can alter cue-maintained behaviors. For example, a range of drugs of abuse has been shown to increase response rates for conditioned reinforcers. Second, second-order schedules allow a direct assessment of the role of the drug-paired CS in drug-reinforced behavior. There is little doubt that the presence of both discrete CSs and environmental drug-paired cues is critical in influencing self-administration behavior in animals and in influencing subjective state and craving in drug users, and therefore the study of the mechanisms underlying such associations are likely to be of importance in improving our understanding of the role of reinforcement in drug addiction.

A final demonstration of the utility of self-administration models comes from studies attempting to mimic an aspect of addiction describing the progression from controlled to uncontrolled drug taking. Historically, self-administration sessions with cocaine have often comprised of daily limited-duration sessions lasting less than 3 h. This method results in stable patterns of responding that show little variability from day to day. However, when rats are given access to cocaine for 6 h or more per day, response rates begin to change over time, to the extent that drug intake progressively increases. Furthermore, increases in the reinforcing efficacy of cocaine are observed as estimated from break points

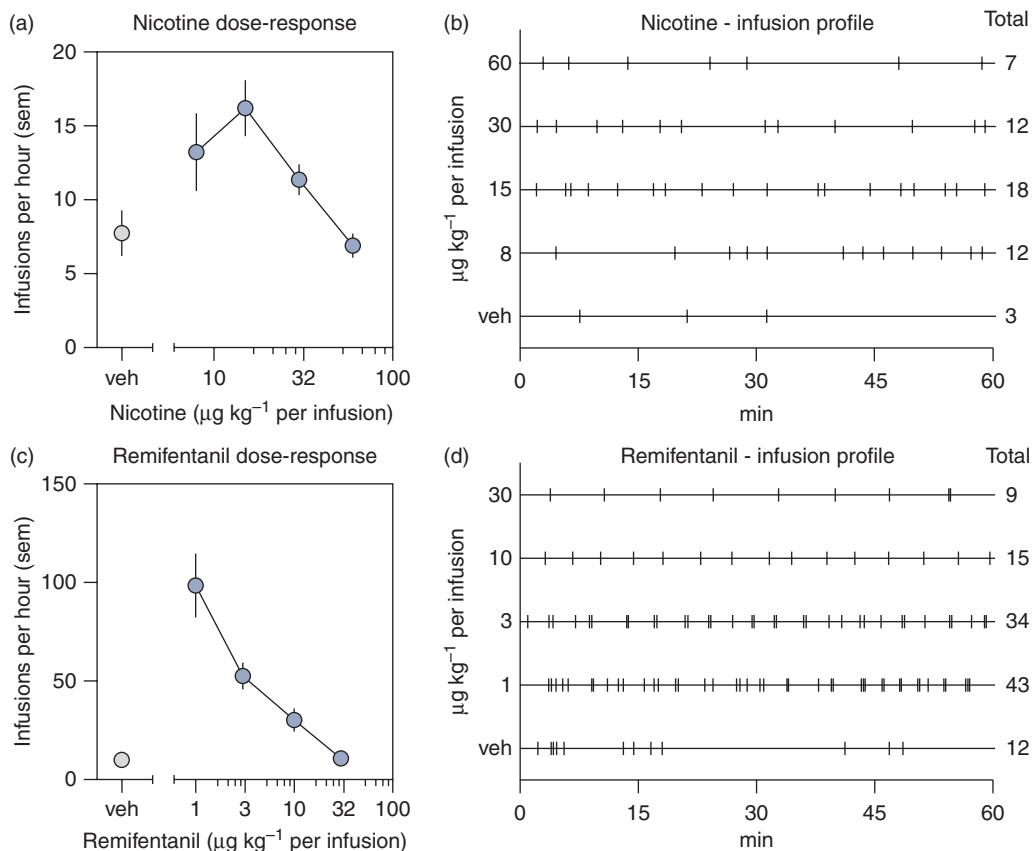

Figure 2 Dose–response relationship and response profiles under an FR schedule of self-administration. Effects of varying the unit dose of nicotine (a) or remifentanil (c) on the response rates of rats under a fixed-ratio 3 schedule of reinforcement. As the unit dose increases, the response rate decreases reflecting titration of drug intake. Panels on the right depict representative response profiles demonstrating the dose-dependent changes in infusion frequency with either nicotine (b) or remifentanil (d). Both examples highlight the importance of assessing response profiles in addition to total response rates. While total infusion numbers are lower for a $30\mu\text{g kg}^{-1}$ infusion dose of remifentanil than for vehicle, the response profile for remifentanil suggests regular inter-infusion intervals characteristic of self-administration of a reinforcing drug under a fixed-ratio schedule. In contrast, the profile of responding for vehicle is far more sporadic. Source: EC O'Connor, D Parker, AN Mead, unpublished results.

under PR schedules. This incremental change has been interpreted as representative of an increased drive to obtain the drug similar to that observed in humans following the transition from social/intermittent drug use to dependency and addiction.

Conditioned Place Preference

The conditioned place preference (CPP) model has been used extensively for the assessment of the reinforcing properties of drugs of abuse. In the CPP model, the animal receives experimenter-administered drug in one compartment of a multicompartment apparatus and the vehicle in a different compartment; the two compartments typically differing in visual and tactile domains. Through repetitions of this contingency, the environment in which the animal receives drug becomes associated with the drug through Pavlovian conditioning. Subsequently, the animal is given a choice test, whereby

it is given free access to both compartments and the relative time spent in the drug and vehicle-paired compartments is viewed as representative of its preference (or aversion) for the drug. Comparisons are often drawn between CPP and the self-administration model, largely on the basis that both models are sensitive to the majority of abused drugs and are based on the principles of positive reinforcement. However, rather than comparing the advantages and disadvantages of the two models, it is probably more constructive to assess the value that the two models provide independently. CPP, by its nature reflects the approach of an animal toward an environment previously associated with the drug. In theory, this approach could represent an expectation or anticipation of drug delivery, the receipt of reinforcement from a conditioned stimulus or an instinctive autoshaping approach to a CS. While it is not entirely clear which of these psychological processes underlies the expression of a CPP, all three interpretations require that the drug acts

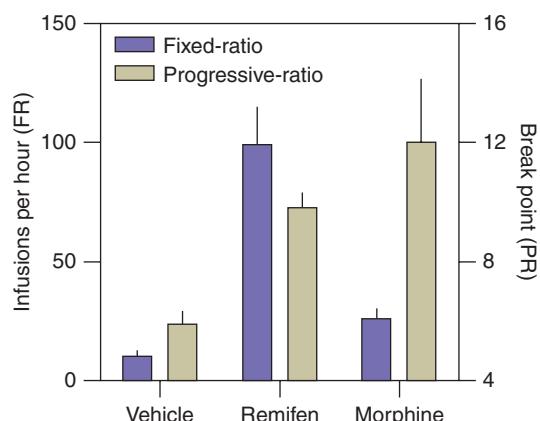

Figure 3 Importance of schedule choice for self-administration studies. Comparison between the assessment of two μ -opioid agonists under either a fixed-ratio schedule or a progressive-ratio schedule of reinforcement. Both the typical μ -opioid agonist morphine and the ultra-short acting μ -opioid agonist remifentanil reinforce self-administration behavior relative to vehicle, but the conclusions regarding reinforcing strength would differ according to the schedule of reinforcement. Under a fixed-ratio schedule, remifentanil maintains higher rates of responding than does morphine, in part due to its shorter half-life. Under a progressive-ratio schedule, both μ -opioid agonists maintain similar levels of responding, as assessed by the 'break point'. (Note: full dose-response functions were generated for both drugs, but only data from the unit dose resulting in the highest response rate or break point for each compound are shown for clarity) Source: EC O'Connor, AN Mead, unpublished results.

as a positive reinforcer during conditioning sessions, and therefore the model is well structured to assess the positive-reinforcing properties of addictive drugs.

Intracranial Self-Stimulation

The ICSS model takes advantage of the fact that animals will perform an operant response for direct electrical stimulation of specific neuronal pathways or brain regions. It is believed that the pathways that support ICSS are those responsible for mediating the response to natural reinforcers. By altering the frequency and intensity of stimulation, it is possible to generate response curves giving an estimation of sensitivity thresholds for a particular brain region. The potential utility of this model for drug addiction research has been supported by the fact that many drugs of abuse reduce reinforcement thresholds for ICSS. This is interpreted as a selective effect on reinforcement sensitivity by controlling for other drug-induced behavioral changes, such as increased or decreased locomotor activity, and demonstrating dissociation between the two. Therefore, ICSS is an example of a model where it is possible to begin to understand the direct effects of drugs of abuse on the systems that underlie positive reinforcement.

Drug Seeking and Relapse

While it can be argued that both the self-administration and CPP models assess aspects of drug-seeking behavior, the dependent variables are not typical tested after a period of protracted abstinence. Clearly, the maintenance of drug self-administration requires an element of drug seeking; however, with the exception of perhaps extinction testing where drug access is replaced with vehicle access, this is most frequently studied in the presence of drug taking. In addition, while second-order schedules provide an insight into drug seeking in the absence of drug taking, this is restricted to the first interval of any session. Similarly, the expression of a CPP may represent drug seeking, though, as discussed previously, other explanations for CPP exist, and normally testing is conducted within a few days of conditioning sessions. As a result, there has been an increasing effort around the development and characterization of animal models of drug seeking and relapse following protracted abstinence.

Reinstatement and Renewal of Drug Seeking

Reinstatement and renewal models of drug seeking are typically centered on the ability of stimuli to reinitiate a previously extinguished operant response for drug. The term 'reinstatement' is used to describe the ability of a discrete CS, drug stimulus, or stressful stimulus to reinitiate responding, while 'renewal' is preferred when referring to the ability of a contextual cue to reinitiate responding. Both variations have key concepts in common and provide an assessment of the ability of stimuli to increase the probability of drug-seeking behavior. As a result, these models are frequently viewed as analogous to relapse in the clinical situation, whereby exposure to certain stimuli has been associated with an increase in the probability of reinitiating drug taking. This comparison highlights one important difference between the reinstatement/renewal models and the clinical relapse situation: in the animal model, it is purely a measure of drug seeking, as the drug is never available during tests, while the clinical situation is also influenced by drug taking. Of course, by excluding drug availability in the animal model, one can be more confident that the behavior observed is driven by the inducing stimulus and not by the primary reinforcing or pharmacological properties of the drug.

There are three general forms of the reinstatement/renewal models of drug seeking. These are more commonly performed in an operant box following a phase of drug self-administration and subsequent extinction of this response. However, similar effects have been demonstrated in reinstatement versions of the CPP model, where the preference for the drug-paired chamber is

reinstated following extinction. In the drug-prime induced reinstatement model, responding is reinstated by a non-contingent priming injection of a drug prior to the test session. In the stress-induced reinstatement model, responding is reinstated by the presentation of a noncontingent stressful stimulus such as a footshock or food deprivation. In all other ways, the test session for both versions of reinstatement is no different to previous extinction sessions. In contrast to these models, cue-induced reinstatement is typically assessed using one of the two methods. During initial self-administration training, a discrete CS such as a light or tone is paired with drug delivery. During extinction sessions, this CS is no longer presented but is instead reintroduced for a reinstatement test session following extinction to assess the ability of the contingent CS to reinstate responding. Renewal studies are typically performed in a similar way, except that rather than removing the drug-paired CS during extinction the contextual cues in the operant chamber are altered prior to being restored for the renewal test. A variation of the cue-induced reinstatement model involves the noncontingent presentation of the CS prior to and/or during the reinstatement session. Both methods have been shown to reliably reinstate responding following extinction, though it is reasonable to assume that the mechanisms underlying one may differ from those underlying the other, so equivalence should not be assumed.

Following extensive research during the past 25 years, a significant amount has been learned for a number of different drugs regarding the neurobiological mechanisms underlying the different forms of reinstatement and renewal. At face value, the classes of stimuli that reinstate responding in reinstatement models appear to translate well to the stimuli which are frequently associated with relapse in abstinent drug addicts. However, due to the limited availability of pharmacological interventions for relapse prevention in human, it has been difficult to assess the predictive validity of such models. At a more basic science level, there is no doubt that such models have helped increase our understanding of the mechanisms that underlie the reinstatement of drug-seeking behaviors following the presentation of different stimuli, and the commonalities in mechanisms among the different forms of reinstatement may help elucidate the neural substrates that underpin reinitiation of drug-seeking behavior *per se*.

One of the more recent developments in the field of animal models of drug relapse has been the description of the incubation of drug seeking following extended withdrawal. The term ‘incubation’ has been used to describe a time-dependent increase in the level of drug seeking following presentation of reinstating stimuli during abstinence, and it has been argued that this increase parallels a similar temporal increase in propensity to relapse in abstaining addicts. By integrating behavioral endpoints of relapse with cellular and molecular changes, there

have been significant strides in our understanding of the mechanisms underlying drug-seeking behavior.

Alcohol Deprivation Effect

The alcohol deprivation effect (ADE) describes the observation that, following a period of abstinence, animals which had previously demonstrated consistent levels of alcohol intake transiently consume significantly greater amounts of alcohol. This effect has also been demonstrated for other drugs of abuse, including stimulants and opioids. It has been argued that the increase in drug intake described by the ADE represents a shift toward uncontrolled drug intake, and that it therefore represents a useful model for the progression to addiction. However, an alternative explanation should also be considered. Similar reports of increased intake have also been observed for natural reinforcers, suggesting that the increased intake may simply represent a general response to a reinforcing stimulus following a period of unavailability, rather than being specific to drugs of abuse (and therefore symptomatic of the move toward the addictive state). Second, when viewed alongside the incubation effect observed in reinstatement models (an effect that has also been demonstrated for natural reinforcers), it is perhaps not surprising that increased consumption of a positive reinforcer would occur at times when levels of reinforcer seeking are apparently increased. While it is not clear whether either the ADE or the incubation effect describes the phenomenon critical for, or specific to, the addictive process, or whether they represent the general properties of reinforced behavior, understanding such effects will be important to understanding the mechanisms that underlie increased drug consumption or seeking following periods of protracted abstinence.

Physical Dependence and Negative Affect

Tolerance and Withdrawal

The study of negative affect during abstinence following chronic drug administration has played a key role in increasing the understanding of the role that negative reinforcement processes may play in addictive behavior. Typically, drugs are administered at either a constant or increasing dose over a period of approximately 1–4 weeks, and monitoring of behavioral and physiological parameters during dosing can frequently reveal tolerance to drug effects. Withdrawal states are subsequently examined following either cessation of dosing (spontaneous withdrawal) or administration of an antagonist at the primary pharmacology of the test drug (precipitated withdrawal). Precipitated withdrawal has the advantage of producing a more immediate and often more severe withdrawal syndrome. Withdrawal behavior can be

assessed using a number of methods. For drugs that induce severe withdrawal symptoms such as opioids, it is often sufficient to monitor behavioral signs and symptoms, food intake, and body weight. However, for detection of more subtle withdrawal signs, a number of other endpoints have been studied. Particularly sensitive endpoints include operant responding for food (under various schedules of reinforcement) and ICSS, which are frequently viewed as measures of anhedonia and therefore representative of negative affect. A variation of the CPP model has also been employed where, instead of pairing a drug effect with one compartment of the apparatus, the assumed aversive state of withdrawal is associated with a compartment to allow the assessment of a conditioned place aversion (CPA). More recently, and with improved telemetry technology, analysis of sleep architecture has also been introduced with success for drugs with milder withdrawal syndromes. This effort was largely driven by the observation that withdrawal from most drugs of abuse in humans results in sleep disturbances, and while the impact of sleep disorders on propensity for relapse and drug use is far from clear, is an excellent example of the power of translational endpoints in drug addiction research.

Neuroadaptive Models

Behavioral Sensitization

In relation to drug addiction, the term behavioral sensitization describes a progressive increase in a behavioral response following repeated administration of a drug at a constant dose. Typically, this is measured through assessment of locomotor activity, as the majority of drugs of abuse will induce changes in locomotor activity. Evidence has also grown for the sensitization of other reinforced behaviors, such as responding for conditioned reinforcement (responding for a CS previously paired with a primary reinforcer such as food), primary reinforcement and Pavlovian-to-Instrumental Transfer (the enhancement of responding for a primary reinforcer during noncontingent presentation of a CS). Behavioral sensitization has received increased focus in the last two decades due to its core role in some recent theories of drug addiction, where it is proposed that behavioral sensitization is representative of a sensitization of the neural systems that underlie the attribution of incentive value to drug-paired stimuli, and therefore the wanting of these drugs. Behavioral sensitization of locomotor activity has been demonstrated for most drugs of abuse, and the conditions for its development have become increasingly well understood. For example, sensitization generally only occurs following intermittent administration of drugs and is largely dependent on conditioning to environmental cues. Similarly, our understanding of the

mechanisms underlying behavioral sensitization has increased greatly, with major focus being placed on the mesocorticolimbic system. The dependency of drug addiction on the development of behavioral sensitization is, like most current theories of disorders of the brain, a topic of intense debate. In addition, key questions remain unanswered around aspects such as the evidence for incentive sensitization in animals and humans, as opposed to sensitization of the locomotor response. However, as a model of drug-induced neuroadaptation, the study of behavioral sensitization has, at the very least, contributed significantly to our understanding of drug-induced plasticity in the neural substrates common to many drug-induced effects and has demonstrated that repeated drug exposure can alter the subsequent response to drugs and drug-paired cues.

Subjective Effects

Drug Discrimination

The drug discrimination model has been used extensively to understand the mechanisms underlying the potential subjective properties of drugs of abuse. The model is based on the ability of the animal to discriminate between the presence and absence of an interoceptive cue induced by a training drug. Assessment of discrimination is made by making the delivery of reinforcement (normally food or water) contingent on an operant response; following drug administration, the animal is required to perform one response, while, following vehicle administration, it is required to perform an alternate response. Once the animal has learned this discrimination, the similarity of the interoceptive cue induced by other drugs can be examined by studying the distribution of responses across the two response options (**Figure 4**). During these generalization test sessions, either both or neither response is reinforced to provide an unbiased measure of preference. While the role of the drug-induced interoceptive cue in processes leading to addiction is not clear, the drug discrimination model generally demonstrates good class specificity (i.e., drugs of a common class/mechanism will show cross-generalization to each other) and as such is a powerful model for understanding drug–drug similarities (**Figure 5**), and the impact of potential therapeutics on drug-induced interoceptive cues.

Conclusions

The purpose of this article is not to provide a thorough account of all behavioral models relevant to the study of drug addiction; this is beyond the scope of an

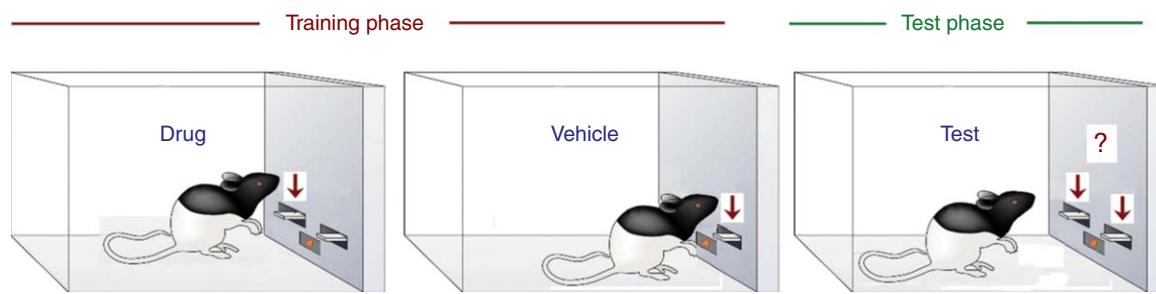

Figure 4 Schematic and the principles of the drug discrimination model. During the training phase, the rats are required to respond on the left lever to obtain food if given a drug injection prior to the session. Alternatively, following a vehicle injection, they are required to respond on the right lever to obtain food. Once rats have successfully acquired this discrimination, a test compound is given and responding on both levers is reinforced by food delivery. The proportion of responses on the drug-paired lever compared to the vehicle-paired lever gives an indication of the similarity of the test drug interoceptive cue to that induced by the training drug.

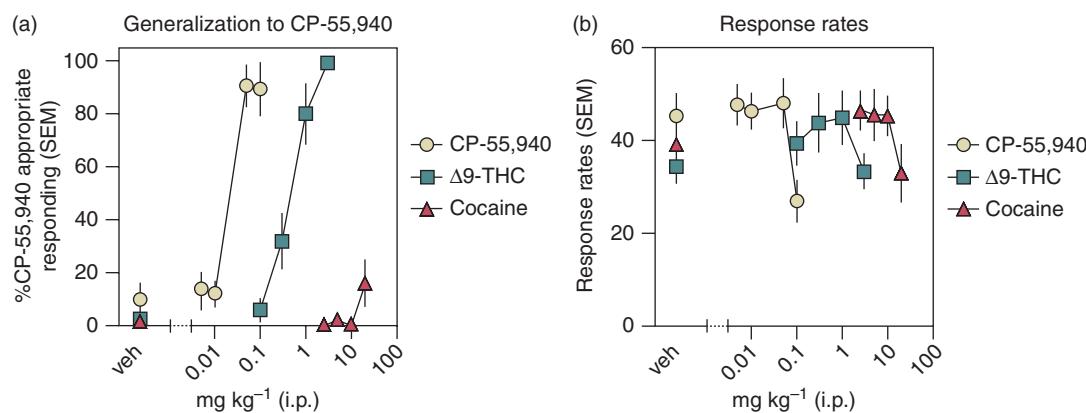

Figure 5 Example of the class specificity of the drug discrimination model. Rats trained to discriminate between the cannabinoid agonist CP-55,940 (0.05 mg kg^{-1}) and vehicle demonstrate generalization to the cannabinoid $\Delta 9$ -tetrahydrocannabinol ($\Delta 9$ -THC) but not the dopamine-reuptake inhibitor cocaine. Generalization is dose dependent demonstrating that the interoceptive cue is dose specific as well as class specific. Comparison of response rates is often used to assess disruption of performance with both sedative and stimulant drugs, resulting in reduced response rates when doses are increased sufficiently. overview, and all of the models described have additional levels of complexity and detail, which warrant consideration prior to study design or interpretation. Instead, the aim is to provide a top-level view of the range of models, which can be applied to answering questions about specific aspects of addictive behavior. If there is one take-home message, it should be that it is simply not possible to model drug addiction in an animal model (this is really no different to any other disorder of the brain). Instead, a more focused approach should be taken to understand specific aspects of the addictive process, whether this is positive reinforcement, negative reinforcement and affect, the progression to uncontrolled drug intake, behavioral sensitization, or drug-seeking behavior. By taking this approach, our understanding of the neurobiological mechanisms and psychological processes of drug addiction has improved dramatically over the past few decades. The challenge moving forward is to

continue asking and answering these focused questions, and then to start putting the information back together again to understand how drug addiction can be treated effectively.

Glossary

Appetitive behavior – Behavior occurring early in a natural behavioral sequence and serving to bring the organism into contact with a particular stimulus eliciting that behavior.

Conditioned reinforcer – A stimulus that becomes an effective reinforcer because of its association with a primary or unconditioned reinforcer (also termed 'secondary' reinforcer).

Conditioned stimulus (CS) – A previously neutral stimulus that does not elicit a particular response but, as a result of becoming associated with an unconditioned stimulus, eventually comes to do so.

Consummatory behavior – Behavior that serves to bring a natural sequence of behavior to consummation and completion.

Discriminative stimulus – A stimulus that controls the performance of instrumental behavior because it signals the availability of a reinforcer.

Extinction – In classical conditioning, the procedure of repeatedly presenting a CS without the unconditional stimulus (US), leading to reduction of a learned response because the CS is no longer paired with the US. In instrumental conditioning, the procedure of no longer reinforcing the instrumental response, leading to reduction of this response because it is no longer followed by the reinforcer.

Instrumental response – A response (also termed 'operant response') that is defined by the consequences it produces in the environment. For example, any sequence of movements that results in depression of a lever in an operant-conditioning chamber that, in turn, results in delivery of a reward represents an instance of that particular operant.

Occasion setting – A contingency in which one cue (e.g., a discriminative stimulus) designates when another will be reinforced.

Positive reinforcement – Positive reinforcement is an instrumental conditioning procedure involving a positive contingency between the instrumental response and a reinforcing stimulus. In this context, a subject receives a positive or pleasant stimulus if a correct response is performed, increasing the frequency and/or future probability of the response.

Reinforcement contingency – Causal relationship between a response and a reinforcer, measured in terms

of the probability of getting reinforced for performing a response as compared to the probability of getting reinforced in the absence of the response. Often refers to the particular schedule of reinforcement that is in effect in studies of learning and conditioning.

Reinforcer – A stimulus whose delivery shortly following a response increases the probability of this response in the future.

Renewal – Recovery of excitatory responding to an extinguished stimulus produced by removal from contextual cues that were present during extinction. Renewal typically occurs when a subject is returned to the environment in which the response was previously reinforced following extinction of this response in a different environmental context.

Schedule of reinforcement – A rule that determines under what specific conditions (i.e., the reinforcement contingency) the occurrence of a response is followed by the delivery of a reinforcer.

Introduction

The conditioning of both the positive reinforcing actions of drugs of abuse and the aversive aspects of drug withdrawal states with environmental stimuli represents an important mechanism for the addictive potential of drugs of abuse. Early studies, pioneered by Abraham Wikler and, subsequently, Goldberg and Schuster, have focused on the classical conditioning of the opiate withdrawal syndrome whereby environmental stimuli paired with morphine withdrawal elicit withdrawal symptoms in opiate addicts. Interest, later, rapidly shifted toward the role of conditioned stimuli in drug-seeking and self-administration associated with the positive reinforcing effects of opiates and psychostimulants. Studies by Davis and Smith, in rats, and by Schuster and Woods, in squirrel monkeys, provided original evidence that conditioning factors influence the initiation, maintenance, and extinction of drug-seeking and -taking behavior. It has since been firmly established that drug-related associative learning, whereby environmental stimuli repeatedly paired with drug consumption acquire incentive-motivational value or set the occasion to engage in drug-seeking behavior, is a critical factor in maintaining or modifying ongoing drug use and in eliciting drug desire during abstinence, precipitating relapse.

Conditioned Locomotor Activity and Sensitization

Drug-paired CSs produce drug-like responses, such as conditioned locomotor activity and increases in mesolimbic dopamine activity when animals are exposed to the same environment where the drug had been administered, an effect that is most prominent with psychostimulants. Cocaine-paired cues have also been shown to produce conditioned increases in the rewarding effects of electrical brain stimulation, eliciting a state similar to that produced by the drug itself, a finding that is consistent with functional brain imaging data that cocaine cues elicit striatal dopamine release in the humans. These conditioned consequences of drug-cue exposure are thought to reflect the incentive motivational properties of drug-associated cues that underlie drug seeking and recidivism in dependent individuals. When animals are repeatedly exposed to drugs of abuse, they show enhanced (i.e., sensitized) locomotor activity and reactivity of mesolimbic dopamine neurons in response to later challenge-administration of the drug. This, often long-lasting, enhancement in behavioral and neural activity has been implicated in enhanced drug-directed appetitive behavior and sensitization of the incentive salience of drug of abuse. It is well established that the expression of behavioral and neural sensitization is strongly influenced by conditioned contextual stimuli in that drug challenges administered in an environment not previously paired with the drug fail to show sensitization and such environment-specific effects have been reported with psychostimulants and opiates. Thus, stimuli conditioned to the availability or subjective effects of drugs are associated with the expression of sensitized neurobehavioral actions of drugs of abuse such that the presence or absence of these stimuli may be linked to fluctuations in susceptibility to relapse and enhanced incentive salience attached to drug-related cues, both during ongoing drug use and during periods of abstinence.

Initiation, Maintenance, and Reacquisition of Drug Seeking

Drug-paired CSs can produce responses that resemble the effects of the unconditioned drug stimulus, such as conditioned locomotor activation, by acting as secondary reinforcers maintaining responding under second-order schedules of reinforcement (Box 4), and reinstating extinguished drug seeking similar to the effects of a small dose of the drug itself. Conditioned responses, therefore, must be assumed to also influence the initiation, maintenance and extinction of drug self-administration. Several lines of evidence support this prediction. For example,

environmental contexts associated with the subjective effects of noncontingent ethanol administration maintain higher levels of responding for ethanol. In other words, an environmental context signaling the effects of ethanol maintains a higher response rate when ethanol is subsequently offered as a response-contingent reinforcer. Moreover, exposure to ethanol-associated contextual cues during extinction and abstinence, but not abstinence alone, reduced the resumption of ethanol intake after abstinence. Importantly, reacquisition of ethanol self-administration was reduced in proportion to the number of abstinence-associated cues present during abstinence, suggesting that ethanol consumption is governed by ethanol-associated cues. In the case of cocaine, discriminative stimuli and, in particular, independently established cocaine-predictive discriminative stimuli (i.e., a tone and a light cue) presented in compound have been shown to increase both response rates and intake of cocaine in rats, suggesting that previously neutral stimuli can come to have profound effects on drug self-administration. In the case of nicotine, it has been established that nicotine-associated cues consisting of a compound, response-contingent, drug-paired cue and a discriminative stimulus signaling availability of the drug exert particularly strong control over nicotine-directed behaviors. These stimuli were found to be as important as nicotine itself in sustaining a high rate of responding once intravenous nicotine self-administration is established, in the degree of resistance to extinction they induce when nicotine is withdrawn, and in the reacquisition of nicotine self-administration after extinction. The role of drug-associated environmental stimuli in the initiation and maintenance of drug self-administration has not gone unchallenged. For example, a discrete cocaine-paired stimulus (CS) did not modify the reinforcing effects of cocaine although it effectively reinstated extinguished cocaine-seeking behavior. It is likely that these discrepancies are related to differences between the conditioned effects of discrete and discriminative/contextual stimuli discussed below. Importantly, in the case of ethanol, the learning of associations between the self-administration context and the subjective effects of ethanol is essential due to the delayed nature in the onset of ethanol's pharmacological actions, whereas this is not necessary in the case of intravenous drug reinforcement where the pharmacological actions of the drug are contiguous both with the operant response and the presentation of the CS. Therefore, ethanol reinforcement may be more sensitive to changes both in drug-predictive contextual and discrete reward-paired cues than in intravenous drug reinforcement. To the extent that a large body of literature supports a role of drug-related learning in the initiation and maintenance, it will be important to consider the implications of these findings both with regard to understanding increases in drug intake or drug

desire as well as for the design of extinction procedures that may be effective in preventing relapse.

Conditioned Reinstatement, Craving, and Relapse

Drug addiction is a chronically relapsing disorder. Long-lasting vulnerability to relapse is a core feature of addiction and an issue of critical importance for the treatment of drug addiction (see **Figure 1**). A major factor precipitating craving and relapse, as recognized both in the clinical and experimental literature, comprises learned responses evoked by environmental stimuli or events that have become associated with the subjective actions of drugs or alcohol. Exposure to such stimuli elicits craving and drug desire that often leads to the resumption of drug or alcohol use in abstinent individuals. Drug-related stimuli can also elicit automatic responses that lead to drug seeking and relapse without the intervention of conscious desire or distinct feelings of craving.

One reason for the enduring, perhaps lifelong, persistence of relapse risk is that craving associated with drug-cue exposure does not readily extinguish. For example, in dependent drinkers, alcohol craving induced by ethanol cues shows little habituation with repeated cue exposure although conditioned responses such as autonomic

reactivity become attenuated. In addition, in humans, the severity of craving induced by drug cues is positively correlated with the history and degree of drug or alcohol dependence. One explanation for this relationship is that experience of the drug during withdrawal – an inevitable event associated with a history of dependence – modifies an individual's reinforcement history to include learning about the subjective effects of drug consumption during withdrawal. This experience introduces a novel motivational dimension that enhances the incentive value of the drug, such that the drug comes to function as a qualitatively different and more effective reinforcer, particularly during subsequent withdrawal experiences.

The role and mechanisms by which drug-associated stimuli contribute to and control addictive behavior in the human is addressed in greater detail elsewhere in this encyclopedia. The focus of this article is on experimental studies in animals. As described below, systematic studies in animals on the role of conditioning factors in drug seeking and relapse have confirmed that environmental stimuli associated with the reinforcing actions of drugs or alcohol – either by means of classical conditioning or by acting as discriminative or contextual stimuli signaling drug availability – reliably reinstate drug seeking in animals in which this behavior had been previously extinguished. These studies have also elucidated the neurocircuitry and signaling mechanism that regulate specific

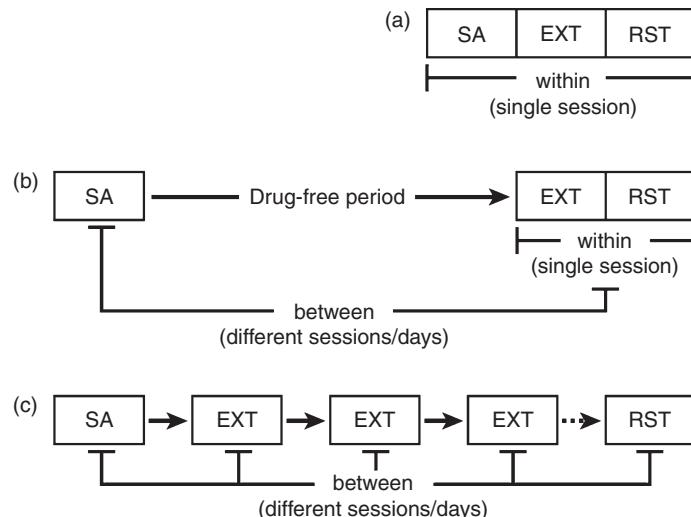

Figure 1 In models of conditioned reinstatement, extinction and reinstatement tests can be conducted according to a 'within-session,' 'between-session,' and 'within-between session' sequence. In the 'within-session' procedure (a), a single extinction session is conducted, followed immediately by the reinstatement test. A limitation of this method is that it does not include an abstinence period and, therefore, does not mimic relapse as traditionally understood. Moreover, animals in this procedure are not drug-free because testing occurs within one hour of the last drug administration. In the 'between-session' procedure (c), extinction sessions are conducted daily and reinstatement tests commence typically 1 day after an extinction criterion is reached. This procedure 'adds' a drug-free (i.e., abstinence) period to the mere extinction of drug-reinforced responding and, thus, more closely resembles relapse in the human where resumption of drug use occurs beyond the acute withdrawal phase. In the 'between-within' procedure (b), no extinction sessions are conducted after rats acquire drug-reinforced responding. Instead, an abstinence period is imposed after which extinction and reinstatement sessions are conducted in a within-session manner. This model is particularly useful for studying the relationship between the duration of abstinence and degree of reinstatement. The great majority of contemporary applications of the extinction-reinstatement model employ 'between-session' or 'between-within-session' procedures.

aspects of conditioned drug seeking, and provided important leads with regard to promising neural targets for pharmacotherapeutic relapse prevention.

Animal Models of Conditioned Drug Seeking and Relapse

Conditioned drug-seeking responses can be demonstrated in a wide range of animal models implemented to investigate specific aspects of the motivational impact of drug-associated environmental stimuli. The most prominent among these is the extinction-reinstatement procedure. Reinstatement, in the learning literature, refers to the recovery of excitatory responding to an extinguished stimulus produced by noncontingent exposure to the unconditioned stimulus (US). Conditioned reinstatement is a term largely confined to the addiction literature and refers to the resumption of responding at a previously drug-paired lever produced by exposure to drug-associated environmental stimuli (see **Box 1** and **2**).

The original demonstration, that conditioned cues previously paired response-contingently with drug infusions reinstate cocaine or morphine seeking following extinction of drug-reinforced instrumental responding in the absence of these cues, was made in the late 1960s and mid-1970s – in rhesus monkeys, by Schuster and Woods and Goldberg and colleagues, and in rats, by Davis and Smith. In contemporary applications, the degree of responding maintained by the contingent presentation of the drug-paired CS in the absence of further drug availability provides an operational measure of craving or relapse (see **Box 1**). A more recently employed set of extinction-reinstatement procedures utilizes drug-related discriminative or contextual stimuli, present non-contingently during drug availability, measuring the recovery of extinguished drug seeking by noncontingent presentation of these stimuli (see **Box 2**). Noncontingent exposure to contextual cues readily elicits reinstatement, whereas reinstatement produced by a discretely drug-paired CS requires response-contingent presentation. Once initiated, however, both types of stimuli maintain behavior at a previously active operandum. These two variants of associative learning likely occur simultaneously during drug use but may be coded, at least in part, through different neural circuitries or activation patterns.

An important consideration concerning the significance of learning factors for drug addiction concerns the role of discrete drug-paired versus discriminative or contextual stimuli. The latter category of stimuli signals the availability of a reinforcer and thereby sets the occasion to engage in behavior that brings the organism into contact with the reinforcing substance. A condition often associated with drug craving in the human is cognitive awareness of drug availability. It has been argued, therefore, that the manner in which drug-associated contextual cues attain their

Box 1 Conditioned reinstatement: discrete cues.

One of the original and most widely employed methods to study the effects of drug cues on the recovery of extinguished drug-seeking behavior. In this procedure, animals are trained to respond at a lever (or other operandum), with the completion of each response requirement (as determined by the schedule of reinforcement in effect) resulting in delivery of an intravenous (e.g., opioids or psychostimulants) or oral (e.g., ethanol) dose of the drug. Each response producing the drug reinforcer is contingently paired with a brief presentation of an environmental stimulus (e.g., a tone or cue light) that, by virtue of these repeated pairings, comes to serve as a conditioned stimulus (CS). Both drug administration and presentation of the CS are contingent upon a response by the animal (i.e., response-contingent). Once reliable drug self-administration is acquired, drug-reinforced instrumental responding is extinguished by ceasing to reinforce responses by drug delivery and withholding presentation of the CS. Extinction sessions are then conducted until responding is substantially lower than that maintained by delivery of the drug and deemed incidental rather than motivated by expectation of obtaining the drug. Subsequently, reinstatement tests are conducted in which the degree of recovery of responding at the previously drug-paired lever, now maintained by response-contingent presentation of the CS only (i.e., without further drug delivery), is operationally defined as a measure of craving or relapse. Extinction and reinstatement tests can be conducted in different sequences as shown in **Figure 1**.

incentive properties is likely to involve the predictive nature of these stimuli (as utilized in contextual reinstatement and the runway model) rather than only classically conditioned stimulus-response associations as modeled with reinstatement procedures utilizing discrete drug-paired CSs. Moreover, by virtue of their presence during drug consumption, contextual cues also become associated with the rewarding effects of the drug and, thus, acquire incentive-motivational value (i.e., elicit memories of previous drug euphoria and the magnitude or value of the rewarding effect of drug consumption). Because of this dual action, these stimuli are particularly powerful in eliciting drug seeking and reinstatement, and this action is likely to underlie their powerful potent and persistent motivating actions both in humans and animals. Most contemporary applications of the reinstatement procedure utilize contextual or discriminative stimulus models.

Another contextual model of drug seeking is the renewal of conditioned place preference (CPP) (see **Box 2**). This procedure evolved from the traditional CPP procedure, one of the original and most widely employed tools for studying conditioned reinforcement. Place-conditioning procedures permit examination of neural substrates involved in the acquisition and expression of the conditioned reinforcing effects of drugs of abuse. Manipulations that specifically alter the expression of CPP, once acquired, provide information on the neural basis of conditioned drug seeking, whereas interference with the acquisition of CPP is relevant for the understanding

Box 2 Conditioned reinstatement: contextual cues.

To study the effects of environmental context on the recovery of drug seeking. Drug availability is conditioned to stimuli (i.e., olfactory, auditory, tactile, or visual cues) present in the self-administration environment, and these stimuli are not paired contiguously with drug infusions nor contingent upon a response. Owing to their predictive nature for drug availability, these stimuli set the occasion for engaging in reward-seeking (i.e., lead to the initiation of responding). Except for using context or noncontingent discriminative stimuli as cue manipulations, these models are identical to the discrete cue (CS) model in terms of the training and experimental sequence, with conditioning followed by extinction in the absence of the cue and, subsequently, reinstatement tests in the presence of the drug-associated cues. Multiple contextual reinstatement procedures exist:

The basic model utilizes differential reinforcement of behavior in the presence of discriminative stimuli. In this procedure, during self-administration learning, responses at the operandum are reinforced by the drug only in the presence of this stimulus. In the absence of the stimulus (or, as more frequently employed, presence of a distinctly different cue) responses remain nonreinforced.

A second frequently employed contextual conditioning model – pioneered by Bouton and Schwartzrenuber in the early 1990s to study how the context influences extinction and resumption of learned behavior – utilizes distinct environments that provide compound contextual cues (i.e., concurrent presence of olfactory, auditory, tactile, and visual cues). Here responding is reinforced by a given drug reinforcer in one context. Drug-reinforced responding then is extinguished in a second context. Subjects subsequently tested in the second context show low drug seeking because the behavior has been extinguished in this context. In contrast, animals tested in the first (drug-paired) context show reactivation or renewal of responding at the previously active operandum.

A variant of the contextual reinstatement procedure above is based on learning of a conditioned place preference (CPP) for an environment paired with experience of the drug. Following extinction of CPP, accomplished by pairings of vehicle rather than drug with the environment, re-establishment – technically termed renewal or reactivation of CPP – is produced by a drug injection. This model can also be employed to study reactivation of an acquired CPP following an imposed period of abstinence.

of mechanisms mediating the acute reinforcing effects of drugs or the learning of Pavlovian associations. The degree of preference for a previously drug-paired environment provides an index of the strength of drug seeking associated with the incentive-motivational effects of a drug-associated stimulus context. Traditional applications of CPP, however, do not involve imposition of abstinence and thus have limitations with respect to providing a tool for studying relapse. In contrast, the CPP renewal procedure has been successfully applied in conjunction with abstinence manipulations, following which drug injections or stress reactivate CPP. Nonetheless, while this procedure is advantageous in that it is easy to perform technically, it has other limitations.

Among these is that it does not provide a pure measure of conditioned reinforcement or reinstatement, but rather of interactions between contextual conditioning and the effects of small priming doses of the drug or stress. An issue to be considered as well is that CPP typically involves noncontingent administration of drugs such that the strength or nature of associations that are formed between drugs and environmental stimuli may differ in CPP versus self-administration procedures. Lastly, the number of learning trials in the CPP procedure is substantially lower than in reinstatement models utilizing self-administration procedures. Possibly due to these differences, the expression of CPP and conditioned reinstatement is sometimes differentially sensitive to pharmacological manipulation.

The operant runway model is a procedure in which a role of conditioning factors in drug seeking can also be readily demonstrated (see **Box 3**). The runway model dates back to the 1930s and has been widely employed to study goal-seeking behavior. It incorporates aspects of both second-order schedule and CPP procedures in that it permits examination of the animals' motivation to engage in drug seeking in a drug-free state before the drug reinforcer is applied and with responding (here runtime) unaffected by the performance-altering consequences of the drug. A unique finding with this procedure was the demonstration that rats receiving cocaine as a reinforcer exhibit approach-avoidance retreat behaviors, on the following day, before entering the goals box where drug administration occurs. This ambivalence is thought to reflect the presence of both positive and negative associations with the goals box, consistent with subjective reports of cocaine users that the initial euphoric effects of cocaine are often followed by an unpleasant state. A limitation of this model is that rats are receiving only a limited number of drug injections each day and under conditions that do

Box 3 Operant runway model of relapse.

A procedure in which run-time from a start-box to a goal-box where the drug is administered provides a dependent measure of drug seeking. In this procedure, a discriminative stimulus present in the start-box, runway, and goal-box is predictive of drug reward obtainable in the goal box, whereas a different discriminative stimulus predicts nonavailability of drug reward. Run-times eventually decrease in the presence of the drug-predictive discriminative stimulus, but not with the nonreward cue. Rats then are placed on extinction conditions under which both the discriminative stimulus and drug injections are absent, with the result that run-time increases progressively. During subsequent reinstatement tests, reintroduction of the drug-paired discriminative stimulus decreases the run-time for reaching the goal-box again. In addition, a drug infusion in the goal-box during extinction reduces run time on the subsequent drug-free day. This decrease in the latency to reach the goal-box as associated with these manipulations serves as a measure of relapse.

Box 4 Second-order schedules of reinforcement.

A reinforcement contingency by which a set of responses on a schedule of conditioned reinforcement is treated as a unit-response under a second schedule that is concurrently in effect. Completion of the unit-response for the first schedule component produces presentation of a CS, and completion of n unit-responses produces the CS accompanied by a single dose of the primary (drug) reinforcer. The contingency then reverts again to the non-drug-reinforced schedule component with response-contingent presentation of the CS only, until completion of n unit response requirements leads to the next drug injection. The principal measure of interest in this procedure is the degree of conditioned reinforcement maintained by the drug-paired CS, prior to drug delivery. Second-order schedules are highly effective for investigating the significance of conditioned reinforcement in ongoing drug seeking and taking.

not permit the animal to control or regulate drug intake. The procedure, therefore, models conditioned reinforcement processes associated with recreational drug use, but not the consequences of voluntary high-dose drug intake on conditioned drug seeking and relapse.

Widely employed also are second order and seeking-taking chained schedules of reinforcement where the measure of interest is conditioned reinforcement maintained by a drug-paired CS or context, leading to eventual availability of the drug reinforcer (see **Boxes 4 and 5**). These schedules produce very high rates of responding and have proven uniquely effective for investigating conditioning factors in ongoing drug seeking and taking and, most recently, in establishing a link between the trait of impulsivity and the reinstatement of cocaine seeking despite a history of footshock stress-punished seeking behavior. Investigation of the neural basis of conditioned drug seeking using these schedules is, however, somewhat constrained by administration of the drug that must follow completion of the CS-maintained component under these reinforcement contingencies. In other words, these schedules provide a narrow drug-free window during which behavior controlled by the CS alone can be studied unaffected by pharmacological effects of the drug on neural function or behavioral performance.

Characteristics of Conditioned Drug Seeking and Reinstatement

Both discretely conditioned and contextual stimuli produce robust reinstatement of drug or alcohol seeking following extinction and abstinence. This effect is reliable across different drug classes including cocaine, amphetamine, heroin, ethanol, and nicotine, and holds across variations in training, conditioning, and reinstatement test procedures. The response-reinstating effects, in particular, of drug-related contextual stimuli show remarkable persistence over repeated tests with nonreinforced

Box 5 Seeking-taking chained schedules.

Chained schedules employed in the context of studies of conditioned drug seeking typically consist of a seeking phase in which responses at a drug-seeking lever are initially required. Following completion of a response requirement or time interval in the first (i.e., seeking) link of the chained schedule, the second link is initiated by making available a drug-taking lever. Responses at this lever produce a drug-reinforcer and presentation of a CS, followed by a time out period, whereupon the seeking link of the chain is reinitiated. The degree of conditioned drug seeking or relapse is measured by the number of seeking responses during sessions in which responses at the taking lever produce only the CS but no drug injection.

In the area of alcohol addiction research, a variant of the seeking-taking schedule is often employed that dissociates ethanol-reinforced consummatory behavior (i.e., ethanol drinking) from appetitive ethanol-seeking responses (i.e., behavior induced and maintained by the incentive-motivational effects of ethanol-associated contextual cues present in the self-administration environment). In this procedure, rats must complete a set of responses at a lever operandum during which time ethanol is not available (appetitive phase). Completion of a response requirement within a specified time results in retraction of the lever and presentation of a sipper tube containing ethanol solution from which rats are then allowed to freely drink for a given amount of time (consummatory phase). Thus, responding during the appetitive phase in this model provides a measure of the day-to-day strength of animals' motivation to initiate and engage in ethanol-seeking behavior when exposed to the ethanol-predictive stimulus environment of the operant conditioning chamber.

exposure, and remain effective in eliciting drug seeking even after prolonged periods of abstinence. In fact, stimuli conditioned to cocaine during a single lifetime drug experience have been shown to elicit drug seeking for up to 1 year. Moreover, it can be demonstrated that the intensity of drug seeking shows time-dependent increases over the initial months of abstinence, a phenomenon referred to as incubation of craving. The persistence of the motivating effects of drug-associated stimuli in the animal literature resembles the long-lasting, compulsive-like nature of craving and relapse-risk associated with exposure to drug cues in humans, and provides experimental confirmation for the hypothesis that learned responses to drug-related stimuli are a significant factor in persistent vulnerability to relapse. Conditioned drug seeking in animals resembles compulsive-like drug seeking in the human not only in terms of persistence. Rats with a history of prolonged daily access to cocaine fail to show suppression of drug seeking maintained by a CS when concurrently presented with a conditioned stressor or exposed to a punishing stimulus, and this behavior appears similar to impaired impulse control. Thus, drug-related cues in rats can sustain drug-directed behavior despite adverse consequences, one of the hallmarks of substance dependence. Important for understanding the scope of drug-related learning in the relapse

process are findings that presentation of drug cues significantly exacerbates reinstatement of drug seeking produced by stress, another major risk factor for relapse. This has originally been demonstrated in rats concurrently exposed to alcohol-related cues and footshock stress. The existence of such interactive effects between drug cues and stress has been corroborated in the context of a pharmacological stress manipulation where yohimbine, a noradrenergic α_2 -receptor antagonist with anxiogenic action, significantly potentiated conditioned reinstatement of cocaine seeking. Lastly, evidence exists that opiate-dependent rats develop a CPP for an environment associated with relief from withdrawal after morphine administration. Thus, drug or alcohol self-administration during withdrawal may similarly convey conditioned incentive value to environmental stimuli associated with amelioration of the negative consequences of withdrawal, thereby exacerbating the effects of drug cues in tests of reinstatement. Consistent with this hypothesis, ethanol-dependent rats repeatedly allowed to self-administer alcohol during withdrawal and presented with an ethanol-paired CS several weeks following withdrawal (i.e., during what has been referred to as the protracted abstinence phase) showed greater conditioned reinstatement than dependent rats not given experience with ethanol during withdrawal.

Important for understanding the significance of drug-related maladaptive learning in addiction are differences that exist between the stimulus control of behavior motivated by cues conditioned to drugs of abuse as opposed to natural rewards essential for survival, well-being, and normal hedonic pursuits. For example, a single pairing of cocaine with drug-predictive discriminative stimuli elicited conditioned reinstatement for 1 year whereas the same discriminative stimuli – paired with a palatable sweet solution – remained effective for less than 3 months. Similarly, while seeking behavior for natural reward (e.g., sucrose) shows incubation, this effect is weaker and more short lived than incubation of conditioned cocaine seeking. Moreover, when exposed to punishing stimuli, animals typically show conditioned suppression of appetitive behavior whereas this is not the case with drug-directed conditioned behavior. Several mechanisms have been proposed by which neural signaling that regulates normal appetitive conditioning differs from that mediating conditioned behavior resulting from drug-related learning. First, neural circuits mediating the effects of drug cues may be distinct from those mediating the conditioned effects of natural reward. Second, neural circuits mediating the effects of drug cues may not be specific to addiction-related events, but normal circuits are activated to a greater degree, thereby creating new motivational states or tilting processes that normally govern responding for natural rewards toward drug-directed behavior. A related possibility is that information about drug versus nondrug cues is processed by distinct populations of neurons, but within

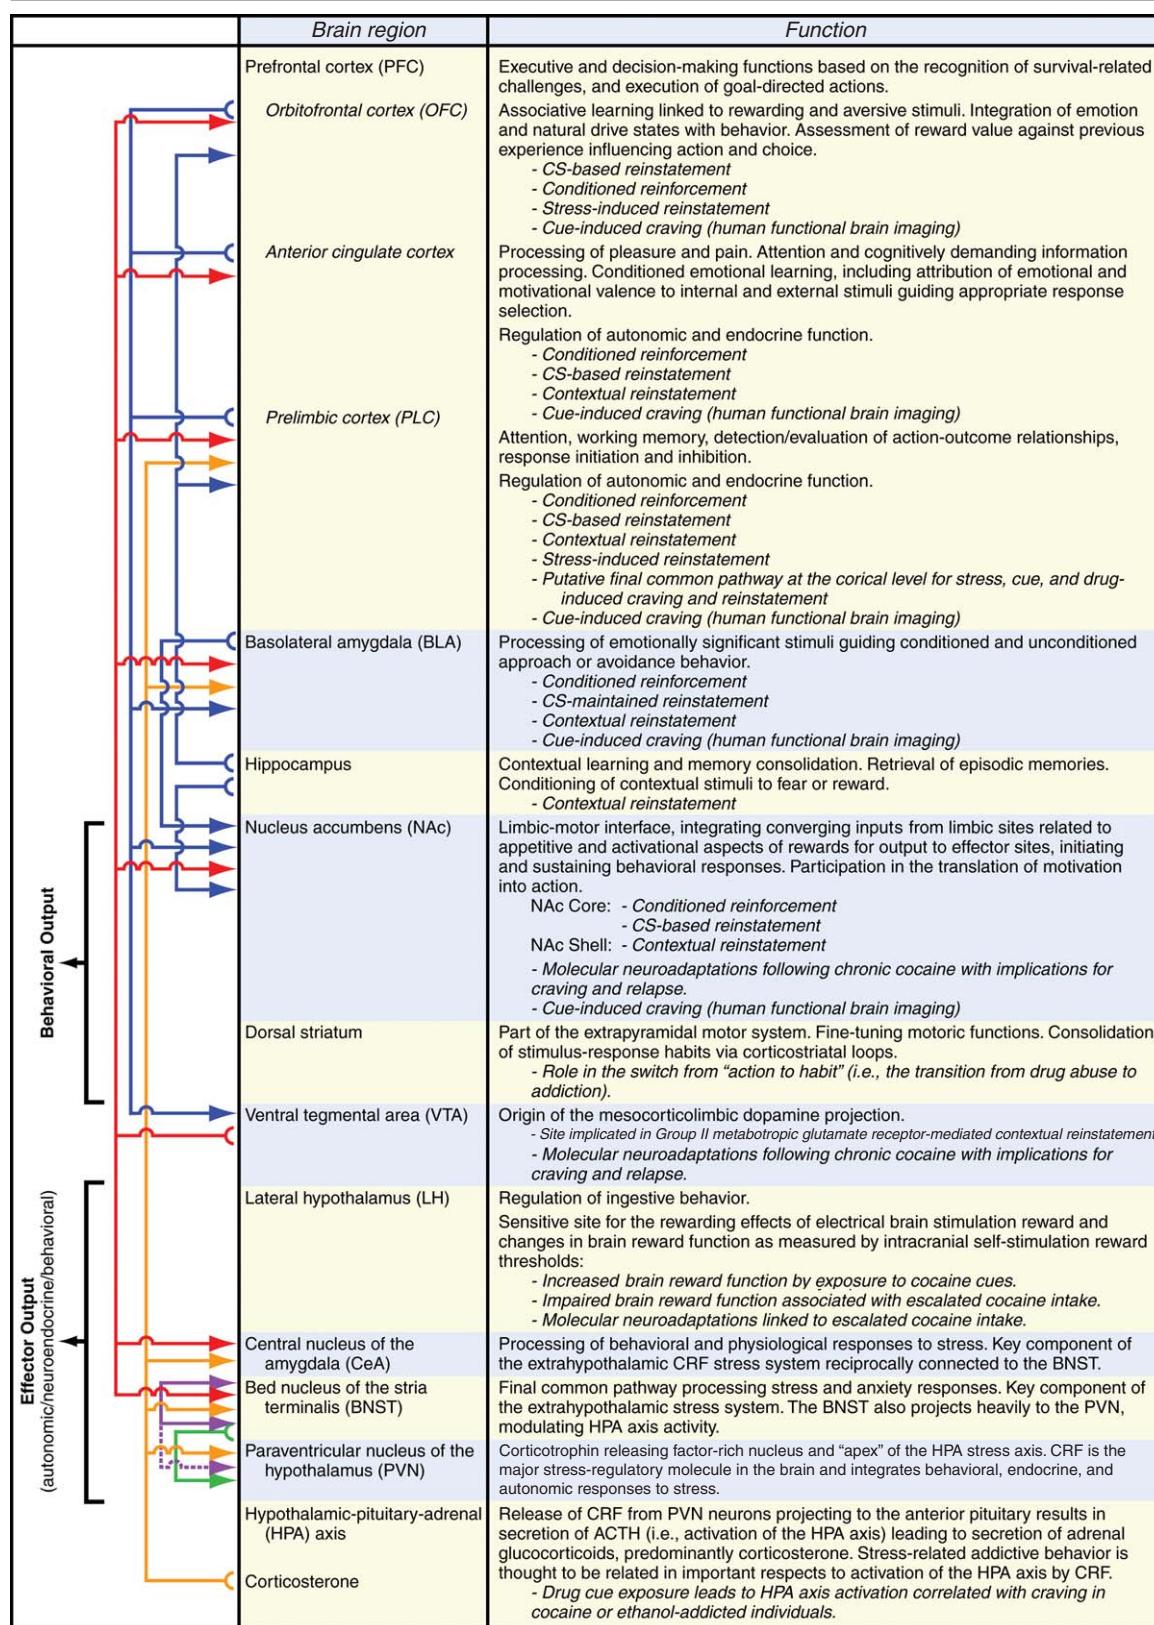

the same circuitry. Third, drug-induced neuroadaptation may provide a switch whereby a circuit not normally involved in drug seeking becomes responsive to drug cues. Some experimental support exists for all of these hypotheses such that it appears likely that several mechanisms may contribute to the differential control of behavior by stimuli conditioned to drug versus natural reward.

Neurocircuitry Mediating Conditioned Drug Seeking and Reinstatement

Drugs of abuse have diverse pharmacological profiles and produce differential behavioral effects. Nonetheless, their conditioned effects share the common feature of activating major components of the brain incentive-motive circuit. Specifically, neural mapping studies, targeted lesions and site-specific pharmacological manipulations in animals implicate a distributed set of brain regions connected by the corticostriatopallidal circuit in conditioned drug seeking and reinstatement. Major components of this circuit include the terminal regions of the mesocortical dopamine pathway that originates in the ventral tegmental area (VTA) and projects to the orbitofrontal, anterior cingulate, and prelimbic divisions of the prefrontal cortex, and of the terminal regions of the mesolimbic VTA dopaminergic projections that include the central and basolateral amygdala, hippocampus, nucleus accumbens (NAcc), as well as projections to the dorsal striatum. These brain regions, their function, and their neurochemical and neuroanatomical connectivity are described in **Table 1** and **Figure 2**.

Among brain regions associated with the mesolimbic dopamine pathway, the NAcc which has a critical role in the primary reinforcing effects of drugs of abuse also participates in mediating drug-directed conditioned responding. Current evidence favors a preferential role of the NAcc core subregion in CS-maintained second-order-schedule performance and reinstatement induced by discrete drug-paired cues, whereas drug seeking elicited by contextual stimuli is dependent on the NAcc shell. Direct evidence exists for a role of the amygdala (including both the central and basolateral nuclei) and the ventral hippocampus in discrete stimulus-reward associations relevant for conditioned drug seeking on a second-order schedule and reinstatement induced by discrete drug-paired CSs. The basolateral and central nuclei of the amygdala may, however, participate also in mediating the effects of contextual stimuli because these brain regions show neural activation in animals exposed to drug-paired contextual cues. The dorsal hippocampus has an important role in contextual memory retrieval and the occasion-setting actions of contextual stimuli, and evidence implicates the dorsal hippocampus in mediating the stimulus-stimulus associations relevant for drug-related contextual learning. The orbitofrontal

Table 1 Major function and role in addictive behavior (italicized) of brain regions implicated in mediating conditioned drug-seeking. Shown in highly simplified form are the major neurochemical pathways by which these brain regions are connected (Semicircles represent the region of origin and arrows the terminal fields of individual neural connections. The identity of the major neurotransmitter in each pathway is represented by different dotted line patterns: dopamine (---), glutamate (- - -), CRF/GABA (— · —), GABA (— · — · —), adrenal glucocorticoid (predominantly corticosterone) feedback (— · — · — · —). Additionally, the schematic indicates major effector output originating from addiction-relevant sites. Note that these are not direct, but polysynaptic pathways via projections to sites including the thalamus, hypothalamus, dorsal and ventral pallidum, and brainstem nuclei. [Abbreviations: ACTH = adrenocorticotrophic hormone, CRF = corticotropin-releasing factor, HPA = hypothalamic-pituitary-adrenal, mGluR = metabotropic glutamate receptor]

cortex and prefrontal cortex, brain regions associated with the mesocortical dopamine pathway, regulate cognitive and executive function as well as emotional responses. Chronic cocaine exposure, and likely exposure to other drugs of abuse, produces neuroadaptive dysregulation in prefrontal glutamatergic afferents to the NAcc that contribute to persistent addictive behaviors, including diminished cognitive and impulse control, heightened sensitivity to drug-associated stimuli, and, presumably, impaired ability to learn alternative responses to compete with drug-seeking behavior. Lastly, the dorsal striatum has been recognized as serving a critical role in consolidating stimulus-response habits associated with addictive behavior via the engagement of corticostriatal spirals. It is important to note that the findings on the neural regulation of conditioned drug-seeking responses in the animal literature are consistent with brain-activation patterns observed in functional brain imaging studies of cue-induced craving in the human – findings that support the validity of conditioned drug-seeking procedures as models of craving and relapse.

Neural mapping data show that, in addition to activation of the corticostriatopallidal circuitry, contextual cues conditioned to ethanol produce activation of brain sites not traditionally linked to conditioned drug seeking and reinstatement. These include the medial parvocellular and magnocellular

paraventricular nuclei (PVNs) of the hypothalamus. Activation of medial parvocellular PVN neurons is positively correlated with hypothalamic–pituitary–adrenal (HPA)-axis activation, suggesting that alcohol cues elicit a stress-like neuroendocrine response. Activation of the magnocellular PVN by ethanol cues represents an effect that is consistent with psychological stress, lending further support to the hypothesis that ethanol cues produce stress-like effects. In addition to influencing the HPA axis, activated PVN neurons, through descending brainstem projections, may influence autonomic responses associated with the anticipation of ethanol reward predicted by ethanol cues as observed in alcoholic subjects. Although not yet clearly documented, activation of these stress regions likely extends to the effects of cues conditioned to other drugs of abuse. This is so because, in the human, drug-cue manipulations associated not only with ethanol but also with cocaine induce a pattern of cue reactivity and craving similar to that induced by stress, and these effects are accompanied by increased HPA-axis activity and anxiety. Thus, subjective responses to drug cues include stress-like reactions and these may contribute to drug seeking (in animals) and resumption of drug use (in humans) elicited by these cues, given the well-established significance of stress as a risk factor for relapse.

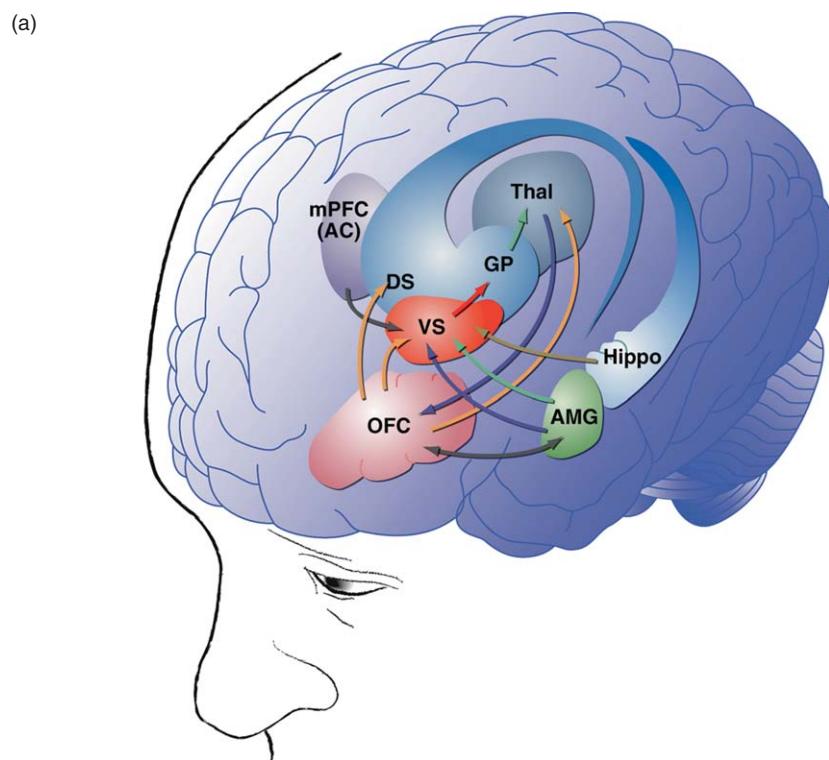

Figure 2 (Continued)

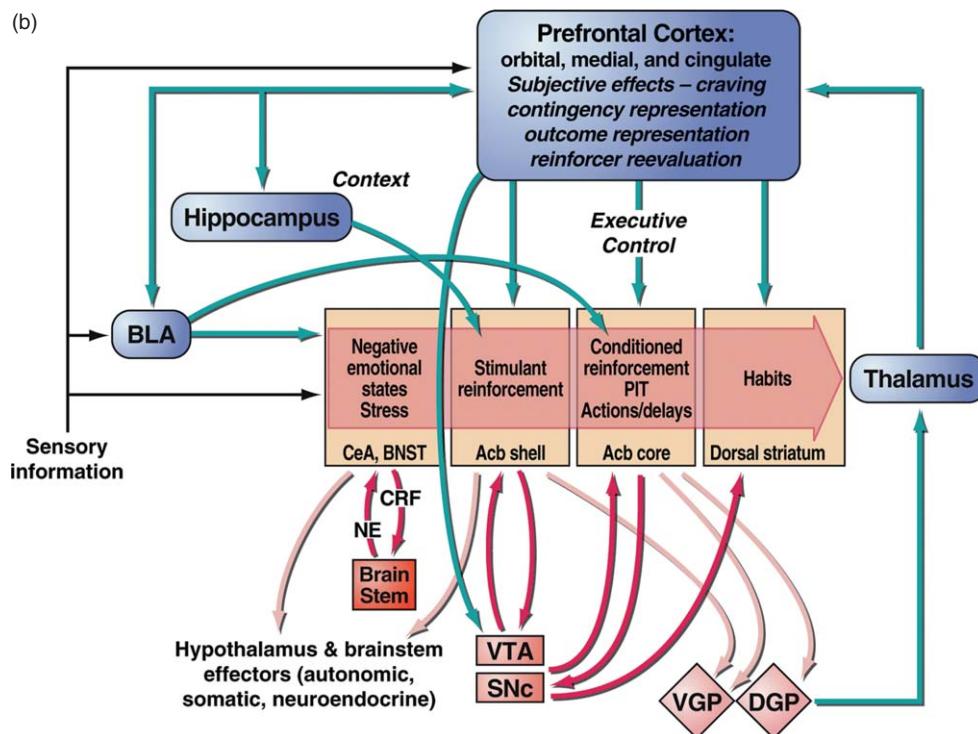

Figure 2 Representation of limbic cortical and associated striatal circuitry, with tentative localization of functions involved in drug addiction. (a) Key structures include the medial prefrontal cortex (mpFC), which also includes the anterior cingulate (AC), orbitofrontal cortex (OFC), hippocampus (Hippo), ventral striatum (VS), nucleus accumbens, dorsal striatum (DS), globus pallidus (GP), amygdala (AMYG), and thalamus (Thal). (b) Limbic corticostriatopallidal circuitry. (i) Processing of conditioned reinforcement and delays by basolateral amygdala and of contextual information by hippocampus. (ii) Goal-directed actions involve interaction of the prefrontal cortex with other structures, possibly including the nucleus accumbens and dorsomedial striatum. (iii) 'Habits' depend on interactions between the prefrontal cortex and dorsolateral striatum. (iv) 'Executive control' depends on the prefrontal cortex and includes representation of contingencies, representation of outcomes and their value, and subjective states (craving and, presumably, feelings) associated with drugs. (v) Drug craving involves activation of the orbital and anterior cingulate cortex and temporal lobe, including the amygdala, in functional imaging studies. (vi) Connections between dopaminergic neurons and the striatum reflect 'spirals' – serial interactions organized in a ventral-to-dorsal cascade. (vii) Reinforcing effects of drugs may engage stimulant, Pavlovian instrumental transfer and conditioned reinforcement processes in the nucleus accumbens shell and core and then engage stimulus-response habits that depend on the dorsal striatum. (viii) The extended amygdala is composed of several basal forebrain structures including the bed nucleus of the stria terminalis, the centromedial amygdala, and, more controversially, the medial portion (or shell) of the nucleus accumbens. Corticotropin-releasing factor is a major transmitter in the extended amygdala, which projects to the brainstem where noradrenergic neurons provide a major projection reciprocally to the extended amygdala. Activation of this system is closely associated with the negative affective state that occurs during withdrawal. Conditioned Withdrawal

As outlined in the introduction to this article, the investigation of conditioning factors in drug abuse has originated with studies on the role of classical conditioning in the opiate withdrawal syndrome. Anecdotal evidence has existed for some time that return to drug-related environments can elicit withdrawal-like symptoms in former opiate addicts, a conditioning phenomenon that may precipitate return to drug use. Using a peppermint-odor cue paired with administration of the opiate antagonist naloxone to

induce withdrawal in methadone-maintained heroin addicts, O'Brien and colleagues demonstrated that, following several conditioning trials, the peppermint odor alone elicited conditioned withdrawal reactions. These results lend credence to subjective reports of such conditioned withdrawal responses occurring naturally although their clinical significance for recidivism remains to be established. Such conditioned withdrawal reactions have also been demonstrated in the rat and monkey. In particular, CSs predicting the onset of heroin withdrawal produced an elevation in the threshold for rewarding electrical brain

stimulation in rats. Such reward deficit are thought to be reflective of the presence of negative affect (i.e., dysphoria, anhedonia, etc.), a state that is likely to contribute to relapse risk. Neuroanatomically, the basolateral amygdala is a critical neural substrate mediating conditioned opiate withdrawal in rats. Given that the basolateral amygdala also regulates the appetitive effects of drug-related stimuli, it appears that the amygdala mediates associative learning whereby both positive and aversive events become conditioned to specific environmental cues. As such, this brain site may be a key element within the corticostriatopallidal circuitry that sustains compulsive drug seeking and relapse associated with both conditioned positive reinforcement and the impact of conditioned withdrawal.

Glossary

Conditioned place preference – The preference animals show for a contextually distinct location that has previously been paired with a drug of abuse.

Drug self-administration – A model for drug addiction in which animals engage in a specific behavior in order to receive the drug of abuse.

Extrasynaptic glutamate – The glutamate located in extrasynaptic areas that is regulated by glial cells and provides activation of presynaptic glutamate receptors. It is regulated separately from synaptically released glutamate.

Locomotor sensitization – The increased locomotor response of an animal to an acute drug injection after a period of chronic drug administration, as compared to an acute injection in a naive animal.

Medial prefrontal cortex – The brain structure involved in executive function as well as decision making and part of a final common pathway in the reinstatement of drug-seeking behavior.

Nucleus accumbens (NAcc) – The part of the ventral striatum that acts as an interface between decision-making brain regions and behavioral output, known to be involved in motivation and reward, including drug reward.

Reinstatement – The return to drug-seeking behavior in animals after extinction training in the drug self-administration paradigm, frequently used as a model for relapse.

Relapse – The return to drug use after a period of withdrawal/abstinence.

Drug addiction refers to the end state of a drug-taking process in which individuals move from recreational drug use to chronic drug abuse to, finally, addiction itself, wherein the person finds it difficult-to-impossible to cease using the drug and the drug use impairs the person's ability to conduct normal life functions. After undergoing treatment for drug addiction, human drug users have great difficulty remaining drug-free and face high rates of relapse back to drug use. 'Relapse' can be defined as the return to drug taking following a period of abstinence. While some modest strides have been made in treating addiction and reducing the risk of relapse, no treatment has emerged as a true panacea. Thus, there is considerable

ongoing research to identify the neurobiological mechanisms underlying relapse.

Models of Drug Addiction

In order to investigate the neurobiology of drug addiction related to relapse, animal models have been developed. Such models include: (1) repeated noncontingent drug administration and the development of locomotor sensitization, (2) conditioned place preference, and (3) drug self-administration. In the locomotor sensitization model, animals are given repeated systemic administration of the drug of interest, typically over 1 week. Nearly all drugs of abuse induce changes in animals' locomotor activity. It has been found that repeated administration of drugs induces locomotor sensitization, which is defined as an animal's increased locomotor response to an acute administration of a drug following chronic drug administration, as compared to the locomotor response to the first acute administration of the drug. Although the sensitization model has enabled the examination of some of the neuronal adaptations induced by repeated drug administration, it lacks the learning components involved in human drug use associated with relapse. In the conditioned place preference model, rats are given drug injections and placed in a contextually distinct location, typically one chamber of a two-chamber apparatus. At other times, rats are given saline injections and placed in the other chamber in the apparatus. Through these pairings, rats learn to associate one chamber with the drug of interest. During a test day, rats are permitted to freely explore the entire apparatus and show a preference for that chamber paired with the drug of abuse, as indicated by time spent in that chamber. Conditioned place preference has been useful because it allows the investigation of the rewarding properties of the drug as well as the associated learning that occurs between the drug and the paired chamber. However, similarly to the sensitization model, conditioned place preference requires the experimenter to administer the drug of abuse, making it a significant departure from the human experience in which humans decide to consume the drug of abuse.

In the drug self-administration model, the animal engages in a particular behavior, such as pressing a lever, in order to receive a small amount of the drug of interest. The drug may be taken orally, through inhalation, or intravenously, and animals used in this model

have included pigeons, mice, rats, and nonhuman primates, thus enabling a variety of experiments to be performed. Studies examining self-administration have provided considerable knowledge about the reinforcing effects of drugs of abuse. Most commonly abused drugs increase mesolimbic dopamine levels throughout the forebrain. Dopamine normally serves as a neuromodulator that indicates the importance of external stimuli and reinforces the animal's learning about the stimuli. Dopamine is particularly important for inducing the neuroplasticity that underlies adaptive changes in the animal's behavior in response to external consequences of the behavior. A critical locus of dopamine's influence on the plasticity underlying reinforcement is the nucleus accumbens (NAcc). Natural rewards and drugs of abuse increase dopamine levels in the NAcc, and blockade of dopamine receptors impairs this reinforcement learning.

Reinstatement Model of Relapse

The drug self-administration model has provided considerable important insight regarding how drugs of abuse induce people to consume more of the drug in the future; however, it has not explained why people relapse to drug use, even after they have undergone treatment and extended abstinence. To model some aspects of the relapse associated with drug addiction, animals are trained to self-administer an addictive drug for a period of time (e.g., 2 weeks) followed by another period, termed 'extinction' training, in which the animal's responses no longer produce the drug reward. During extinction training, the animal's behavioral responses eventually decrease (extinguish) as the animal learns that drug reward is no longer achieved by pressing the lever. When the animals have reached a sufficiently low level of responding, relapse to drug-seeking is then induced in a reinstatement session. Reinstatement refers to the return to drug-seeking behavior (e.g., lever-pressing) even though the behavior is not rewarded with the drug. Thus, reinstatement serves as index of the animal's drug-seeking, not drug-taking, behavior and presumably reflects the animal's desire and drive to receive the drug of abuse.

Several triggers are known to induce relapse in humans, each of which has been modeled in rats. Human drug addicts frequently return to drug use after being exposed to the cues or places associated with the drug taking. This is modeled in 'cue- or context-induced reinstatement', in which cues or the context, previously paired with the drug infusions, are present again during the reinstatement test. Human addicts also return to drug use following a stressor, which is modeled in 'stress-induced reinstatement'. In this model, immediately prior to the reinstatement test, rats receive a stressor such as a

series of footshocks, or in an alternative method, an injection of the α_2 -adrenergic antagonist yohimbine. These stressors induce reinstatement of drug seeking. Another trigger occurs when people consume a small amount of the drug itself, believing that they can handle 'just one hit' or 'just one drink'. In addicts, this small amount of the drug then serves as a kind of reminder that induces a full return to drug taking and relapse. In 'drug prime-induced reinstatement', animals receive a noncontingent administration of the drug and are then tested for the reinstatement of drug seeking.

During the reinstatement test, animals significantly increase their responding, which serves as an index of drug-seeking behavior, but the animals never receive a drug infusion during the reinstatement test. The lack of a drug reward during the reinstatement test is critical for studying relapse, as it permits examination of the neurobiology of reinstatement without concern for the reinforcing effects of the drug of abuse on drug seeking (e.g., lever pressing). The focus of this article is drug-induced reinstatement/relapse to drug seeking.

Neurotransmitters Underlying Drug-Induced Reinstatement

As noted, most, if not all, drugs of abuse increase dopamine levels. Drugs such as cocaine and amphetamine do this directly through actions on the dopamine transporter located presynaptically on dopaminergic neurons. Other drugs, such as heroin, nicotine, and alcohol, do this indirectly by increasing activity in dopamine-producing neurons located in the ventral tegmental area (VTA). Thus, it is not surprising that drug-induced reinstatement depends on activation of dopamine receptors. Blockade of either D1 or D2 dopamine receptors by a systemic administration of dopamine receptor antagonists reduces reinstatement induced by cocaine, alcohol, and heroin. Similarly, dopamine reuptake inhibitors, which mimic cocaine's action, and D2 agonists induce reinstatement of cocaine seeking. Drugs that work on the dopamine transporter, including cocaine and amphetamines, also appear to have effects on the noradrenergic and serotonergic systems through their transporters. However, the role of those systems in drug-induced reinstatement is not as obligatory. Serotonin and norepinephrine reuptake inhibitors do not induce cocaine seeking in rats, but norepinephrine reuptake inhibitors induce cocaine seeking in squirrel monkeys, although with decreased efficacy compared to a dopamine reuptake inhibitor or cocaine itself.

Drugs that work through other systems and indirectly increase dopamine levels also require those other systems to induce reinstatement. Thus, heroin- or opiate-induced reinstatement is prevented by systemic blockade of

mu-opioid receptors, and nicotine-induced reinstatement is blocked by systemic administration of nicotinic antagonists. Although alcohol acts in part as an allosteric agonist at γ -aminobutyric acid (GABA) receptors, it has other pharmacological effects in the brain, making its mechanism of action relatively complex. Thus, it is not surprising that blockade of other systems, such as the mu-opioid receptors or the endocannabinoid CB1 receptors, inhibits reinstatement of alcohol seeking. Systemic CB1 receptor antagonist administration prevents reinstatement of cannabinoid seeking. The endocannabinoid system also appears to be involved in relapse to drug seeking for other drugs of abuse, as systemic blockade of the CB1 receptors also prevents relapse to alcohol-, nicotine-, cocaine-, and methamphetamine-seeking behavior.

The interactions between the endocannabinoid system and relapse to non-cannabinoid drugs of abuse raises the issue of cross-reactivity. ‘Cross-reactivity’ of drug-induced reinstatement refers to the ability of one drug to induce reinstatement in animals that originally self-administered a different drug. Intriguingly, the ability of one drug to induce reinstatement of seeking for another drug does not mean the reverse is true. For example, heroin administration induces reinstatement of cocaine seeking, but cocaine administration has no effect on the reinstatement of heroin seeking. Moreover, drug classes respond differentially to reinstatement by the same drug of abuse. For example, endocannabinoid agonists induce reinstatement of alcohol seeking but have no effect on the reinstatement of cocaine seeking. The neurobiology of cross-reactivity has not been extensively studied but may have clinical relevance as drug addicts frequently use multiple classes of addictive drugs.

Neural Circuitry of Drug-Induced Reinstatement

As noted, the reinforcing effects of drugs of abuse appear to depend on the dopaminergic system, particularly the dopamine projections from the VTA to the NAcc. Drug-induced reinstatement not only involves activity in those systems but also recruits additional brain circuits. This is not surprising, as drug-seeking behavior mimics relapse and reflects the animal’s drive to obtain the drug of abuse. Thus, structures involved in decision making, such as the medial prefrontal cortex (mPFC), are also necessary for drug-induced reinstatement. However, the actual array of structures necessary for drug-induced reinstatement depends on the drug of abuse.

Relapse to Cocaine Seeking

Local inactivation of brain structures, using either GABAergic agonists or sodium-channel blockade, has

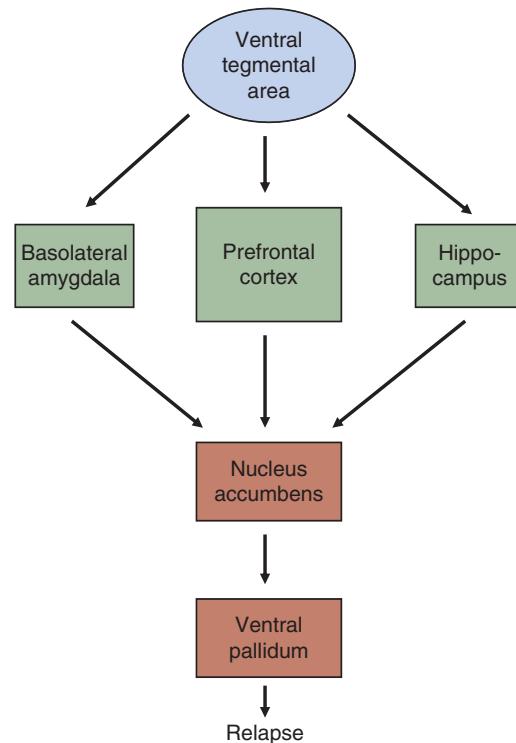

Figure 1 Schematic diagram of the neural structures underlying the relapse to drug-seeking behavior. The ventral tegmental area provides the dopaminergic input to most of the forebrain. The dorsomedial prefrontal cortex, basolateral amygdala, and hippocampus provide glutamatergic inputs to the nucleus accumbens, which sends GABAergic fibers to the ventral pallidum and regulates behavioral output. Although the basolateral amygdala and hippocampus are involved in cue- and context-induced reinstatement, the dorsomedial prefrontal cortex is required for cue-, context-, and drug-induced reinstatement, suggesting that it is a critical part of the final common pathway regulating drug-seeking behavior in rats.

been particularly useful in elucidating the structures responsible for relapse. Cocaine-prime reinstatement depends on activity in the VTA, the dorsal mPFC, the NAcc core, and the ventral pallidum (VP; see Figure 1). In contrast, inactivation of the substantia nigra, ventral mPFC, the NAcc shell, the basolateral amygdala, the central nucleus of the amygdala, or the medial dorsal thalamus has no effect on cocaine-induced reinstatement. Those areas involved in cocaine seeking are part of a circuit, in which the dorsal mPFC projects to the NAcc core, which in turn projects to the VP. Although the VTA projects to all three structures, blockade of dopamine receptors in the dorsal mPFC, and not the NAcc core or VP, prevents cocaine-induced reinstatement. This suggests that, during reinstatement, cocaine increases dopamine levels in the dorsal mPFC, thereby activating projections to the NAcc core. The NAcc core then integrates this information and controls behavioral output through the VP. Cue-, context-, and stress-induced reinstatement to cocaine seeking also

depend on activity in the dorsal mPFC, NAcc core, and VP, suggesting that these structures serve as a final common pathway for relapse to cocaine-seeking behavior.

Paradoxically, although inactivation of the NAcc shell has no effect on drug-induced reinstatement of cocaine seeking, blockade of dopamine receptors in the NAcc shell prevents reinstatement. It appears that the D1 and D2 class of dopamine receptors work together following a cocaine prime to induce reinstatement and that blockade of either class alone prevents such reinstatement. Moreover, recent work also indicates a critical role for the glutamatergic system in the NAcc shell during cocaine-induced reinstatement, as blockade of the α -amino-3-hydroxyl-5-methyl-4-isoxazole-propionate (AMPA) receptors in the shell prevents reinstatement. Continued work on the NAcc shell and core will elucidate their respective roles during drug-induced reinstatement.

It is not surprising that structures such as the NAcc and the mPFC are involved in cocaine-induced reinstatement. Evidence from studies with humans shows that presentation of drug-associated cues increases activity in those regions homologous to the dorsal mPFC in the rat. The dorsal mPFC is involved in decision making, and drug addicts have difficulty in decision making, frequently choosing drug-seeking and drug-using behavior despite the known negative consequences of those choices. Dysfunction in the dorsal mPFC and its outputs would, therefore, be expected as a consequence of chronic drug abuse. The NAcc serves as a critical node in the integration of information from the dorsal mPFC and memory- and emotion-related structures such as the basolateral amygdala and hippocampus. Through this integration, the NAcc then controls the behavioral output of the organism. Although the basolateral amygdala and hippocampus are not known to be involved in cocaine-induced reinstatement, activity in the basolateral amygdala or hippocampus is necessary for cue- or context-induced reinstatement, respectively. The animal and circuitry studies, therefore, support the hypothesis that enduring changes in the brain regions regulating decision making and behavioral output underlie the propensity to relapse.

Relapse to Heroin Seeking

Heroin-induced reinstatement appears to depend on a wider range of structures. It requires the same structures as cocaine-induced reinstatement but also requires activity in the basolateral amygdala, the central nucleus of the amygdala, the bed nucleus of the stria terminalis, and the substantia nigra. Although the mechanisms underlying the similarities and differences between heroin and cocaine reinstatement are not known, they clearly must depend on the pharmacological differences between the drugs. Heroin acts at mu-opioid receptors and disinhibits the dopaminergic neurons in the VTA through

mu-opioid receptors on the GABAergic neurons in the VTA, whereas cocaine acts directly on the dopamine system to block dopamine reuptake. One critical effect of this is that cocaine induces a much larger dopamine release than heroin does in structures such as the NAcc. In addition, as mu-opioid receptors are located throughout the forebrain, heroin influences neurons through direct effects on mu-opioid receptors in the structure as well as indirectly through the increase in dopamine release in the structure.

Continued work on relapse to heroin seeking as well as relapse for other drugs of abuse will provide critical knowledge on the neural circuitry and will, hopefully, confirm that structures such as the dorsal mPFC and the NAcc are involved in a final common pathway underlying relapse.

Glutamatergic System during Drug-Induced Relapse

Evidence strongly implicates that, following drug self-administration, the glutamatergic system, particularly in the NAcc, plays a critical role during drug-induced reinstatement. Much of the work on this issue has focused on cocaine-seeking behavior, but recent findings with heroin have bolstered support that alterations in the glutamatergic system underlie relapse in general. During cocaine- or heroin-induced reinstatement, increased dopamine levels activate dorsal PFC glutamatergic projections to the NAcc core, producing a significant increase in glutamate levels in the NAcc core. The necessity of this glutamate increase in the NAcc core has been demonstrated through studies showing that AMPA receptor blockade in the NAcc core prevents drug-induced reinstatement to cocaine or heroin seeking. Moreover, inactivation of the dorsal PFC prevents the glutamate increase in the NAcc core as well as reinstatement. Studies with stress-induced reinstatement of cocaine seeking and cue-induced reinstatement of heroin seeking confirm the critical role of the glutamatergic system in the NAcc core during drug seeking in general, as blockade of AMPA receptors in the NAcc core prevents reinstatement in those models. Intriguingly, blockade of the glutamatergic *N*-methyl-D-aspartic acid (NMDA) receptors in the NAcc core or shell induces reinstatement, suggesting that the AMPA receptors are the major contributors to the drive in the NAcc core that produces relapse but leaving unclear the role of NMDA receptors in the NAcc during relapse.

In contrast to rats with a history of self-administering cocaine or heroin, naive rats that receive a drug-priming injection do not have an increase in NAcc core glutamate levels. Rats that passively received cocaine or heroin also do not show the glutamate increase following a drug-priming injection. These findings strongly

suggest that chronically self-administering the drug of abuse, rather than simply repeated exposure to the drug, produces the critical alterations in the glutamatergic system that underlie relapse. Considerable work on cocaine-seeking behavior has elucidated the mechanisms underlying the increased glutamate release during cocaine-induced reinstatement. It appears that, following cocaine self-administration, basal glutamate levels in the NAcc core, as measured by microdialysis, are decreased compared to those found in naive rats. The basal levels are believed to reflect the extrasynaptic glutamate that is tightly regulated by glial cells. In naive animals, the basal (extrasynaptic) glutamate levels provide tonic activation of the group II metabotropic glutamate receptors (mGluR2/3s) located on the presynaptic glutamate terminals in the NAcc core that normally inhibit glutamate release. Thus, when a cocaine-priming injection is administered, activity in the dorsal mPFC projections and subsequent glutamate release in the NAcc core are quickly terminated by mGluR2/3s' activity. In contrast, rats that have undergone cocaine self-administration have decreased basal (extrasynaptic) glutamate levels in the NAcc core, thus

providing reduced tonic mGluR2/3 activation. When a cocaine prime is administered, increased dopamine levels activate the dorsal PFC projections to the NAcc core. Without the inhibitory effects of mGluR2/3 activation, the dorsal PFC projections produce a significant and sustained increase in glutamate levels that activate NAcc core neurons, leading to the drug-seeking behavior. **Figure 2** provides a diagram of how glutamate regulates the prefrontal cortical inputs to the NAcc.

The mechanism underlying the decreased basal glutamate levels in rats with a cocaine history depends, at least in part, on changes in the regulation of glutamate by glial cells. Extrasynaptic glutamate levels are controlled by glutamate transporters and the glutamate–cystine exchanger on glial cells. After chronic cocaine or nicotine self-administration, rats have reduced glutamate–cystine exchanger activity in the NAcc core, which contributes to the reduced basal glutamate levels. Confirmation of the critical role of this system in the glutamate dysregulation and drug seeking comes from studies using *N*-acetylcysteine, a cystine pro-drug. Systemic administration of *N*-acetylcysteine has been shown to restore basal glutamate levels to normal levels and to prevent

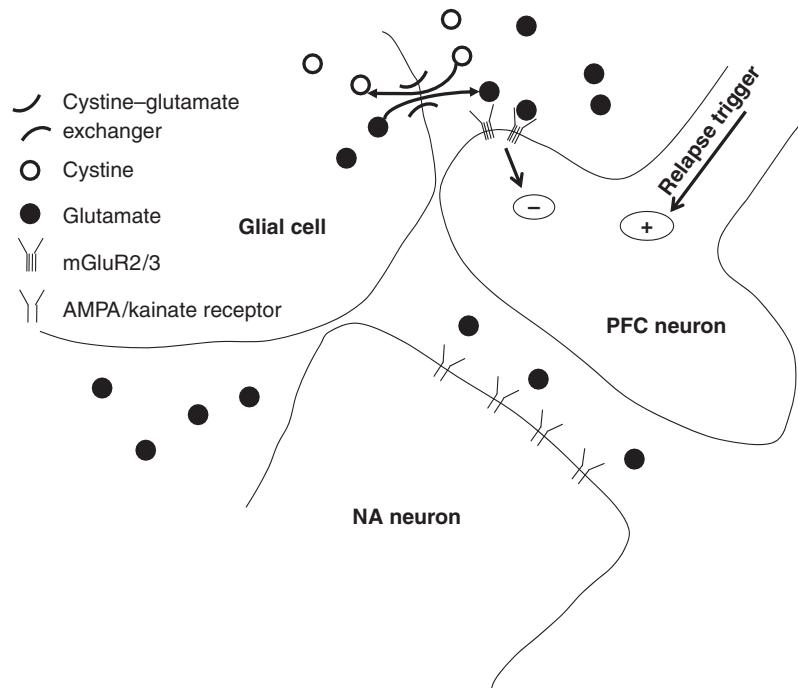

Figure 2 Schematic diagram of the regulation of glutamate in the nucleus accumbens (NA). In naive (non-drug treated) rats, prefrontal release of glutamate is inhibited by the extrasynaptic glutamatergic activation of mGluR2/3s that reside on the presynaptic neuron. Cocaine given to a naive rat, therefore, does not produce measurable increases in glutamate in the NA. In contrast, in rats that have experienced chronic cocaine, extrasynaptic (basal) glutamate levels are decreased due to reduced activity of the cystine–glutamate exchanger, thereby providing less tonic inhibition on the presynaptic glutamate release. When cocaine is administered to such a rat, as in a drug-prime reinstatement test, the cocaine-induced stimulation of the prefrontal neuron without the tonic inhibition by the mGluR2/3s results in increased glutamate levels and drives drug-seeking behavior. *N*-acetylcysteine restores the basal glutamate levels by activating cystine–glutamate exchange, and thereby increasing stimulation of the mGluR2/3s and inhibiting synaptic glutamate release and reinstatement.

cocaine- or heroin-induced reinstatement. The mechanism of *N*-acetylcysteine's action is through activating the glutamate–cystine exchanger, as administration of the exchanger inhibitor central pattern generator (CPG) reverses *N*-acetylcysteine's effects.

Concurrent mGluR2/3 blockade also prevents *N*-acetylcysteine's effects of reducing reinstatement, suggesting that restoration of glutamate levels inhibits reinstatement through its modulation of presynaptic activity through mGluR2/3 activity. Other work has shown that *N*-acetylcysteine also prevents heroin-seeking behavior in rats, suggesting that dysregulation of extra-synaptic glutamate may be involved in relapse in general. In fact, double-blind, pilot clinical trials have shown *N*-acetylcysteine to be effective at reducing cocaine craving and cocaine use in human drug addicts as well as at reducing the number of cigarettes smoked by human smokers. Thus, considerable evidence points to dysregulation of the glutamatergic system, at least in the NAcc core, as a major basis for relapse and as a potential therapeutic target in the treatment of drug addiction.

Conclusions

Considerable progress in our understanding of relapse has been accomplished through the use of reinstatement models of drug-seeking behavior, particularly drug-prime-induced reinstatement. This model has been particularly advantageous as animals initially learn to engage in an operant behavior to receive a drug reward. The reinstatement test permits the animal to engage in drug-seeking behavior without receiving a drug reward, thus enabling studies to separate the reinforcing effect of the drug of abuse from the neurobiology of drug seeking. Although the initial reinforcing effects of drugs of abuse clearly depend on an increase in mesolimbic dopamine, the neurobiology underlying relapse involves a more complicated brain circuit in which dopamine plays a critical, but not exclusive, role. In particular, long-term drug use induces a glutamatergic dysfunction in the dorsal mPFC and the NAcc core. Evidence suggests that, for cocaine-induced reinstatement, increased dopamine levels in the dorsal mPFC activate efferents to the NAcc core that, in turn, produce a significant increase in glutamate that drives NAcc core activity and reinstatement behavior. As a result of the cocaine prime, the glutamate increase in the NAcc core occurs because the chronic cocaine-induced reduction in extra-

synaptic glutamate levels result in less inhibitory regulation of glutamate release through mGluR2/3s. The reduced basal levels of glutamate appear to be the result of dysfunction in how glial cells regulate extra-synaptic glutamate. This neurobiological mechanism has resulted in novel glutamatergic therapeutic agents with a potential for treating addiction.

Glossary

Incentive – A stimulus that elicits approach. Incentive motivation refers to a central motivational state that enhances the salience and effectiveness of incentives. The incentive-sensitization view of Robinson and Berridge argues that sensitization in the mesoaccumbens dopamine (DA) pathways underlies the enhanced motivation to seek and self-administer drugs.

Sensitization – In drug-sensitization experiments, refers to the enhancement of a drug response that results from previous exposure to the drug. A descriptor preceding this term refers to the effect sensitized, as with a behavioral (behavioral or locomotor sensitization) or a neurochemical response (DA or glutamate sensitization). Sensitization of psychological processes has also been proposed as in incentive sensitization to refer to the enhancement of neuronal drug effects mediating the incentive valence of drug stimuli.

Test for sensitization – In drug-sensitization experiments, a test that assesses the ability of a drug to elicit a response that is greater than that observed when it was administered for the first time. Animals are challenged with the drug on a test conducted some time after they were repeatedly administered the drug. Sensitization can be assessed by comparing responding to the first and last drug injections in the same animals (within subject) or by comparing responding to the challenge drug injection in animals previously exposed to the drug or saline (between subject).

The term sensitization has a long history of use in several fields, including those focusing on the development of allergies, the induction of psychotic states, the effects of repeated exposure to analgesic and other drugs, and the formation of conditioned associations. It is used to describe the finding observed in many biological preparations that presentation of a strong stimulus produces a long-lasting increase in the subsequent response to the same or a weaker stimulus. Thus, sensitization has been used to describe increased reflex responses following their repeated elicitation as well as increased behavioral and biochemical responding to stressors and increased responsiveness of the immune system to antigens following repeated exposure. The last four decades have also

witnessed a growing interest in sensitization of the behavioral and biochemical responses to drugs. This has been driven, in part, by the need to understand the consequences of prolonged exposure to agents with central nervous system effects, either when these are used therapeutically – as in the case of opiates to control pain – or when they are used recreationally as in the case of abused drugs such as ethanol, nicotine, morphine, amphetamine, cocaine, and others. In the latter case, delineation of the neuronal systems underlying the behavioral effects of these drugs, including their ability to support self-administration, has helped focus the search for molecular, cellular, and systems-level mechanisms underlying sensitization and to understand the contribution of these neuroadaptations to the enhanced drug seeking and drug taking that is characteristic of drug abuse. This is illustrated below for the psychostimulants amphetamine and cocaine.

Behavioral Sensitization

Drugs typically produce multiple effects not all of which may exhibit sensitization. For example, the anorectic and lethal cardiovascular effects of amphetamine show tolerance or diminish with repeated exposure while its locomotor stimulant or stereotypic effects show sensitization. Similarly, in the biphasic locomotor response to moderate to high doses of morphine, the initial hypolocomotor response shows tolerance while the subsequent hyperlocomotion shows sensitization. Thus, it is important to note that sensitization is a phenomenon associated with specific drug effects rather than to drugs themselves. Whether sensitization is observed can also be influenced by other factors including the intensity of the drug-exposure regimen (e.g., drug dose, number, intermittency of injections), the time of testing following exposure, and the presence during testing of stimuli previously paired or unpaired with the drug. Notably, these factors can interact. Exposure to high doses of amphetamine, cocaine, and other drugs generally leads to enhanced responding when animals are tested long (i.e., weeks), but not soon (i.e., days later), after exposure. In addition, intermittent rather than continuous exposure to moderate doses of amphetamine has been reported to produce enhanced responding at different withdrawal periods; although it is possible that sensitization following continuous exposure to

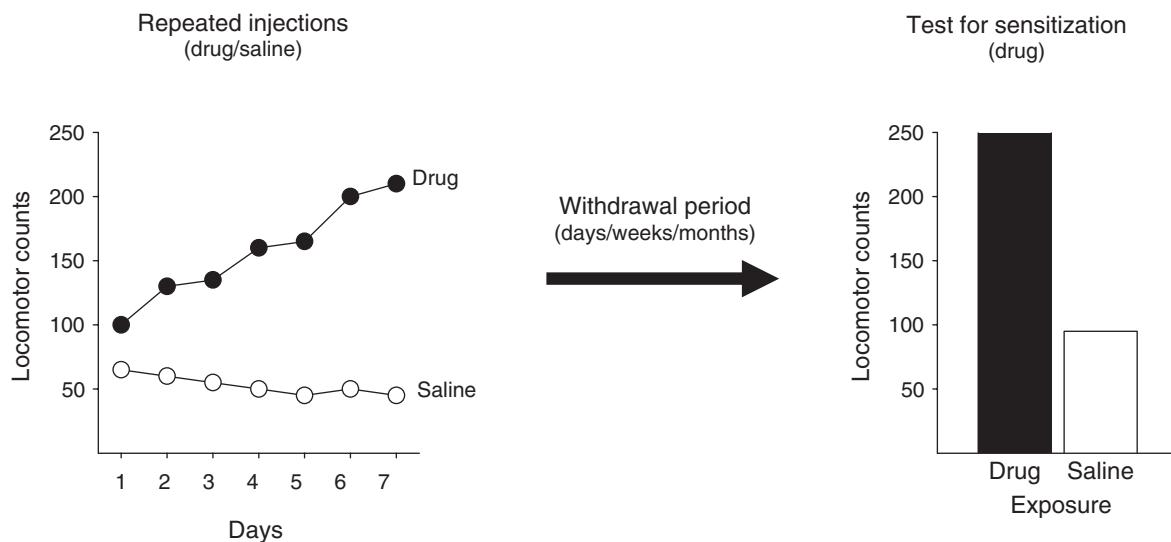

Figure 1 Illustration of procedures commonly used to produce and assess locomotor sensitization. Here, rats were administered seven daily injections of saline or drug and tested following a drug-challenge injection 3 weeks later. When locomotion is monitored during the exposure phase (left), a progressive enhancement in locomotor responding from the first to the last drug injection is often (but not always) observed, permitting within-subject assessment of sensitization. Comparing responding to a drug-challenge injection (right) in animals previously exposed to saline or the drug permits between-subject assessment of sensitization following a withdrawal phase.

amphetamine may also be observed but at significantly longer, not-yet-tested withdrawal periods.

The most studied response to amphetamine and cocaine in rodents is locomotion. Both drugs increase locomotion acutely across low to moderate doses and this response becomes enhanced with repeated injections. Similar findings have been obtained with other responses as well, including rotational behavior in unilateral 6-hydroxydopamine (6-OHDA)-lesioned animals and different stereotyped behaviors following moderate to high doses. Because stereotypies and locomotion constitute opposing behavioral outputs, it is important to note that development of sensitization in one will interfere with expression of sensitization in the other. Locomotor sensitization has been demonstrated using either within-subject comparisons of responding to the first and to the last drug injection or between-subject comparisons of responding in animals previously exposed to saline or to the drug (Figure 1). A notable characteristic of sensitization of drug effects is that it is enduring; locomotor sensitization has been observed up to 1 year after drug exposure in the rat. Such findings indicate that long-lasting neuroadaptations are produced that underlie this enhanced behavioral output. Because drug exposure also produces short-term transient neuronal effects, it remains unclear whether the sensitization observed within-subjects during drug exposure reflects the same neuronal changes underlying the sensitization observed between subjects after a long withdrawal period.

Importantly, exposure to psychostimulants also enhances the subsequent self-administration of these drugs. Indeed, exposure to a number of drugs leads to

enhanced conditioned place preference, facilitates acquisition of drug self-administration, and enhances motivation to obtain the drug, once the behavior has been acquired (Figure 2). As outlined below, sensitization of drug-induced locomotion and drug self-administration are produced by the same drug-exposure regimens via actions in the same nuclei, are prevented by the same pharmacological interventions, and are accompanied by the same neuroadaptations, providing strong support for the proposition that the enhanced expression of complex motivated behaviors can represent yet another manifestation of behavioral sensitization.

Anatomical and Neuronal Substrates of Behavioral Sensitization by Psychostimulants

While amphetamine and cocaine interact with serotonin-, norepinephrine-, and dopamine (DA)-containing neurons, it is recognized that they increase locomotor activity and support self-administration primarily by binding to DA transporters and by increasing extracellular levels of DA in forebrain sites. The mesocorticolimbic DA pathways, particularly those projecting from the ventral tegmental area (VTA) to the nucleus accumbens (NAcc), are known to be critical for the production of these effects (Figure 3). Both effects are blocked by DA-receptor antagonists or 6-OHDA lesions of DA neuron terminals in the NAcc. Sensitization of the ability of a drug such as amphetamine to increase locomotion, NAcc

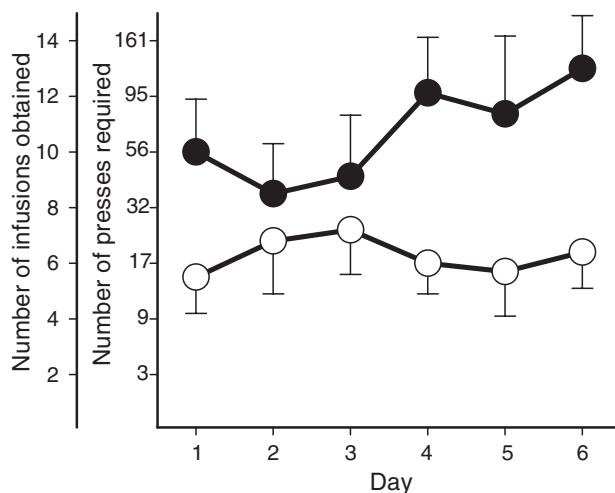

Figure 2 Previous exposure to amphetamine promotes the pursuit of the drug in rats. Data are shown as group mean (\pm SEM) number of amphetamine infusions (200 μ g/kg/infusion) obtained on each of 6 days of testing on a progressive ratio (PR) schedule of reinforcement. The number of presses required to obtain the successive infusions is also shown. Rats previously exposed to amphetamine (filled circles) worked more and obtained significantly more amphetamine infusions on these PR tests than rats previously exposed to saline (open circles). PR testing was conducted 2–3 weeks following exposure to the drug ($5 \times 1.5 \text{ mg kg}^{-1}$ amphetamine or saline, intraperitoneally (IP)). Adapted from Vezina P, Lorrain DS, Arnold GM et al. (2002) Sensitization of midbrain dopamine neuron reactivity promotes the pursuit of amphetamine. *Journal of Neuroscience* 22: 4654–4662.

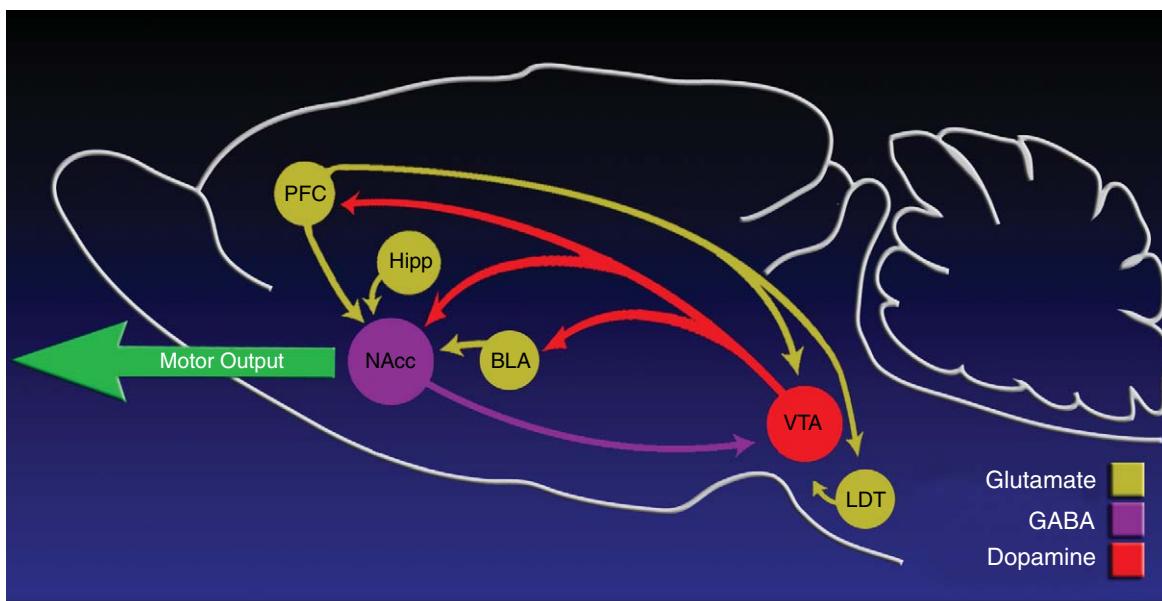

Figure 3 The mesoaccumbens DA projections are imbedded in a circuit of pathways in the basal ganglia with nuclei topographically interconnected to promote the flow of information from limbic areas to pyramidal and extrapyramidal motor systems. The NAcc is a major interface of this circuit because it receives rich sensory DA and glutamate projections from the VTA and the indicated forebrain regions and, in turn, sends projections to nuclei connected to motor systems. BLA = basolateral amygdala; Hipp = hippocampus; LDT = laterodorsal tegmentum; PFC = prefrontal cortex.

DA overflow, and to support self-administration is produced by infusions of amphetamine into the VTA but not into a number of DA-neuron terminal fields, including the NAcc. Thus, it is likely that the induction of sensitization of these effects is produced by a cascade of neuronal events initiated by the acute increase in extracellular levels of DA

in the VTA and that its eventual expression requires the manifestation of neuroadaptations in forebrain sites including the NAcc.

A number of neurotransmitters in the VTA have been implicated in the induction of sensitization by psychostimulants. This site is richly innervated by several afferent

projections using several neurotransmitter systems from several forebrain and hindbrain regions. In addition to somatodendritically derived DA, these include acetylcholine, serotonin, peptides, and inhibitory and excitatory amino acids. There is some evidence that, during exposure to psychostimulants, γ -aminobutyric acid (GABA)-mediated inhibition of VTA DA neurons is decreased while glutamate-mediated excitation is increased. Indeed, a number of findings indicate that during drug exposure there is a transient increase in the activation of DA neurons in this site – an effect also supported by other transient changes, including decreased DA D₂ autoreceptor sensitivity and increased α -amino-3-hydroxyl-5-methyl-4-isoxazole-propionate (AMPA) receptor function. The critical role of glutamate is underscored by the finding that activation of all three glutamatereceptor subtypes (*N*-methyl-D-aspartic acid (NMDA), AMPA, and metabotropic) is required for the induction of locomotor sensitization and the enhancement of drug self-administration by amphetamine. Activation of ionotropic glutamate receptors promotes calcium influx into dopamine neurons through AMPA and NMDA receptors as well as L-type calcium channels leading to the recruitment of second messenger pathways involving a number of protein kinases. Evidence from pharmacological activation and inhibition studies supports a role for calcium, calcium- and calmodulin-dependent protein kinase (CaMK), mitogen-activated protein kinase (MAPK), as well as protein kinase A (PKA) and C (PKC), although the nature of their contribution to sensitization remains unknown. It is conceivable that phosphorylation of some of their target proteins by these kinases leads to long-term alterations such as changes in the synthesis of candidate proteins and their transport to forebrain sites like the NAcc where amphetamine is known to produce enhanced responding in sensitized rats. Notably, inhibition of protein synthesis in the VTA blocks the induction of locomotor sensitization by psychostimulants.

The adaptation most consistently associated with the expression of locomotor sensitization by psychostimulants is the enhancement in the ability of these drugs to increase extracellular levels of DA in the NAcc. As with the sensitization of drug-induced locomotion and drug self-administration, this adaptation is produced by amphetamine in the VTA, its induction requires activation of D₁ DA receptors in this site, and its expression is dependent on CaMK-II in the NAcc. These findings suggest a close relation between the sensitization of the NAcc DA-activating effects of psychostimulants and behavioral manifestations of sensitization such as enhanced locomotion and drug self-administration. It has been argued that activity in mesoaccumbens DA neurons encodes the incentive valence of a drug. Thus, these findings also support the resulting argument that enhanced reactivity in

these neurons should similarly enhance this encoded valence and, as a result, enhance the incentive to pursue and self-administer the drug. Interestingly, some of the first reports of sensitized DA release were from studies using striatal slice preparations, suggesting a similar association between enhanced extracellular levels of striatal DA and the expression of sensitized stereotypies.

A number of other long-lasting adaptations have also been reported to occur in forebrain following repeated exposure to psychostimulants. These include alterations in dendritic morphology, increased glutamate overflow, functional upregulation of AMPA receptors, and changes in synaptic strength at cortico-accumbens glutamate synapses, as well as changes in the AMPA receptor-subunit expression and membrane insertion. Interest in these adaptations has been fueled in part by the finding that activation of NAcc-AMPA receptors is required for the expression of acute and sensitized psychostimulant-induced locomotion. However, the nature of the contribution of AMPA-receptor-mediated glutamate transmission in the NAcc to the expression of psychostimulant sensitization remains controversial. It remains a point of debate, for example, whether increased or decreased medium spiny neuron activity maps onto increased behavioral output. Importantly, terminals releasing DA and glutamate form synaptic contacts on the same dendritic spines of these neurons in the NAcc, suggesting that glutamate-DA interactions contribute to the expression of behavioral sensitization. However, the nature of the relation between altered pre- and postsynaptic glutamate and DA transmission remains to be determined. Delineation of adaptations in a number of postreceptor pathways in medium spiny neurons and the afferents they receive may ultimately provide some answers to these questions. Indeed, a number of proteins have been implicated in the effects observed following repeated exposure to psychostimulants, including CaMK-II, PKA, casein kinase, Darpp-32, cyclic adenosine monophosphate (cAMP) response-element-binding protein (CREB), extracellular signal-regulated kinase (ERK), and immediate early gene Fos-related antigens like delta FosB.

Sensitization in the Human

The assessment of the effects of acute and repeated psychostimulant exposure on neurotransmission in the human has been aided, over the course of the last two decades, by the development of functional neuroimaging techniques – such as positron emission tomography (PET) – that use radioactively labeled benzamide ligands for DA D₂/D₃ receptors and that can be coupled to magnetic resonance imaging (MRI). The resulting studies of the effects of

different drugs on DA reactivity in the human forebrain have recently achieved sufficient spatial resolution to allow assessment of different striatal subregions. As established in rodents, a number of reports have now shown that, when acutely administered, psychostimulants similarly increase extracellular levels of DA especially in the ventral subregions of the human striatum. Notably, these effects correlate with positive mood states and craving as well as novelty and sensation seeking. Despite such findings, the evidence for sensitization of DA overflow in the human was originally more equivocal than that observed in rodent studies. As a result, it has been argued that drug sensitization as a mechanism for drug abuse and other forms of pathology does not extend to the human case and is, thus, of limited value. Indeed, a number of imaging studies using PET and functional MRI (fMRI) techniques appear to support this argument. These generally report a reduced, rather than an augmented, striatal DA response to a psychostimulant challenge in cocaine-addicted patients, compared to controls. More recent evidence has emerged, however, demonstrating that drug sensitization does, in fact, occur in the human.

Sensitization to a number of drug effects is observed in the human when sufficiently high amphetamine concentrations are administered to nondrug-dependent subjects. These include potentiated indices of vigor and energy levels as well as potentiated eyeblink and mood-elevating responses. The latter sensitized drug-induced elevation in mood has been found to correlate positively with the personality trait of novelty seeking. In addition, some of the measures assessed (e.g., increases in vigor) were

observed a full year following exposure to the drug. Importantly, these studies did not typically observe sensitization of drug liking. This finding is consistent with evidence indicating that NAcc-DA is not associated with the pleasure derived from drug intake but rather with the motivational salience of the drug and the cues associated with it. Interestingly, cocaine-dependent abusers develop tolerance to the euphoric effects of psychostimulants despite the fact that they show enhanced drug seeking.

Similarly, significantly greater amphetamine-induced DA release has been observed in the ventral striatum 2 weeks and again 1 year following the administration of amphetamine in studies conducted in nondrug-abusing human subjects (Figure 4). Again, the extent of the DA sensitization observed was found to correlate positively with sensitization of energy level and eyeblink rate as well as the personality trait of novelty seeking. In contrast, the opposite effect has been reported in experiments conducted in detoxified patients with a history of cocaine dependence: less, rather than more, striatal DA release is observed in response to a psychostimulant challenge.

The results of these studies reveal that a number of factors can influence whether sensitization is observed in the human. These include the measures assessed, the challenge dose of the drug administered on the test, and the subject population studied. Indeed, at least two additional significant differences can be denoted between studies conducted in healthy subjects and those in drug-abusing patients that might account for the different results reported. Unlike healthy subjects, drug-abusing subjects have, by definition, been exposed to

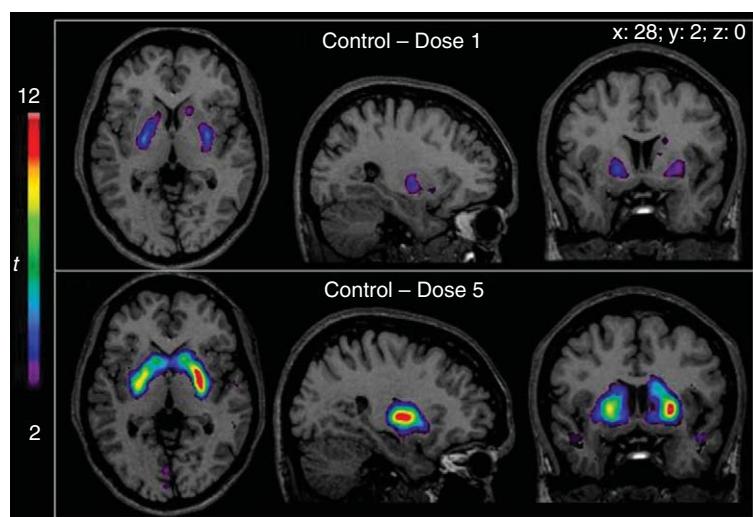

Figure 4 Previous exposure to amphetamine sensitizes ventral striatal DA release in the human. Shown are *t*-statistical maps of [¹¹C]raclopride binding potential change illustrating a decrease in binding potential (increase in DA release) after the first, and a greater effect following the fifth, amphetamine administration relative to a drug-free control condition. The fifth administration was administered approximately 1 year following the first. Amphetamine was administered by mouth (0.3 mg kg⁻¹). Colored *t*-maps ($>t = >\text{DA release}$) are overlaid on an averaged MRI of all the participants. Adapted from Boileau I, Dagher A, Leyton M, et al. (2006) Modeling sensitization to stimulants in humans. *Archives of General Psychiatry* 63(12): 1386–1395.

substantial amounts of drug and it is likely that even in detoxified patients the intensity of this exposure may interfere with the subsequent expression of sensitization. This possibility is supported by findings from the preclinical rodent literature showing that enhanced drug-induced NAcc DA overflow is not observed in the days following drug exposure but rather weeks to months later. The withdrawal period necessary to observe sensitization may be longer in the human, and longer still following prolonged intense drug exposure. Another critical difference between studies conducted in these two groups involves the various environmental stimuli surrounding exposure to the drug and those constituting the testing conditions. Again, an accumulating preclinical rodent literature indicates that stimuli that predict the availability of the drug promote sensitized responding whereas stimuli that predict its absence inhibit the expression of sensitization. In studies conducted in the human, it is likely that the constellation of stimuli afforded by the PET-testing environment exerts different effects in individuals that have received the drug only in their presence (healthy subjects) compared to individuals that have generally associated these cues with the absence of drug (drug-abusing patients). Thus, the results of the human studies described above suggest that the presence of cues predicting drug availability is associated with sensitized responding while the absence of these cues or the presence of stimuli predicting the absence of drug is associated with the absence of sensitized responding. Clearly, such cues capable of affecting the expression of sensitization can regulate the salience that is attributed to drug cues and, in so doing, influence predisposition to drug addiction and relapse susceptibility.

Other Factors Affecting Drug Responding

The evidence reviewed above indicates that long-term neuroadaptations produced by previous exposure to psychostimulants could strongly influence liability to initiate or resume drug use. However, it is important to remember that other adaptations are capable of augmenting drug intake in the absence of sensitization. For example, escalation of drug intake is observed in rats given long (6-h) rather than short (1-h) access to cocaine in a self-administration paradigm. It has been argued that these findings reflect tolerance rather than sensitization of the appetitive (locomotor and DA activating) properties of the drug because escalation of intake is not accompanied by sensitized responding in tests conducted during or soon after the escalating phase of the experiments. Importantly, sensitization is known not to be observed in the days immediately following exposure to intense psychostimulant-exposure regimens but rather to manifest at later time points weeks or months later. Thus, escalation of drug intake during intense drug exposure or in the days immediately following this exposure may be due to factors other than sensitization such as the incremental recruitment of opponent processes or tolerance to the psychostimulant's aversive or suppressive effects. On the other hand, enhanced responding long after drug exposure likely reflects the expression of sensitization of the drug's incentive effects. In this case, sensitization could exert its impact on behavior during self-administration testing in individuals previously exposed to the drug, as well as long after exposure to the drug in these sessions.

These findings indicate that different adaptations can show different temporal profiles (Figure 5) and, as such, can potentially influence responding differently at different times following drug exposure. Although not all cases

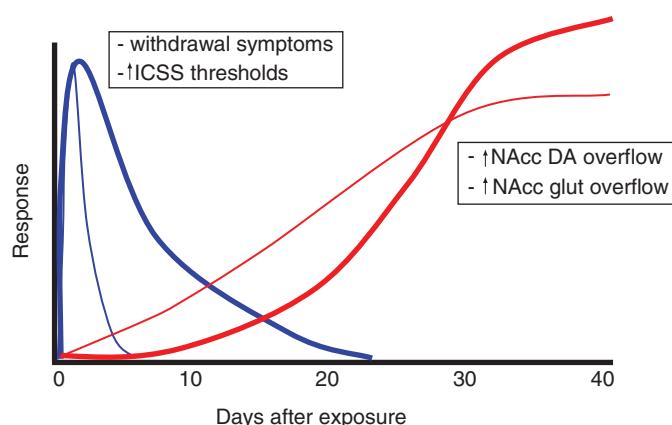

Figure 5 Different adaptations observed following drug exposure show different temporal profiles. Shown in this illustration are the duration and manifestation times of adaptations known to result from drug exposure. Withdrawal symptoms and blunting of reward – associated with increases in intracranial self-stimulation thresholds – appear soon after discontinuing drug exposure, while sensitization of NAcc DA and glutamate overflow, associated with enhancement of the appetitive properties of drugs, appears later. Increasing the intensity of the drug-exposure regimen prolongs the duration of the former and may delay the expression of the latter (thicker lines).

have been evaluated, findings reported to date suggest that the intensity of the drug exposure regimen can influence the duration and time of appearance of the adaptations observed, with more intense exposure regimens leading to longer-lasting manifestations of withdrawal symptoms and delayed (and perhaps longer-lasting) expression of sensitized responses. It remains unclear whether these corresponding shifts in the temporal manifestation of these effects following increasingly intense drug exposure reflect parallel but unrelated neuroadaptations or the competing influence of some effects over others.

Drug Withdrawal – Motivational View

G F Koob, The Scripps Research Institute, La Jolla, CA, USA

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Allostasis – Stability of physiological systems through change in set points.

Binge/intoxication stage – Stage of the addiction cycle characterized by active drug taking, often to excess.

Compulsivity – Elements of behavior that result in perseveration in responding in the face of adverse consequences or perseveration in the face of incorrect responses in choice situations.

Corticotropin-releasing factor – Neuropeptide that mediates hormonal, sympathetic, and behavioral responses to stressors.

Dependence – The manifestation of withdrawal symptoms.

Extended amygdala – Basal forebrain macrostructure comprising the bed nucleus of the stria terminalis, the central medial amygdala, and a transition zone in the posterior part of the medial nucleus accumbens (i.e., posterior shell).

Impulsivity – A predisposition toward rapid, unplanned responses to internal and external stimuli without regard for the negative consequences of these responses to oneself.

Motivational symptoms of withdrawal – Symptoms of withdrawal associated with negative emotional states.

Negative emotional state – Unpleasant state associated with dysphoria, irritability, pain, and decreased reward processing.

Opponent process – Theoretical construct in which the initial hedonic response to a stimulus is followed by the opposite hedonic response. The opposite hedonic response is slower in onset and slower to resolve than the initial hedonic response.

Preoccupation/anticipation stage – Stage of the addiction cycle that follows the withdrawal/negative affect stage and precedes the binge/intoxication stage and is characterized by preoccupation with obtaining the drug (craving).

Protracted abstinence – Persistence of motivational symptoms of withdrawal during the period after acute withdrawal from chronic drug use.

Somatic symptoms of withdrawal – Physical/body symptoms associated with drug withdrawal.

Withdrawal – Abstinence or removal from chronic drug use, usually characterized by signs and symptoms opposite to the acute effects of the drug.

Withdrawal/negative affect stage – Stage of the addiction cycle after cessation of drug use characterized by motivational signs of withdrawal.

Stages of the Addiction Cycle

Conceptual Framework: Motivational View of Addiction

Drug addiction is a chronically relapsing disorder characterized by (1) compulsion to seek and take the drug, (2) loss of control in limiting intake, and (3) emergence of a negative emotional state (e.g., dysphoria, anxiety, and irritability) reflecting a motivational withdrawal syndrome when access to the drug is prevented (defined here as dependence with a ‘little d’). Withdrawal from drugs of abuse is one symptom of what is defined symptomatically as addiction and is historically focused on what were defined as the physical symptoms of withdrawal and reflected signs and symptoms of a physical nature usually opposite to the acute effects of the drug itself. For example, with opioids, pupillary dilation was a telltale sign of opioid withdrawal, whereas pupillary constriction was a telltale sign of opioid intoxication. Similarly for alcohol, sympathetic-like responses, such as hyperthermia, reflected withdrawal, whereas hypothermia characterized acute intoxication. However, to be discussed below, these somatic measures are basically a red herring for the more motivational measures of withdrawal from the perspective of negative reinforcement, drug-seeking, and craving associated with acute and protracted abstinence. Nevertheless, the somatic signs of withdrawal are an index of dependence with a ‘little d’ and provide a quantifiable measure by which to assess the level of dependence and to relate to more motivational measures.

Motivation is a state that can be defined as a “tendency of the whole animal to produce organized activity” (Hebb, 1972), and such motivational states are not constant but rather vary over time. Early work by Wikler stressed the role of changes in drive states associated with dependence. In dependent subjects, the positive reinforcing effects of opioids remain, but subjects who become dependent describe withdrawal changes as a hunger or primary need, and the effects of morphine on such a state as

satiation or gratification of the primary need (Wikler, 1952). The concept of motivation was linked inextricably with hedonic, affective, or emotional states in addiction in the context of temporal dynamics by Solomon's opponent process theory of motivation. Solomon and Corbit postulated that hedonic, affective, or emotional states, once initiated, are automatically modulated by the central nervous system with mechanisms that reduce the intensity of hedonic feelings, and these are manifested as withdrawal symptoms but in the emotional domain. Positive hedonic responses occur shortly after presentation of a stimulus, correlate closely with the intensity, quality, and duration of the reinforcer, and show tolerance. In contrast, negative hedonic responses appear after the positive hedonic process has terminated, are sluggish in onset, slow to build up to an asymptote, slow to decay, and get larger with repeated exposure. The thesis here is that opponent processes begin early in drug-taking, reflect changes in the brain reward and stress systems, form the negative emotional state that constitutes motivational withdrawal, and form one of the major motivations for compulsivity in drug-taking.

Thus, dependence or manifestation of a withdrawal syndrome after removal of chronic drug administration is defined in terms of motivational aspects of dependence such as emergence of a negative emotional state (e.g., dysphoria, anxiety, and irritability) when access to the drug is prevented, rather than on the physical signs of dependence. Indeed, some have argued that the development of such a negative affective state can define dependence as it relates to addiction: "The notion of dependence on a drug, object, role, activity or any other stimulus-source requires the crucial feature of negative affect experienced in its absence. The degree of dependence can be equated with the amount of this negative affect, which may range from mild discomfort to extreme distress, or it may be equated with the amount of difficulty or effort required to do without the drug, object, etc" (Russell, 1976).

Drug addiction has been conceptualized as a disorder that involves elements of both impulsivity and compulsivity, in which impulsivity can be defined behaviorally as a predisposition toward rapid, unplanned responses to internal and external stimuli without regard for the negative consequences of these responses to oneself. Compulsivity can be defined as elements of behavior that result in perseveration in responding in the face of adverse consequences or perseveration in the face of incorrect responses in choice situations. These elements are analogous to the symptoms of Substance Dependence outlined by the American Psychiatric Association: continued substance use despite knowledge of having had a persistent or recurrent physical or psychological problem and a great deal of time spent in activities necessary to obtain the substance.

From a psychiatric perspective, impulse control disorders are characterized by an increasing sense of tension or arousal before committing an impulsive act; pleasure, gratification, or relief at the time of committing the act; and regret, self-reproach, or guilt following the act. In contrast, compulsive disorders are characterized by anxiety and stress before committing a compulsive repetitive behavior and relief from the stress by performing the compulsive behavior. As an individual moves from an impulsive disorder to a compulsive disorder a shift occurs from positive reinforcement driving the motivated behavior to negative reinforcement driving the motivated behavior.

Binge, Withdrawal, Preoccupation/Anticipation

Collapsing the cycles of impulsivity and compulsivity yields a composite addiction cycle composed of three stages – preoccupation/anticipation, binge/intoxication, and withdrawal/negative affect – in which impulsivity often dominates at the early stages and compulsivity dominates at terminal stages. Negative reinforcement can be defined as the process by which removal of an aversive stimulus (e.g., negative emotional state of drug withdrawal) increases the probability of a response (e.g., dependence-induced drug intake). These three stages are conceptualized as interacting with each other, becoming more intense, and ultimately leading to the pathological state known as addiction, but a key component of this addiction process remains what is defined here as a motivational withdrawal state. This article focuses on the role of withdrawal in addiction, with a focus on the negative emotional state comprising the motivational withdrawal state of the withdrawal/negative affect stage of the addiction cycle.

Somatic versus Motivational Withdrawal

Somatic Withdrawal Measures in Humans and Animals with Different Drugs of Abuse

Two drugs, opioids and alcohol, provide the most dramatic examples of the somatic signs of withdrawal and have served as models for measures of withdrawal *per se*. These somatic signs are called "somatic" because they are expressed as responses of the body (e.g., gasps and writhes) and are both centrally and peripherally mediated. For opioids, somatic withdrawal signs in humans are dramatic, dose- and duration-of-abstinence-dependent, and include a number of overt measurable signs such as yawning, lacrimation, rhinorrhea, perspiration, gooseflesh, tremor, dilated pupils, anorexia, nausea, emesis, diarrhea, weight loss, and elevations in temperature and blood pressure (Table 1). In animals (rodents), opioid withdrawal signs are well characterized when precipitated by administration of a competitive opioid antagonist such as naloxone. A weighted scale was

Table 1 Human symptoms of physical/somatic withdrawal

<i>Drug</i>	<i>Withdrawal signs</i>	
<i>Opiates</i>	Craving Anxiety Yawning Perspiration Runny nose Lacrimation Mydriasis Gooseflesh Piloerection Tremors Muscle twitches Hot/cold flashes Aching bones/muscles Anorexia Insomnia	Increased blood pressure Increased temperature Increases respiration Increased pulse Restlessness Nausea Febrile facies Vomiting Diarrhea Weight loss Spontaneous ejaculation/orgasm Hemoconcentration leucocytosis Eosinopenia Increased blood sugar
<i>Alcohol</i>	Anorexia Insomnia Tremors Mild disorientation Convulsions	Increased blood pressure Increased temperature Increased heart rate Delirium tremens
<i>Nicotine</i>	Restlessness Insomnia	Hunger Weight gain
<i>Marijuana</i>	Decreased appetite Weight loss Sleep difficulties Strange dreams	Stomach ache Chills Shakiness Sweating

developed and widely adopted that included both graded signs of weight loss, diarrhea, escape attempts, wet dog shakes, abdominal constrictions, facial fasciculations/teeth chattering, salivation, ptosis, abnormal posture, penile

grooming/erection/ejaculation, and irritability (**Table 2**). When the somatic signs of withdrawal from opioids are directly compared with more motivational measures, the motivational measures are more sensitive

Table 2 Rodent symptoms of physical/somatic withdrawal

<i>Drug</i>	<i>Withdrawal signs</i>	
<i>Opiates</i>	Weight loss Increased escape attempts Abdominal constrictions Wet dog shakes Diarrhea Facial fasciculations Teeth chattering	Swallowing movements Profuse salivation Chromodacryorrhea Ptosis Abnormal posture Erection/ejaculation Irritability
<i>Alcohol</i>	Irritability Hyperresponsiveness Abnormal motor responses	Anxiety-like behavior Decreased reward sensitivity Seizures
<i>Nicotine</i>	Teeth chattering Chews Gasps Writhes Ptosis	Shakes Tremors Yawning Dyspnea Seminal ejaculation
<i>Marijuana</i>	Wet dog shakes Facial rubbing Ataxia Hunched posture Tremor	Ptosis Piloerection Locomotor depression Mastication

and show more efficacy in defining the withdrawal state. Spontaneous withdrawal shows many of the same signs, but they are significantly less intense.

For alcohol, the somatic signs of withdrawal in humans are equally dramatic but also life threatening and are characterized by tremor, increases in heart rate, increases in blood pressure, increases in body temperature, anorexia, and convulsions. In its severest form, alcohol withdrawal can result in pronounced hyperthermia that can evolve into delirium tremens, a state of marked sympathetic hyperactivity, hyperthermia (which can be fatal), and hallucinations (**Table 1**). In animals (rodents), alcohol withdrawal signs are characterized by hyperactivity, tail tremors, tail stiffness, head tremors, general tremors, ventromedio distal flexion, wet shakes, teeth chattering, akinesia, spastic rigidity, and induced and spontaneous convulsions (**Table 2**). With alcohol, the withdrawal is only spontaneous because no known competitive antagonist can precipitate withdrawal. Similar to opioids, withdrawal from alcohol is dose- and duration-of-abstinence-dependent, with peak withdrawal occurring between 10 to 16 h post-alcohol administration, with high-dose blood alcohol levels at the time of withdrawal (300–400 mg dl⁻¹).

For nicotine, a nicotine abstinence syndrome in humans after chronic nicotine exposure has been characterized and has both somatic and affective components. Acute nicotine withdrawal is characterized by somatic symptoms, such as bradycardia, gastrointestinal discomfort, and increased appetite leading to weight gain, as well as motivational symptoms including depressed mood, dysphoria, irritability, anxiety, frustration, increased reactivity to environmental stimuli, and difficulty concentrating.

In rats, a somatic syndrome associated with nicotine withdrawal also has been characterized (see **Table 2**). The somatic signs of nicotine withdrawal resemble those seen in opiate withdrawal, including the symptoms of abdominal constrictions, facial fasciculation, and ptosis. These somatic signs are called somatic because they are expressed as responses of the body (e.g., gasps and writhes) and are both centrally and peripherally mediated. The nicotine withdrawal syndrome has been observed after spontaneous nicotine withdrawal, as well as withdrawal precipitated by nicotinic acetylcholine receptor antagonists.

For marijuana, cannabis withdrawal in humans was not included in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, but an accumulation of data from both inpatient and outpatient studies has led to a proposal for criteria for cannabis withdrawal in humans (see **Table 1**). The most common symptoms associated with cannabis withdrawal are decreased appetite/weight loss, irritability, nervousness, anxiety, anger, aggression, restlessness, and sleep disturbances. Onset of withdrawal

typically occurs between days 1 and 3. Peak effects are experienced between days 2 and 6, and most symptoms last 4 and 14 days. The long onset of cannabis withdrawal appears to be directly related to the long half-life and slow decline of blood levels of Δ^9 -tetrahydrocannabinol (THC).

Some clinicians have argued for the existence of a protracted abstinence state of cannabis withdrawal that can be quite prolonged and may last up to 15–18 months. Mild flu-like symptoms may occur a week or more later, and other subjective effects of protracted abstinence include cognitive deficits and sleep disturbances.

Cannabis withdrawal syndromes have been described in both rats and mice that involve precipitation of withdrawal with a cannabinoid-1 receptor antagonist. Spontaneous somatic withdrawal from THC has not been observed, but a mild somatic withdrawal syndrome has been observed during abstinence from a synthetic cannabinoid. Rats show a variety of somatic withdrawal signs, including wet dog shakes, scratching, facial rubbing, ptosis, mastication, hunched posture, and ataxia (**Table 2**). In mice exposed to chronic administration of THC, administration of the cannabinoid-1 receptor antagonist SR14716A produced a robust withdrawal syndrome. Signs, in order of prevalence, included wet dog shakes, facial rubbing, ptosis, hunched posture, frontpaw tremor, piloerection, and ataxia. The signs of wet dog shakes, ptosis, and hunched posture are similar to the signs observed in rats. These signs are also common with opioid withdrawal.

No generally established spontaneous or precipitated somatic withdrawal signs have been observed for psycho-stimulant drugs. In humans, some have argued that increased appetite, hypersomnia, and fatigue constitute somatic signs, but for the conceptual framework of this article, these symptoms still fall into the motivational withdrawal category.

Motivational Withdrawal Measures in Humans and Animals: Anxiety-Like Symptoms, Aversive-Like Symptoms, Elevations in Reward Thresholds

A common response to acute withdrawal and protracted abstinence from all major drugs of abuse is the manifestation of anxiety-like responses. Animal models of the withdrawal/negative affect stage include measures of anxiety-like responses, measures of conditioned place aversion (rather than preference), and measures of increases in reward thresholds using brain stimulation reward to precipitated withdrawal or spontaneous withdrawal from chronic administration of a drug (**Table 3**).

Animal models have revealed anxiety-like responses to all major drugs of abuse during acute withdrawal, with the dependent variable often a passive response to a novel

Table 3 Symptoms of motivational withdrawal

↑ Anxiety-like behavior
↑ Conditioned place aversions
↑ Drug-induced elevations in reward thresholds

and/or aversive stimulus, such as the open field or elevated plus maze, or an active response to an aversive stimulus, such as defensive burying of an electrified metal probe. Withdrawal from repeated administration of cocaine produces an anxiogenic-like response in the elevated plus maze and defensive burying test. Precipitated withdrawal in opioid dependence and nicotine dependence also produces anxiety-like effects. Spontaneous ethanol withdrawal produces anxiety-like behavior.

Place aversion has been used to measure the aversive stimulus effects of withdrawal, mostly in the context of opioids. In contrast to conditioned place preference, rats exposed to a particular environment while undergoing precipitated withdrawal from opioids spend less time in the withdrawal-paired environment when subsequently presented with a choice between that environment and an unpaired environment. Such an association continues to be manifested weeks after animals are detoxified (e.g., after the morphine pellets are removed) and can be measured from 24 h to 16 weeks later. Additionally, a place aversion in opioid-dependent rats can be observed with doses of naloxone below which somatic signs of withdrawal are observed and following a single injection of morphine. Similar acute withdrawal-like effects have been observed using anxiety-like responses following bolus injections of ethanol.

Electrical brain stimulation reward or intracranial self-stimulation has a long history as a measure of activity of the brain reward system and of the acute reinforcing effects of drugs of abuse. All drugs of abuse, when administered acutely, decrease brain reward thresholds. Brain stimulation reward involves widespread neurocircuitry in the brain, but the most sensitive sites defined by the lowest thresholds involve the trajectory of the medial forebrain bundle that connects the ventral tegmental area with the basal forebrain. Although much emphasis was focused initially on the role of the ascending monoamine systems in the medial forebrain bundle, other nondopaminergic, descending systems in the medial forebrain bundle clearly have a key role.

Acute intravenous cocaine self-administration in animals reduces reward thresholds, consistent with the well-documented effects of drugs of abuse in lowering brain reward thresholds. However, with more prolonged access to the drug, the decreases in reward thresholds (i.e., rewarding effects) are replaced with elevations in reward thresholds (i.e., antirewarding effects) after the initial decrease in reward thresholds, presumably reflecting an

acute withdrawal or opponent process-like effect. Such elevations in reward thresholds begin rapidly, can be observed within a single session of self-administration, and are greater with greater exposure to cocaine, bearing a striking resemblance to human subjective reports. Chronic administration or self-administration of all drugs of abuse produces elevations in reward thresholds during spontaneous or precipitated acute withdrawal (**Table 3**). These elevations in threshold can be short (minutes to hours) or can last for days, depending on dose, drug, time of exposure, and precipitant.

Neurobiological Bases of Withdrawal

Neurobiological Mechanisms of Somatic Signs of Withdrawal

No single structure appears responsible for expression of the somatic opioid withdrawal syndrome, suggesting a widespread distribution of the neuroanatomical substrate for the somatic signs of withdrawal. Key areas hypothesized to be involved in the somatic signs of opioid withdrawal include the locus coeruleus, amygdala, medial thalamus, globus pallidum, periaqueductal gray, locus coeruleus, nucleus paragigantocellularis, nucleus raphe magnus, and spinal cord. Numerous neurochemical systems have been implicated in the somatic signs of opioid withdrawal, and include α_1 noradrenergic antagonists, β noradrenergic antagonists, α_2 noradrenergic agonists, glutamatergic antagonists, γ -aminobutyric acid (GABA) agonists, nociceptin agonists, neuropeptide Y, cholecystokinin agonists, neurokinin-1 antagonists, neuropeptide FF antagonists, and nitric oxide synthase inhibitors. The somatic signs of withdrawal from other drugs of abuse have been less extensively studied but presumably involve similar structures and similar neurochemical systems for similar signs. For example, α_2 adrenergic agonists, GABA agonists, nitric oxide synthase inhibitors, neuropeptide Y, and serotonin reuptake blockers block the irritability, tremor, and rigidity signs of ethanol withdrawal.

Motivational Withdrawal: Decreased Reward Neurotransmission

The acute reinforcing effects of drugs of abuse are mediated by the activation of dopamine, serotonin, opioid peptides, and GABA systems either by direct actions in the basal forebrain (notably the nucleus accumbens and central nucleus of the amygdala) or by indirect actions in the ventral tegmental area. Thus, a logical explanation for motivational withdrawal would be compromised reward system neurotransmission. Within-system neuroadaptations to chronic drug exposure include decreases in function of the same neurotransmitter systems in the

same neurocircuits implicated in the acute reinforcing effects of drugs of abuse. Decreases in activity of the mesolimbic dopamine system and decreases in serotonergic neurotransmission in the nucleus accumbens occur during drug withdrawal in animal studies. Imaging studies in drug-addicted humans have consistently shown long-lasting decreases in the numbers of dopamine D₂ receptors in drug abusers compared with controls. Additionally, cocaine abusers have reduced dopamine release in response to a pharmacological challenge with a stimulant drug. Decreases in the number of dopamine D₂ receptors, coupled with the decrease in dopaminergic activity, in cocaine, nicotine, and alcohol abusers have been hypothesized to result in decreased sensitivity of reward circuits to stimulation by natural reinforcers. Support for such a hypothesis in animal studies are data showing increased sensitivity to dopamine receptor antagonists in decreasing drug self-administration in dependent animals (i.e., dependence defined as signs of withdrawal following withdrawal from extended access). These findings suggest an overall reduction in the sensitivity of the dopamine component of reward circuitry that may at least partially explain the dysphoria associated with motivational withdrawal.

Alcohol dependence has long been associated with decreased GABAergic neurotransmission during alcohol withdrawal. Chronic ethanol decreases GABA_A receptor function, and chronic ethanol decreases GABA release in interneurons in the central nucleus of the amygdala. The observation that very low doses of the GABA_A agonist muscimol, when injected into the central nucleus of the amygdala, blocks the increased ethanol intake associated with acute withdrawal suggests that the changes in GABAergic function in the central nucleus of the amygdala may have some motivational significance in ethanol dependence.

Decreases in reward neurotransmission have been hypothesized to reflect a within-system neuroadaptation and contribute significantly to the negative motivational state associated with acute drug abstinence. Decreased reward system function may also persist in the form of long-term biochemical changes that contribute to the clinical syndrome of protracted abstinence and vulnerability to relapse. For example, although the activation of cyclic adenosine monophosphate response-element binding protein and c-fos triggered by activation of dopamine systems is relatively short-lived, more long-term changes in other transcription factors such as ΔFosB may persist for weeks.

Brain neurochemical systems involved in arousal-stress modulation may also be engaged within the neurocircuitry of the brain stress systems in an attempt to overcome the chronic presence of the perturbing drug and to restore normal function despite the presence of drug. Both the hypothalamic–pituitary–adrenal axis and

the brain stress system mediated by corticotropin-releasing factor (CRF) are dysregulated by chronic administration of all major drugs with dependence or abuse potential, with a common response of elevated adrenocorticotropic hormone, corticosterone, and amygdala CRF during acute withdrawal. Acute withdrawal from all drugs of abuse produces an anxiety-like state that can be reversed by CRF antagonists, and CRF antagonists also block the increased drug intake associated with dependence (Table 4).

A particularly dramatic example of the motivational effects of CRF in dependence can be observed in animal models of ethanol self-administration in dependent animals. During ethanol withdrawal, extrahypothalamic CRF systems become hyperactive, with an increase in extracellular CRF within the central nucleus of the amygdala and bed nucleus of the stria terminalis of dependent rats (Table 4). The dysregulation of brain CRF systems is hypothesized to underlie both the enhanced anxiety-like behaviors and enhanced ethanol self-administration associated with ethanol withdrawal. Supporting this hypothesis, the subtype nonselective CRF receptor antagonists α-helical CRF_{9–41} and D-Phe CRF_{12–41} (intracerebroventricular administration) reduce both ethanol withdrawal-induced anxiety-like behavior and ethanol self-administration in dependent animals. Exposure to repeated cycles of chronic ethanol vapor produces substantial increases in ethanol intake in rats both during acute withdrawal and during protracted abstinence (2 weeks post-acute withdrawal). Intracerebroventricular administration of a CRF₁/CRF₂ antagonist blocks the dependence-induced increase in ethanol self-administration during both acute withdrawal and protracted abstinence. When administered directly into the central nucleus of the amygdala, CRF antagonists also attenuate anxiety-like behavior and ethanol self-administration in ethanol-dependent rats. These data suggest an important role for CRF, primarily within the central nucleus of the amygdala, in mediating the increased self-administration associated with dependence.

Systemic injections of small-molecule CRF₁ antagonists also block both anxiety-like responses and the increased ethanol intake associated with acute withdrawal. CRF antagonists injected intracerebroventricularly or systemically also block the potentiated anxiety-like responses to stressors observed during protracted abstinence and the increased ethanol self-administration associated with protracted abstinence. Similar interactions with CRF have been observed with the dependence associated with extended access to intravenous self-administration of cocaine, nicotine, and heroin (see Table 4).

Functional norepinephrine antagonists block the anxiogenic-like and aversive effects of opiate withdrawal and block excessive drug intake associated with dependence on ethanol, cocaine, and opioids (see Table 4). A

Table 4 CRF, κ -opioid, and norepinephrine antagonists vs. motivational withdrawal

focal point for many of these effects is the extended amygdala but at the level of the bed nucleus of the stria terminalis. The dynamic nature of the brain stress system response to challenge is illustrated by the pronounced interaction of central nervous system CRF systems and central nervous system norepinephrine systems.

Conceptualized as a feed-forward system at multiple levels (e.g., in the pons and basal forebrain), CRF activates norepinephrine, and norepinephrine in turn activates CRF. Norepinephrine stimulates CRF release in the paraventricular nucleus of the hypothalamus, the bed nucleus of the stria terminalis, and the central nucleus of the amygdala. Such feed-forward systems were further hypothesized to have powerful functional significance for mobilizing an organism's response to environmental challenge, but such a mechanism may be particularly vulnerable to pathology.

Much evidence shows that dynorphin is increased in the nucleus accumbens in response to dopaminergic activation and, in turn, that overactivity of the dynorphin systems can decrease dopaminergic function. κ Opioid agonists are aversive, and withdrawal from cocaine, opioids, and ethanol is associated with increased dynorphin in the nucleus accumbens and/or amygdala. Evidence demonstrates that CRF-induced place aversions are blocked by κ antagonists (see **Table 4**).

Implications for Addiction

Motivational Properties of Acute Withdrawal

The development of the aversive emotional state that drives the negative reinforcement of addiction has been defined as the dark side of addiction and is hypothesized to be the motivational withdrawal component of the hedonic dynamic known as opponent process when the initial drug effect is euphoria. The negative emotional state that comprises the withdrawal/negative affect stage defined above consists of key motivational elements, such as chronic irritability, emotional pain, malaise, dysphoria, alexithymia, and loss of motivation for natural rewards, and is characterized in animals by increases in anxiety-like behavior, dysphoric-like responses, and reward thresholds during withdrawal from all major drugs of abuse. Two processes are hypothesized to form the neurobiological basis for motivational withdrawal: loss of function in the reward systems (within-system neuroadaptation) and recruitment of the brain stress or anti-reward systems (between-system neuroadaptation). Antireward is a construct based on the hypothesis that brain systems are in place to limit reward. As dependence and withdrawal develop, brain stress systems such as CRF, norepinephrine, and dynorphin are recruited, producing aversive or stress-like states. Concurrently, within

the motivational circuits of the ventral striatum-extended amygdala, reward function decreases. The combination of decreases in reward neurotransmitter function and recruitment of antireward systems provides a powerful source of negative reinforcement that contributes to compulsive drug-seeking behavior and addiction.

Motivational Properties of Protracted Abstinence

The overall conceptual theme argued here is that drug addiction represents a break with homeostatic brain regulatory mechanisms that regulate the emotional state of the animal. However, the view that drug addiction represents a simple break with homeostasis is not sufficient to explain a number of key elements of addiction. Drug addiction, similar to other chronic physiological disorders such as high blood pressure, worsens over time, is subject to significant environmental influences, and leaves a residual neuroadaptive trace that allows rapid re-addiction even months and years after detoxification and abstinence. Relapse, or the return to drug abuse following periods of abstinence, is one of the principal characteristics of substance dependence. The development of dependence has been suggested to play an important role in the maintenance of compulsive use and relapse following periods of abstinence.

In human alcoholics, numerous symptoms that can be characterized by negative emotional states persist long after acute physical withdrawal from ethanol. Fatigue and tension have been reported to persist up to weeks post-withdrawal. Anxiety has been shown to persist up to months, and anxiety and depression have been shown to persist in up to 20–25% of alcoholics for up to 2 years post-withdrawal. These symptoms, post-acute withdrawal, tend to be affective in nature and subacute and often precede relapse. Negative emotion, including elements of anger, frustration, sadness, anxiety, and guilt, is a key factor in relapse, and the leading precipitant of relapse is negative affect. This state has been termed protracted abstinence and has been defined in humans with a Hamilton Depression rating ≥ 8 , with the following three items consistently reported by subjects: depressed mood, anxiety, and guilt.

Animal work has shown that prior dependence lowers the dependence threshold, such that previously dependent animals made dependent again display more severe physical withdrawal symptoms than groups receiving alcohol for the first time. This supports the hypothesis that alcohol experience and the development of dependence in particular can lead to relatively permanent alterations in responsiveness to alcohol. However, relapse often occurs even after physical withdrawal signs have ceased, suggesting that the neuropharmacological changes

that occur during the development of dependence can persist beyond the final overt signs of withdrawal (“protracted motivational withdrawal syndrome”). Such protracted withdrawal has motivational significance. A history of dependence in rats and mice can produce a prolonged elevation in ethanol self-administration in daily 30 min sessions long after acute withdrawal and detoxification. The increase in self-administration is also accompanied by increased behavioral responsiveness to stressors and increased responsiveness to antagonists of the brain CRF systems. These persistent alterations in ethanol self-administration and residual sensitivity to stressors can be arbitrarily defined as a state of protracted abstinence. Protracted abstinence defined as such in the rat spans a period after acute physical withdrawal has disappeared when elevations in ethanol intake over baseline and increased behavioral responsiveness to stress persist (2–8 weeks post-withdrawal from chronic ethanol). The persistent increase in drug self-administration during protracted abstinence has been hypothesized to involve an allostatic-like adjustment such that the set point for drug reward is elevated (hedonic tolerance). These characteristics of drug addiction imply more than simply a homeostatic dysregulation of hedonic function and executive function, but rather a dynamic break with homeostasis of these systems that has been termed allostasis.

Allostatic View of Addiction

Allostasis, originally conceptualized to explain persistent morbidity of arousal and autonomic function, is defined as stability through change. Allostasis involves a feed-forward mechanism rather than the negative feedback mechanisms of homeostasis, with continuous re-evaluation of need and continuous readjustment of all parameters toward new set points. Thus, the very physiological mechanism that allows rapid responses to environmental challenge becomes the driving force of pathology if adequate time or resources are not available to shut off the response (e.g., the interaction between CRF, norepinephrine, and dynorphin in the basal forebrain that could lead to pathological anxiety and dysphoria). Allostatic mechanisms have also been hypothesized to be involved in maintaining a functioning brain emotional system that has relevance for the pathology of addiction. The plasticity is hypothesized to account for the negative emotional state associated with addiction and involves decreased function of brain reward transmitters and circuits and recruitment of the brain antireward or brain stress systems (**Figure 1**). Repeated challenges, such as the case with drugs of abuse, lead to attempts of the brain via molecular, cellular, and neurocircuitry changes to maintain stability but at a cost, which

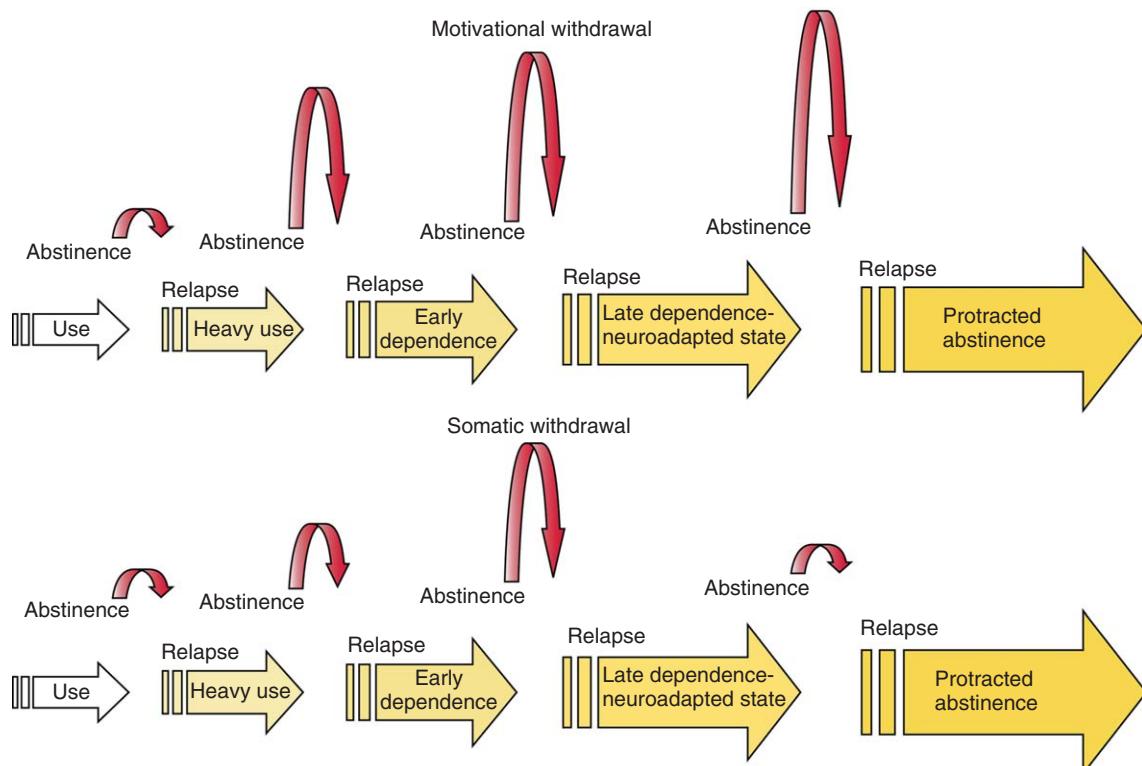

Figure 1 The hypothetical intensity of somatic and motivational withdrawal over the time-course of the development of addiction. Notice that motivational withdrawal is hypothesized to develop earlier, reach a higher intensity, and continue to sensitize with continued movement through the addiction trajectory. Reproduced with permission from Heilig M and Koob GF (2007) A key role for corticotropin-releasing factor in alcohol dependence. *Trends in Neurosciences* 30: 399–406.

includes a worsening of the negative emotional state during acute and protracted withdrawal. Such a cost fits the definition of allostatic load. For the drug addiction framework elaborated here, the residual negative emotional state is considered an allostatic state. How other known brain neurochemical systems hypothesized to be involved in emotional homeostasis and localized to the extended amygdala (e.g., vasopressin, orexin, and nociceptin) participate, where the extended amygdala projects to convey the emotional valence, and how individuals differ at the molecular-genetic levels of analysis to convey loading on these circuits remain challenges for future research.

Implications for Diagnosis of Addiction

The models of dependence with a ‘little d’ and other symptoms associated with Dependence with a ‘big D’ outlined above have both face and construct validity. Face validity is validation of the model by the similarity of the response (i.e., tremor responses in humans and in animals during the peak of alcohol withdrawal). Construct validity is validation in which the model has explanatory power for the human condition or functional equivalence for the human condition. For example, ample evidence indicates impaired reward function in animals showing escalation in drug intake with extended access to intravenous drugs of abuse and in animals with withdrawal-induced excessive drinking. Similarly, evidence exists of impaired stress responsivity during drug withdrawal that is paralleled in the human condition. The robust decrease in dopaminergic function in the mesolimbic dopamine system in rats during acute withdrawal suggests that a similar effect occurs in humans.

Such construct validity provides a powerful argument that a negative emotional state produced by excessive use of drugs is a key diagnostic for the syndrome of addiction. As such, two important issues are manifest. First, such a negative emotional state may not be as severe as those associated with anxiety disorders or depressive disorders, but clearly they may overlap in symptomatology. Second, the physical (somatic) signs of withdrawal are not the key elements of withdrawal that should be measured. Thus, a compelling argument can be made that the diagnostic criteria for addiction should indeed include an additional withdrawal measure, one for motivational withdrawal in addition to classic physical withdrawal. Defining the actual symptoms of such motivational withdrawal may ultimately require some biological measures in the domains of imaging, response to a drug challenge, or genetic markers.

Glossary

Agonist – A substance that binds to and activates a receptor protein.

Antagonist – A substance that binds to a receptor protein without activating it but when bound to the receptor prevents an agonist from activating it.

Behavioral disinhibition – Alleviation of a constrained behavior.

Behavioral sensitization – Enhancement of the locomotor-activating effect of a drug upon repeated exposure (the opposite to tolerance development).

Conditioning – A neutral cue repeatedly presented together with a stimulus acquires the ability to elicit the reaction produced by the stimulus itself.

Drug discrimination – The ability to detect the presence of a substance producing an internal state similar to that produced by a well-experienced drug.

Mesolimbic dopamine system – A group of dopamine-carrying neurons originating in the ventral tegmental area in the midbrain and projecting to the nucleus accumbens in the ventral striatum.

Smoking and drinking often occur together and the use of either substance can trigger the use of the other in drug-experienced individuals. These associations have been established in epidemiological and experimental studies. Thus, 70–90% of alcoholics smoke, as compared to 20–30% in nonalcoholic comparable populations. Smokers also consume twice as much alcohol as do nonsmokers, and the risk for being a heavy smoker increases with the number of DSM-IV criteria fulfilled for alcoholism. Alcoholism is 10–14 times more common among smokers than nonsmokers, and collecting information about smoking habits has been advanced as a possible screening tool for heavy alcohol consumption. Smoking cessation is more difficult to attain in former or current alcohol problematics and successful smoking or alcohol cessation may improve the likelihood of alcohol reduction or smoking cessation, respectively, although evidence to the contrary is also available. Interestingly, there is a correlation between onset of tobacco addiction at early age and addiction to alcohol or other drug abuse later in life.

The reasons for the extensive co-abuse of nicotine and ethanol are multifactorial, including cultural, psychosocial, psychiatric, genetic, and pharmacologic/toxicologic factors. Here psychiatric, genetic, and pharmacologic/toxicologic factors will be considered.

Ethanol Nicotine and Society

Alcohol and nicotine are the two drugs of abuse that produce the most severe health problems and the highest costs to society. In the United States, in 1998, the total costs of alcohol abuse and dependence was estimated to be 184 636 million dollars. In Sweden (9 million inhabitants and the home country of the author), the number of annual deaths related to excessive alcohol intake is approximately 5000 and that to smoking (nicotine) approximately 8000. The co-abuse of these drugs may potentiate each other's detrimental effects and more alcoholics die from smoking-related diseases than from alcohol-related ones, reflecting the fact that a large proportion of alcoholics are smokers. The main reasons for the individual and society having difficulties in reducing the use of ethanol and nicotine are the well-established addictive properties of both drugs, and that both drugs are legal and are culturally accepted.

Psychiatric Disorders and Abuse of Ethanol and/or Nicotine

Several psychiatric disorders are associated with enhanced rates both of nicotine and ethanol dependence, and it is possible that the genetic and neurochemical underpinnings of such disorders at least partly underlie the extensive abuse of nicotine and/or ethanol that is observed. Of special interest in this respect are schizophrenia, bipolar disorder, and attention-deficit hyperactivity disorder (ADHD) in which the rates of nicotine and ethanol dependence are especially high and which all have been connected to dysregulations of brain dopamine function. Dopamine systems have been heavily implicated also in ethanol and nicotine dependence, as well as in other substance dependencies. There are also associations with underlying personality traits, which to a large extent are genetically determined. Heightened impulsivity, novelty seeking, reward dependence, and so

on are traits associated particularly with Cloninger's type II alcoholism and neuroticism with type I. Some of these personality traits are also seen in connection with ADHD, especially when presented in combination with conduct disorder (CD), which indicate that they may be manifestations of neurochemical alterations associated with these neuropsychiatric conditions and their genetic background. That this may be the case is suggested by the fact that many of these personality traits are abolished upon pharmacological treatment of ADHD. Individuals with ADHD-CD generally debut very early with cigarette smoking and alcohol use and often display a rapid foray into the antisocial type of alcoholism (type II).

The neurochemistries underlying ADHD, schizophrenia, and bipolar disorder thus may be directly involved in mediating the increased risk for both ethanol and nicotine abuse. However, the extensive drug use in these groups of patients could also represent self-medication. The cognitive enhancing effects of nicotine have been suggested to explain the extensive smoking in schizophrenia and could be related to nicotine's stimulatory effect on cholinergic and mesocortical dopamine systems. The same mechanisms could underlie extensive nicotine use in ADHD. Indeed, cognitive symptoms observed in schizophrenia and in ADHD, for example, attention and working memory deficits and disturbed executive function, are overlapping and, in both conditions, reduced catecholamine transmission in the frontal cortex may be involved. When interpreted in terms of self-medication, the use of alcohol is probably best explained by the drug's anxiolytic and calming effects. Anxiety and restlessness are prominent features of schizophrenia, bipolar disorder, and ADHD.

Heredity

It has become increasingly recognized that hereditary factors influence the risk for developing drug addiction. Adoption studies and numerous twin studies performed in various populations have demonstrated that 50% of the variance with respect to alcoholism is explained by genes. The collaborative study of the genetics of alcoholism (COGA) has further underlined the importance of genes, as have a number of candidate gene studies. Further, for habitual smoking, the genetic contribution is high, as much as 60–70%, and the genetic risk for alcoholism correlates with that for habitual smoking. Whether the genetics underlying alcoholism and nicotine dependence are shared with those of other drug addictions has not been clearly established. Twin studies indicate that the debut of drug use is determined by sociocultural factors, whereas continued use and dependence is determined by genes and nonshared environmental factors.

The common genetic background to nicotinism and alcoholism could involve a number of neurotransmitter systems in the brain, since both drugs have a rich pharmacology. Systems related to the intoxicating and feel-drug effects of alcohol have been implicated, since these effects are diminished in young men with alcoholic fathers compared to young men with nonalcoholic fathers, and this low alcohol response predicts future alcohol dependence. Further, nicotine users display a decreased sensitivity to the intoxicating effect of ethanol. Animal studies provide further support for common genetic factors underlying the sensitivity to both ethanol and nicotine. One of these factors could be a polymorphism in the α_4 subunit of the nicotinic acetylcholine receptor (nAChR).

Pharmacology

Interactions with Nicotinic Acetylcholine Receptors

The nAChR is a member of the family of cysteine-loop ligand-gated ion-channels, including also GABA_A, 5-HT₃, and glycine receptors. The nAChR is composed of five subunit proteins forming a cation channel passing through the neuronal cell membrane. Acetylcholine and nicotine bind to the receptor and thereby regulate the permeability of the ion-channel, neuronal activity, and transmitter release. The different subunits ($\alpha_2-\alpha_{10}$, $\beta_2-\beta_4$) are differentially expressed in the brain. Nicotine produces its pharmacological effects via nAChRs, especially via $\alpha_4\beta_2$ and α_7 homomeric receptors (see further below), that also are the most abundant nAChRs in the brain. *In vitro* and *in vivo*, the nAChR may undergo desensitization upon agonist exposure and some of the pharmacodynamic effects of nicotine may derive from activation of nAChR and others from inactivation (desensitization). Nicotinic acetylcholine receptors are present also in the peripheral nervous system, both in ganglia and at the motor endplate.

Relevant concentrations of ethanol interact with various cysteine-loop receptors. As early as in 1967, results indicated that ethanol interacts with nAChR in the peripheral nervous system of the frog, and based on similar electrophysiological studies, it was suggested in 1980 that ethanol's interaction with nAChRs could underlie the addictive properties of the drug. A number of studies have later been performed on nAChRs from *Torpedo*, showing how ethanol affects nAChRs with respect to both activation and deactivation. Several studies have shown that ethanol directly interacts also with central nAChR *in vivo*, in neuronal cell cultures and in different cells expressing nAChRs from rat or man. Ethanol's interaction with nAChRs is determined by the type of receptor

expressed – response potentiation is observed in some subtypes (e.g., $\alpha_2\beta_4$, $\alpha_4\beta_4$, $\alpha_2\beta_2$, $\alpha_4\beta_2$ (human); $\alpha_3\beta_4,\alpha_2\beta_4$ (rat)), whereas antagonism (e.g., α_7 oligomers (human and rat) or no effect is observed in others. Ethanol is a nAChR co-agonist rather than an agonist in its own right, that is, it potentiates the effect of acetylcholine but does not activate the receptor by itself. Chronic ethanol administration influences radioligand binding of nicotine to nAChRs, but the effects vary across studies and depend on what brain region is investigated.

Interactions with the Brain Reward System

Drugs of abuse activate brain catecholamine systems and this activation is associated with locomotor stimulation. It was suggested in the late 1970s that these effects are of importance also for the rewarding properties of addictive drugs. All drugs of abuse have subsequently been demonstrated to increase dopamine release, and this effect is most pronounced in the nucleus accumbens (NAcc), a major target of the mesolimbic dopamine system and a central component of the brain reward system. The mesolimbic dopamine system has its cell-bodies in the ventral tegmental area (VTA) of the mid-brain. The function of the mesolimbic dopamine system is severely impaired upon cessation of subchronic exposure to drugs of abuse, including ethanol and nicotine.

The mechanisms underlying the mesolimbic dopamine activations have been disclosed for both nicotine and ethanol. Nicotine directly stimulates $\alpha_4\beta_2$ nAChRs probably located on the cell-bodies of mesolimbic dopamine neurons in the VTA. Thereby, the regular firing rate of the neurons is increased. Nicotine increases also burst firing of dopamine neurons and this effect is mediated via activation of α_7 nAChRs located on afferent glutamatergic neuronal terminals. Stimulation of these α_7 receptors releases glutamate that, in turn, excites the dopamine neurons into burst firing and causes pronounced dopamine release in the NAcc.

The dopamine synthesis and locomotor stimulating effects of ethanol in mice are at least partly mediated by central nAChRs. In addition, the dopamine releasing and dopamine synthesis enhancing effects of ethanol in the limbic system of the rat involve nAChRs in the mesolimbic cell-body region. Thus, ethanol-induced mesolimbic dopamine activation involves nAChRs in the VTA, and the effect appears localized to the anterior VTA. However, local perfusion of ethanol in the VTA does not increase dopamine release in the NAcc, whereas local perfusion in the NAcc does, and this effect is prevented by nAChR blockade in the anterior VTA. These results indicate that ethanol produces an effect in the NAcc that secondarily increases endogenous ACh release and nAChR activation in the anterior VTA. These *in vivo* findings contrast to results obtained *in vitro* showing that

ethanol directly stimulates neuronal activity in isolated dopamine neurons. Whether or not this latter effect involves nAChRs is not known. The idea of an indirect mechanism of action put forward above is reinforced by findings that ACh depletion prevents ethanol-induced dopamine release and that ethanol consumption enhances ACh release in the VTA, in parallel with dopamine release in the NAcc. The event produced by ethanol in the NAcc that eventually leads to nAChR activation in the VTA is an interaction with another cysteine-loop receptor – the glycine receptor. Ethanol may still interact directly with nAChRs in the VTA, provided that it is simultaneously present in the NAcc. This could be explained by the fact that ethanol is a co-agonist rather than an agonist at nAChR, and when ethanol is simultaneously applied in the NAcc, acetylcholine is released in the VTA, enabling ethanol to influence ventral tegmental nAChRs.

Contrary to the case of nicotine, $\alpha_4\beta_2$ nAChRs are not involved in ethanol's effects outlined above. Instead, $\alpha_3\beta_2$ and/or β_3 containing receptors have been implicated. As regards α_7 receptors, ethanol is an antagonist rather than agonist at these receptors. Consequently, the dopamine-related effects of ethanol are not altered by α_7 receptor blockade. Such blockade also fails to mimic the ethanol effect. In conclusion, the available evidence indicates that ethanol increases mesolimbic dopamine activity via indirect and/or direct activation of $\alpha_3\beta_2$ and/or β_3 containing nAChRs in the anterior VTA.

Co-administration of ethanol and nicotine produces complex results with respect to ethanol-induced locomotor stimulation in mice, where nicotine either potentiates or counteracts the stimulatory effect of ethanol depending on the dose of ethanol. In rats, nicotine and ethanol produce additive effects on dopamine release in NAcc, both when the drugs are administered systemically and when ethanol is given systemically and nicotine locally in the VTA.

Alcohol Consumption/Self-Administration Studies

Systemic administration of a nicotinic antagonist reduces ethanol consumption in a two-bottle choice test and both ethanol and nicotine self-administration in operant procedures. Furthermore, local nAChR antagonism in the VTA reduces lever-pressing for nicotine self-administration as well as ethanol intake and preference in the two-bottle test. Dopamine levels in the NAcc have been concomitantly measured and the results parallel the ethanol consumption findings. In analogy with the pharmacological studies, $\alpha_4\beta_2$ receptors mediate nicotine self-administration but not alcohol consumption that instead involves α_3 and α_6 containing nAChRs. The partial nAChR antagonist varenicline, an established

smoking cessation agent, also reduces ethanol consumption in rats. However, there are also studies that have failed to demonstrate an ethanol consumption-reducing effect of nAChR antagonists.

It has been proposed that nAChRs are involved not only in the pharmacological effects of ethanol but also in mediating ethanol-conditioned dopamine release. Receptor nAChR blockade, thus, may prevent dopamine-induced orientation toward the ethanol bottle. This hypothesis received support when it was shown that a stimulus previously associated with ethanol intake later by itself increased dopamine output in the NAcc, an effect prevented by nAChR blockade. Further, responding with conditioned reinforcement for alcohol-associated stimuli involves nAChRs, and α_3 and α_6 containing receptors, rather than $\alpha_4\beta_2$, may be involved also in these effects. Brain acetylcholine systems, probably via nAChR activation, have been implicated in mediating conditioning also to various other rewards.

Taken together, a certain nAChR population (containing $\alpha_3\beta_2$ and/or β_3 subunits) in the cell-body region of the mesolimbic dopamine system is involved both in ethanol-conditioned activation of the system and in the pharmacological activation produced by ethanol. This coincidence is interesting, since ethanol intake in alcoholics often triggers further ethanol consumption, even though the individual already may be heavily intoxicated. This phenomenon could be explained if ethanol pharmacologically activates the same neuronal mechanisms as those involved in conditioned initiation of ethanol consumption – establishing a *circulus viciosus*. If the same neurocircuitry mediates conditioned dopamine release to stimuli associated also with other drugs, ethanol's pharmacological activation of it could contribute to ethanol-induced relapse to other addictive drugs, as often observed among drug-dependent individuals.

In addition, in humans, nAChR blockade decreases the stimulatory and euphoric effects of ethanol. Some evidence further indicates, that ethanol consumption as such is decreased by nAChR blockade in alcohol-dependent individuals.

Drug Discrimination Studies

Generally, ethanol does not substitute for nicotine in rats trained to discriminate nicotine. This is not surprising, since ethanol produces a range of effects of which those related to activation and blockade of certain γ -aminobutyric acid (GABA) and glutamate receptors, respectively, may be the most important for producing the ethanol discriminative cue. These findings do not exclude the fact that ethanol interacts with nAChRs but indicate that this interaction does not contribute significantly to its discriminative cue in rats.

Subchronic/Chronic Interactions

According to epidemiologic studies, an early smoking debut is a risk factor for future alcohol dependence. Animal studies show that subchronic nicotine administration changes the sensitivity of the mesolimbic dopamine system not only to nicotine but also to ethanol, indicating that the increased risk for alcohol dependence among nicotine users is due to pharmacological consequences of the drug. Indeed, studies have shown that chronic nicotine administration increases ethanol consumption in rats, even though contradictory results also are available. The presence of nicotine during ethanol consumption is not required to produce the effect. Instead, nicotine appears to produce a sustained neurochemical effect that promotes ethanol intake. Further, the findings that the exposure of mice to nicotine during a limited period very early in life enhances ethanol consumption in adult life support this idea.

That the ethanol intake-promoting effect of smoking is related to nicotine rather than to other components of cigarette smoke is supported not only by animal experiments, but also by clinical studies showing that ethanol consumption is also increased in nicotine gum users and in snuffers. Ethanol consumption is most pronounced in individuals using both cigarettes and snuff, indicating dose-dependency and/or complementary mechanisms (see below).

Relation to Behavioral Disinhibition/Impulsivity

The mechanisms underlying the chronic nicotine effect is unknown but could involve an increased responsiveness of mesolimbic dopamine neurons, perhaps on the basis of a paradoxical upregulation of the number of central nAChRs in response to chronic nicotine exposure. Such upregulation has been demonstrated both in rats and in humans. A puzzling finding is that the ethanol intake enhancing effect of nicotine in rats is resistant to concomitant chronic antagonism pretreatment and that both a blood-brain barrier penetrating and a nonpenetrating nAChR antagonist increase ethanol intake by themselves after chronic pretreatment. To account for these findings, it has been proposed that the ethanol-consumption-promoting effect of nicotinic drugs is related to intermittent blockade of ganglionic nAChRs rather than to stimulation of central nAChRs. Furthermore, the effect on ethanol consumption pharmacologically and statistically correlates with alterations of nicotine-induced behavioral disinhibition rather than with sensitization to the locomotor-stimulatory effect of nicotine, as originally hypothesized. The expression of nicotine-induced behavioral disinhibition is prevented by co-treatment with serotonin-facilitating drugs. Decreased serotonin

transmission has since long been linked to impulsive features and to increased ethanol consumption.

Chronic studies show that the combined treatment with a blood–brain barrier nonpenetrating nAChR antagonist and nicotine produces the largest effects both on ethanol consumption and on nicotine-induced behavioral disinhibition. Thus, intermittent blockade of peripheral nAChRs in combination with intermittent stimulation of central receptors appears to be the most powerful treatment to promote ethanol consumption. This result may parallel the findings in human snuffers who also smoke – snuffers more or less constantly expose themselves to nicotine, which should desensitize peripheral nAChRs, resembling peripheral blockade. Recent results have shown that subchronic pretreatment with a peripheral nAChR blocker decreases GABA_A-mediated depression of dopamine release in NAcc, resulting in prolonged dopamine release after systemic as well as local ethanol administration.

In conclusion, chronic nicotine administration enhances behavioral disinhibition, reflected i.a. in increased ethanol intake, which may derive from long-term consequences of intermittent desensitization of peripheral nAChRs. Human studies parallel these findings, showing that smokers are more impulsive than nonsmokers and ex-smokers, both as estimated with personality inventories and in experimental models. These results indicate that nicotine-induced impulsivity is reversible or that those who manage to quit smoking do so because they are less impulsive. Prospective studies are needed to resolve this issue. In the context of behavioral disinhibition, it is interesting to note that nicotine exposure during the last trimester has been associated with enhanced ethanol consumption in adult life in mice and with dose-dependent risks for ADHD symptoms and for being subjected to criminal arrests or being hospitalized for substance abuse in humans.

Glossary

Delusions – A false belief based on incorrect inference about external reality that is firmly sustained despite what almost everyone else believes and despite what constitutes incontrovertible and obvious proof of evidence to the contrary.

Hallucinations – Perceptions that occur without external stimulation of the relevant sensory organ.

Hallucinosis – This poorly defined term has been applied to a variety of clinical situations, including hallucinatory syndromes without associated delusions, or hallucinations in the setting of neurological conditions or sensory impairment, usually with preserved insight.

Illusions – A misperception or a misinterpretation of a real external stimulus.

Insight – In neuropsychiatry, insight refers to people's understanding of their illness, and to understanding how the illness affects individuals' interactions with the world. Applied to hallucinations, insight refers to the awareness of the hallucinatory nature of the experience.

received various definitions (e.g., hallucinations with preserved insight or vivid internal images), none of which is universally accepted. The same holds true for the term 'hallucinosis' which has been applied to a variety of clinical situations. Both terms are confusing and unnecessary. Finally, hallucinations are also distinct from vivid mental imagery and from dreams, although, in the latter case, transitional forms exist.

Frequency

The prevalence of hallucinations in the general population is not negligible. In one prevalence study, hallucinations were occasionally present during the daytime in the quarter of a large, noninstitutionalized sample aged 15 years or over. In another study, the general incidence was 10–30 cases per 1000 persons per year, with variations related to age and gender. Although hallucinations occur in a range of organic and psychiatric conditions, and under the influence of drugs or alcohol, they also occur in normal individuals. The rest of this article focuses on hallucinations occurring in the course of neurological or sensory diseases, in psychiatric conditions, or under the influence of hallucinogenic substances.

Introduction: General Aspects

Definitions

The term hallucination in its modern sense was first introduced by Jean Etienne Esquirol in his textbook *Des maladies mentales* (1837). Hallucinations are generally defined as perceptions that occur without external stimulation of the relevant sensory organ. Hallucinations are therefore linked to a sensory modality and may be auditory, visual, somatosensory (tactile or somatic), olfactory, gustatory, or multimodal, occurring in more than one modality. Visual hallucinations may be elementary or simple (lines, dots, geometrical patterns) or complex (objects, animals, people, landscapes, etc.). Auditory hallucinations may also be simple (knocks and rings) or complex (music and voices). The person may or may not have insight into the fact he or she is having a hallucination.

Hallucinations should be distinguished from illusions, which are misperceptions or misinterpretations of a real external stimulus. The term 'pseudohallucinations' has

Evaluation

To identify and rate hallucinations, the examiner relies on the patient's and/or the caregiver's accounts. Many patients do not spontaneously report their hallucinations, so that the information has to be sought by using specific questions or scales. To identify hallucinations, single items from scales have been used, as well as self-developed questionnaires or inventories. The latter are useful to record the variety of psychotic symptoms, but they do not allow examiners to rate the symptoms. Scales for rating hallucinations and other psychotic symptoms have been developed mainly in the field of psychiatry (e.g., the Positive and Negative Syndrome Scale, the Scale for Assessment of Positive Symptoms, or the Brief Psychiatric Rating Scale) and in the field of dementia (e.g., the Neuropsychiatric Inventory).

Hallucinations Associated with Neurological or Sensory Disease

Cortical Activation as a Common End Pathway for Hallucinations

Pioneering works following World War I established that occipital stimulation generated visual hallucinations, and that hallucinations became more complex when stimulation shifted from primary visual cortex to association visual cortices. It was also shown that seizures secondary to occipital lesions were often preceded by a visual aura. The role of the cortex in generating hallucinations was confirmed by Penfield and colleagues who obtained auditory and visual hallucinations in patients undergoing surgery for epilepsy by stimulating the auditory and visual cortices. The role of specific areas of cortex has been further demonstrated by using functional imagery. Using functional magnetic resonance imaging (fMRI) in patients with Charles Bonnet syndrome (see below), it was shown that various types of visual hallucinations correlate with cerebral activity in ventral extrastriate visual cortex, that the content of the hallucinations reflects the functional specializations of the region, and that the patients who hallucinate have increased ventral extrastriate activity, which persist between hallucinations. To summarize, hallucinations in a sensory modality result from the activation of cortical areas normally associated with the processing of sensory stimuli in the same modality. Simple (elementary) hallucinations result from primary sensory cortex activation, and complex hallucinations result from the activation of association sensory areas. In the context of neurological or sensory diseases, visual hallucinations are the more prevalent type, and cortical activation underlying hallucinations may result from various mechanisms which are now reviewed.

Cortical Irritation

In this model, hallucinations result from intrinsic overactivity in the corresponding sensory cortical area. This mechanism is generally considered to occur in migraine and in epilepsy auras. In migraine, visual symptoms precede the headache in 20% of the cases. Typically, the aura is a flickering uncolored unilateral zigzag line in the center of the visual field, which progresses toward the periphery, leaving a scotoma. The phenomenon is reversible in less than 30 min. Clinical and imaging studies indirectly suggest a relationship between migraine aura and cortical spreading depression, a wave of neuronal and glial depolarization, followed by long-lasting suppression of neural activity. In partial epilepsy, hallucinations were part of the aura in 13% of the cases in one large series. They are more often simple than complex, and involve the following sensory modalities in

decreasing frequency order: visual, somato-sensory, auditory, olfactory, and gustatory. The simple hallucinations probably reflect epileptic discharges in a primary sensory cortex. However, other mechanisms have been advocated for epileptic complex hallucinations, relying on the Jacksonian concept of dissolution, or on the concept of activation of specific circuits by a focal discharge.

Deafferentation and Release Phenomena

General disinhibition theories for hallucinations were first forwarded by Jackson. In the perceptual release theory of West, hallucinations arise when the constant flow of sensory inputs is impaired, allowing the emergence of earlier perceptions or traces into consciousness. More specifically, the release or deafferentation theory has been applied to visual hallucinations associated with impairment of visual input. The core hypothesis is that stimulus-driven, bottom-up visual processing inhibits the spontaneous activity of the visual cortical areas and facilitates the release of stored images. More recent conceptualizations suggest that the lack of input leads to chronic hyperexcitability. Visual hallucinations associated with eye disease in nondemented persons have received the name of Charles Bonnet syndrome. The prevalence rate of visual hallucinations in visually impaired populations is around 10%, and their main risk factors are a lower visual acuity, a lower contrast sensitivity, and an older age. Hallucinations may be simple or, more often, complex. Insight is preserved. The neurophysiological link from deafferentation to hallucinations remains unclear. Using induced hallucinations in normal-sighted individuals, ffytche has proposed that hallucinations in eye disease result from the shift from tonic to burst firing in thalamocortical circuitry. Lesions of the retrochiasmal visual pathways, typically ischemic, are associated in up to 40% of the cases with hallucinations in the hemianopic field. Hallucinations, simple or complex, are usually transient. Hallucinations are associated with circumscribed, occipital ischemic lesions, while larger lesions, affecting the temporal–visual associative areas, preclude the development of hallucinations. This finding supports the hypothesis that hallucinations result from release from inhibitory input of visual areas bordering the damaged occipital lesion.

The concept of cortical release has been applied to hallucinations in nonvisual sensory modalities associated with the impairment of the corresponding sensory pathways. For instance, hearing loss may be associated with auditory hallucinations, typically of a musical nature. In a series of 125 elderly subjects with hearing impairment, one-third had hallucinations, mostly elementary (including tinnitus), and 5% heard voices or music. In patients with musical hallucinations and deafness, a positron emission tomography (PET) study showed that brain activity

increased as a function of the severity of the hallucination in a distributed network distinct from the primary auditory cortex, which included the posterior temporal lobes, the right basal ganglia, the cerebellum, and the inferior frontal cortices. Phantom sensations, that is, the vivid impression that an amputated limb is still present, and, in some cases, is painful, are present in almost all patients with limb amputation. In this case, the hallucinatory phenomenon seems secondary to the reorganization of the somato-sensory cortical maps following the deafferentation.

Dream Intrusions and Status Dissociatus

Relations between dreams and hallucinations have been debated for a long time. It has been postulated that hallucinations may result from a dissociation between dream and sleep mechanisms. Jean Lhermitte, in the 1920s, first suggested this dissociation could occur in patients with peduncular hallucinosis (hallucinations secondary to a lesion of the upper brainstem). Hypnagogic and hypnopompic hallucinations (perceptions that occur while going to sleep and on waking) represent transitional forms of misperceptions, between dream and hallucination. They are not considered as hallucinations proper in some classifications. Hypnagogic and hypnopompic hallucinations occur in normal persons, but they are more frequent and severe in patients with narcolepsy, a chronic sleep disorder characterized by excessive daytime sleeping and cataplexy. In this condition, hypnagogic hallucinations occur when patients fall asleep directly into rapid eye movement (REM) sleep, suggesting that the hallucinations share mechanisms with dreams. Polysomnographic studies have suggested that narcoleptic-like mechanisms could explain some hallucinations in other conditions, such as Parkinson's disease. Prolonged dream-like vivid hallucinations are also present in status dissociatus, a parasomnia due to extreme dissociation between wakefulness, REM sleep, and nonrapid eyemovement (NREM) sleep. Status dissociatus is observed in various medical diseases, such as treated narcolepsy–cataplexy, dementia, multiple system atrophy, status-post-cardiac surgery, Morvan's chorea, protracted alcohol withdrawal, fatal familial insomnia, and the Guillain–Barré syndrome.

Multifactorial Models

Hallucinations may occur in the course of neurodegenerative diseases. Their lifetime prevalence is approximately 50% in patients with Parkinson's disease, and the prevalence is even higher in patients with dementia with Lewy bodies. In most cases, hallucinations occur with a clear sensorium and a chronic course. Complex visual hallucinations are the most common type, but other sensory modalities may be involved. Hallucinatory

images are superimposed on the normal background scene, they may be relatively stereotyped in a given patient and, in most instances, the patient is an observer rather than an actor in the hallucinated scene. Insight may be preserved, fluctuating, or lost. In the two latter cases, cognitive impairment is usually present. Hallucinations often combine with other minor phenomena such as visual illusions and sense of presence, and, mostly in demented patients, with delusions. Although a number of clinical and biological risk factors have been identified, the pathophysiology of Parkinson's disease-associated psychosis remains unclear. Hallucinations could result from various and probably concomitant mechanisms, including: (1) dopaminergic overactivity and/or imbalance in monoaminergic (relatively preserved) and cholinergic (altered) neurotransmission; (2) alteration of brainstem sleep/wake and dream regulation; (3) dysfunction of the visual pathways, nonspecific (coincidental ocular disease) and/or specific, such as PD-associated retinal dysfunction and functional alterations in the ventral stream of visual cortical pathways; (4) dysfunction of top-down mechanisms of vision, such as impaired attentional focus; and finally, (5) antiparkinsonian drugs and other pharmacological agents may interfere with the preceding mechanisms at many levels. No simple model can account for the full diversity and heterogeneity of factors associated with hallucinations in PD. Diederich *et al.* forwarded an integrative model based on Hobson's work on factors regulating consciousness. This model emphasizes dysregulation of the gating and filtering of external perception and internal image production. A more general model for recurrent complex visual hallucinations occurring in the course of a variety of conditions has been proposed by Collerton *et al.*, based on cognitive models of scene perception. In this Perception and Attention Deficit model, a combination of impaired attentional binding and poor sensory activation of a correct proto-object (or template), in conjunction with a relatively intact scene representation, bias perception to allow the intrusion of a hallucinatory proto-object into a scene perception.

Hallucinations in Psychiatry

Hallucinations and Schizophrenia

Prevalence and phenomenology

Hallucinations are a core clinical feature of major psychiatric disorders. Besides disorganization and negative symptoms, hallucinations constitute a core dimension of schizophrenia with delusions (Schneider's first rank symptom), and are associated with poor social functioning. Hallucinations in schizophrenia may occur in any sensory modality, but auditory verbal hallucinations are the most common and characteristic. Voices are perceived

as distinct from the person's own thought and as coming from the extrapersonal space. The content is often pejorative or intrusive. The classical view is that schizophrenic patients lack insight into their illness and psychotic symptoms. However, poor awareness of psychotic experience seems to be a trait of the acute rather than the chronic psychopathology of schizophrenia. Lifetime prevalence rates of auditory vocal hallucinations in schizophrenia range from 50% to 70%. The phenomenology and the prevalence of hallucinations in schizophrenic patients vary according to the marital status, the educational level, and the cultural background, suggesting that environmental factors influence the expression of the hallucinations. The phenomenology may vary according to the age of onset. The French concept of 'chronic hallucinatory psychosis' refers to a chronic hallucinatory and delusional disorder affecting mainly women and that differs from paranoid schizophrenia by a late onset, the absence of formal thought disorder and intellectual impairment, a better response to treatment, and a better outcome. Accusatory or abusive auditory verbal hallucinations are more frequent in these late-onset cases. This entity is included into late-onset schizophrenia in current classifications such as the *Diagnostic and Statistical Manual of Mental Disorders* (DSM).

Brain structure and functional neuroimaging studies

Recent works using sophisticated analysis techniques such as voxel-based morphometry found that verbal hallucinations are associated with reduced gray matter volumes in the temporal lobe, more specifically in the left superior temporal gyrus, including the primary auditory gyrus, and in nonsensory regions such as the right dorsolateral frontal cortex. Studies aiming at capturing the cerebral activity associated with verbal hallucinations have shown temporal lobe activation, on the left side in most studies. This activation may include, or not, the primary auditory cortex (Heschl's gyrus). Nonsensory cortical and subcortical areas are also involved in some studies, including language production area (Brodmann's area), anterior cingulate area, and cerebellar regions, suggesting that disturbances in a distributed network may be associated with verbal hallucinations. Finally, some studies have addressed the question of cerebral asymmetry and connectivity in patients with verbal hallucinations. Evidence for altered asymmetry is inconclusive, but there is evidence, from works using diffusion tensor imaging or fMRI, for disrupted connectivity between the temporal, prefrontal, and anterior cingulate cortex.

Cognitive models

The prevailing cognitive model was proposed by Frith in the 1990s and postulates that verbal hallucinations derive from inner speech that has been misidentified as coming

outside the self, because of defective self-monitoring. In this model, frontal regions involved in verbal generation fail to modulate activation in areas involved in speech perception. This view has been later criticized or refined. Although most authors postulate an impaired processing of inner speech, the way to integrate the somewhat heterogeneous functional neuroimaging data may vary. Some models insist on the interactions between top-down and bottom-up processes. Furthermore, the role of emotion and attention is also supported by some activation studies.

Neurotransmitters

At a molecular level, studies in schizophrenic patients have reported dopaminergic abnormalities in a number of cortical and subcortical regions that have been related to positive symptoms such as hallucinations. Direct or indirect (preclinical or pharmacological) evidence suggest that schizophrenia is associated with excessive stimulation of striatal dopamine D2 receptors, which has been positively correlated with positive symptoms and more specifically hallucinations, and deficient stimulation of prefrontal dopamine D1 receptors, which could be a factor in the cognitive impairments of schizophrenia. However, other neurotransmitters, including serotonin, glutamate, γ -amino butyric acid (GABA), and acetylcholine have been implicated, either directly, or through interactions with dopaminergic systems. How multiple neurotransmitters and risk genes interact to produce the positive symptoms of schizophrenia is poorly understood.

Hallucinations and smoking

Recent research has focused on the fact that schizophrenic subjects have an auditory sensory-gating deficit which could be corrected by tobacco use. The prevalence of smoking among schizophrenic subjects is higher than in the general population. Schizophrenic smokers have higher psychotic symptoms scores (including hallucinations) than nonsmokers, and the intensity of symptoms is positively correlated to tobacco consumption. These findings suggest a form of self-medication, considering that tobacco could counteract the sensory deficit. Eighty percent of schizophrenic patients have an impaired auditory sensory transmission of repeated auditory stimuli (P50 wave inhibition deficit), which is transiently improved by nicotine. Current theories imply that the P50 wave inhibition prevents schizophrenic patients from filtering unimportant auditory stimulation, thus facilitating the emergence of auditory hallucinations and delusional interpretations.

Hallucinations and Bipolar Disorders

Few studies are devoted to hallucinations in the course of bipolar disorders. Compared with those of schizophrenia,

hallucinations in bipolar disorders are less severe, more often visual, and less often auditory. Characteristics of hallucinations seem to be similar among manic and both bipolar- and unipolar-depressed subjects. Among patients with major affective disorders, those with hallucinations are less well-educated, have higher anxiety scores, less insight into the illness, and longer hospitalizations. Recent researches have shown that childhood sexual abuse and other early traumas are associated with serious mental illness and more specifically positive symptoms, particularly hallucinations. In one study, about half of the bipolar patients had experienced hallucinations (mostly auditory followed by visual) and 16% revealed sexual abuse. These findings suggest that childhood sexual abuse could increase the vulnerability of bipolar patients to later experience auditory hallucinations.

Posttraumatic Stress Disorders and Borderline Personality Disorders

Several studies suggest that patients with posttraumatic stress disorders (PTSDs) have perceptual disturbances, and are predisposed to hallucinations and paranoia. Psychotic symptoms, especially hallucinations, are frequently experienced by survivors of early (e.g., sexual abuse) and later (e.g., exposure to military combat) trauma. The nature of delusional and hallucinatory symptoms in borderline personality disorder (known to have experienced trauma in childhood) is not well documented. Psychotic episodes are common among patients with borderline personality disorder, narrowly due to concomitant disorders. However, the nature of the relationship between trauma and hallucinations is poorly understood from a psychological perspective. As previously stated, hallucinations may result from the misattribution of mental events to an external source: this is likely to occur when experiencing mental events that are automatic and associated with low cognitive effort such as intrusive memories of trauma. The latter may be experienced as hallucinations by individuals whose source-monitoring abilities are compromised by severe mental illness. This mechanism may be reinforced during stressful periods, for instance, when an adult survivor of abuse suffers additional negative experiences. In line with this hypothesis, many patients experiencing hallucinations report that hallucinations began following a retraumatising experience.

Ekbom Syndrome: the Delusional Parasitosis

In this condition, the subject has the strong delusional belief of being infested with parasites. Patients give detailed descriptions of the activity of the parasites (crawling, biting, burrowing), translating tactile hallucinations. Delusional parasitosis is referred to as the

Ekbom's syndrome, after the Swedish neurologist, who published seminal cases in 1937, or as 'delusional disorder, somatic type' in the DSMIV criteria. Secondary functional delusional parasitosis can occur in psychiatric conditions such as schizophrenia or depression.

Hallucinogens and Alcohol

Hallucinogenic Substances

Hallucinogens include natural substances extracted from plants, such as mescaline and psilocybin, and synthetic substances such as lysergic acid diethylamide (LSD), 3,4-méthylène-dioxy-méthylamphétamine (MDMA, or ecstasy), and phencyclidine (PCP). The perceptual, cognitive, and psychological effects of these compounds are unpredictable, and are heavily dependent on the expectations of the user and the environment. The effects also depend on the dose, with differences in nature, and not only in intensity, with higher or lower doses. The hallucinations induced by these compounds are mainly auditory and visual, and are associated with, or preceded by, intensification of perceptions, synesthesia, illusions, and derealization. Visual hallucinations often consist of geometric patterns, sometimes persons or objects. Geometric patterns have been classified into four groups, called 'form constants.' It has been postulated that these hallucinations arise in the primary visual cortex (V1), and that the form of the retino-cortical map and the micro-architecture of V1 determine their geometry. In most cases, insight on the hallucinatory nature of the phenomenon is maintained. Perceptual symptoms may be re-experienced in the absence of any recent hallucinogen intoxication (hallucinogen persisting perception disorder, or flashbacks).

The drug category of hallucinogens encompasses many compounds, which exhibit a wide range of pharmacological properties. The three prototypical drugs – mescaline, psilocybin, and LSD – are agonists at 5-HT_{2A} (serotonergic) receptors. Recent research has confirmed that 5-HT_{2A} receptors are an important site of action for the hallucinogens, and have also directed attention on the modulatory roles of 5-HT_{2C} (for the phenethylamines) and 5HT_{1A} receptors (for the tryptamines).

Other drugs may act through different mechanisms such as cannabinoid agonism (tetrahydrocannabinol), N-methyl-D-aspartate (NMDA) antagonism (phencyclidine), muscarinic receptor antagonism (scopolamine), and mixed action monoamine release (MDMA).

Alcohol

Hallucinations occur in up to 10% of alcohol withdrawal patients. They are commonly visual, though they may be

auditory, tactile, and olfactory. They usually occur early, in the first 24 h following the last drink, and are associated with insomnia, agitation, and enacting-dream behaviors with partial or absent awareness of reality. Polysomnographic studies have shown the presence of an atypical transitional state between REM-sleep and wake (status dissociatus, see above).

Alcoholic hallucinosis is a much rarer condition of acute onset, occurring after one or more decades of heavy alcohol consumption. The clinical picture includes hallucinations, generally auditory, often accompanied by delusions of reference and persecution, persisting for variable periods of time, regardless of whether the patient is abstinent. The toxic effect of alcohol on frontal lobe functions is well known, suggesting that alcohol hallucinosis may share mechanisms with the positive symptoms of schizophrenia.

Therapeutic Aspects

Antipsychotic Drugs

Antipsychotic drugs are the first-line treatment for patients suffering from hallucinations occurring in the course of psychiatric conditions, especially schizophrenia. In line with the dopamine theories of schizophrenia mentioned above, antipsychotics inhibit the actions of dopamine by acting on D₂ and D₃ dopaminergic receptors. Although it has been assumed that antipsychotics are antagonists at the D₂/D₃ receptors in the brain, *in vitro* assays suggest that they are in fact inverse agonists at these receptors. Recently, a D₂/D₃ partial agonist drug (aripiprazole) has also shown antipsychotic properties. Action at serotonin receptors (5HT_{1A}, 5HT_{2A}) might also be important for the action of some second-generation (atypical) antipsychotics. However, the exact characteristics that make these new antipsychotics atypical are a matter of debate, and there may be significant differences between the drugs within this class. The atypical antipsychotic effect could, at the molecular level, be due to a fast dissociation of the drug from the D₂ receptor, rather than to a high 5-HT₂ occupancy. All these drugs treat primarily the positive symptoms of schizophrenia, including the hallucinations. A meta-analysis has shown that some (but not all) of the second-generation antipsychotic drugs are most efficacious than first-generation drugs for treatment of positive (and negative) symptoms. However, the effect on hallucinations, among other positive symptoms, was not specifically assessed. Due to the side effects associated with the use of conventional (first- or second-generation) antipsychotics, there is a need for alternative pharmacological treatment.

Preliminary studies suggest that metabotropic glutamate receptor agonists could represent a promising new class of antipsychotics.

Repetitive Transcranial Magnetic Stimulation

Recently, repetitive transcranial magnetic stimulation (rTMS) has emerged as a possible alternative treatment of hallucinations in schizophrenic patients resistant to antipsychotic drugs. Several studies and recent meta-analysis of controlled studies suggest that low-frequency rTMS delivered to the left temporo-parietal cortex induce a significant, although modest-to-moderate, reduction of overall positive symptoms in patients receiving active treatment. However, the effect size is higher and more robust when only auditory hallucinations are taken into account, thus confirming that the temporal association cortex plays a crucial role in the pathophysiology of auditory hallucinations.

Hallucinogens

A L Halberstadt and M A Geyer, University of California, San Diego, La Jolla, CA, USA

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Classical hallucinogen – A drug that is capable of producing a complex syndrome of effects typically involving alterations in perception, mood, and cognition. It specifically refers to substances with pharmacology and behavioral effects similar to lysergic acid diethylamide (LSD), mescaline, and psilocybin.

M100907 – A serotonin antagonist that binds selectively to 5-HT_{2A} receptors, with approximately 70-fold lower affinity for the rat 5-HT_{2C} receptor. Other names for this compound, known chemically as (+)- α -(2,3-dimethoxyphenyl)-1-[2-(4-fluorophenyl)ethyl]-4-piperidinemethanol, include MDL 100,907 and volinanserin.

SER-082 – An indolonaphthyridine derivative developed by Sandoz that acts as a mixed 5-HT_{2C/2B} receptor antagonist.

Serotonin – This substance, also known as 5-hydroxytryptamine (5-HT), is a monoamine neurotransmitter found in the central nervous system of vertebrate animals.

Stereoselectivity – In reference to a chiral substance, the phenomenon that one enantiomer is more pharmacologically active than the other stereoisomer. The more potent enantiomer is referred to as the eutomer, whereas the less potent enantiomer is the distomer.

Tolerance – Reduction or loss of the response to a drug after repeated exposure.

WAY-100635 – *N*-[2-[4-(2-Methoxyphenyl)-1-piperazinyl]ethyl]-*N*-2-pyridinyl-cyclohexanecarboxamide, a selective 5-HT_{1A} receptor antagonist.

Humans have used hallucinogenic drugs for thousands of years, typically as crude botanical preparations. Modern scientific interest in these drugs was stimulated by the identification of mescaline as the active agent in the Peyote cactus by Arthur Heffter, in 1897, and the discovery of the hallucinogenic properties of (+)-lysergic acid diethylamide (LSD) by Albert Hofmann, in 1943. Hallucinogens produce alterations of cognition, perception, and affect at nontoxic dosages. Most commonly, the effects of these agents involve marked perceptual disturbances, changes in thought and mood, depersonalization,

visual hallucinations, and somatic symptoms. It is important to note that several different pharmacological classes of agents produce effects in humans that are hallucinogen-like. These classes include cannabinoids such as tetrahydrocannabinol (THC) and the glutamate *N*-methyl-D-aspartate (NMDA) antagonists phencyclidine (PCP) and ketamine, in addition to the classical phenylalkylamines, tryptamines, and indolealkylamines acting on serotonergic systems. There is clearly some overlap between the subjective effects produced by the former two classes and those produced by the prototypical hallucinogens LSD, mescaline, and psilocybin. Nonetheless, human and animal subjects readily distinguish the subjective effects of THC, PCP, and ketamine from those of the hallucinogens, whereas it is reported consistently that LSD, mescaline, and psilocybin produce similar effects. To differentiate hallucinogens from other classes of drugs that do not fit within this classification, the term ‘classical hallucinogens’ has been proposed to describe substances whose psychopharmacology is similar to that of LSD, mescaline, and psilocybin. For the purposes of this article, only those substances that meet the above definition will be referred to as hallucinogens. One indication that the classical hallucinogens represent a discrete drug class is the finding that these agents produce reciprocal cross-tolerance. This effect does not occur between hallucinogens and members of other drug classes, indicating that the classical hallucinogens share a common mechanism of action.

Structure and Pharmacology of Hallucinogens

Classical hallucinogenic drugs belong to two groups of chemicals: indoleamines and phenylalkylamines (Figure 1). The indoleamine class includes two subsets, ergolines such as LSD and tryptamines such as *N,N*-dimethyltryptamine (DMT), 5-methoxy-DMT (5-MeO-DMT), and psilocybin. The phenylalkylamine class of hallucinogens includes phenethylamines such as mescaline, as well as phenylisopropylamines such as 1-(2,5-dimethoxy-4-methylphenyl)-2-aminopropane (DOM), and 1-(2,5-dimethoxy-4-iodophenyl)-2-aminopropane (DOI). Radioligand-binding studies have demonstrated that the tryptamines are nonselective serotonin (5-HT) receptor ligands that display moderate to high affinity for 5-HT₁ sites (including 5-HT_{1A}, 5-HT_{1B}, and 5-HT_{1D} receptors) and 5-HT₂ sites (including 5-HT_{2A} and

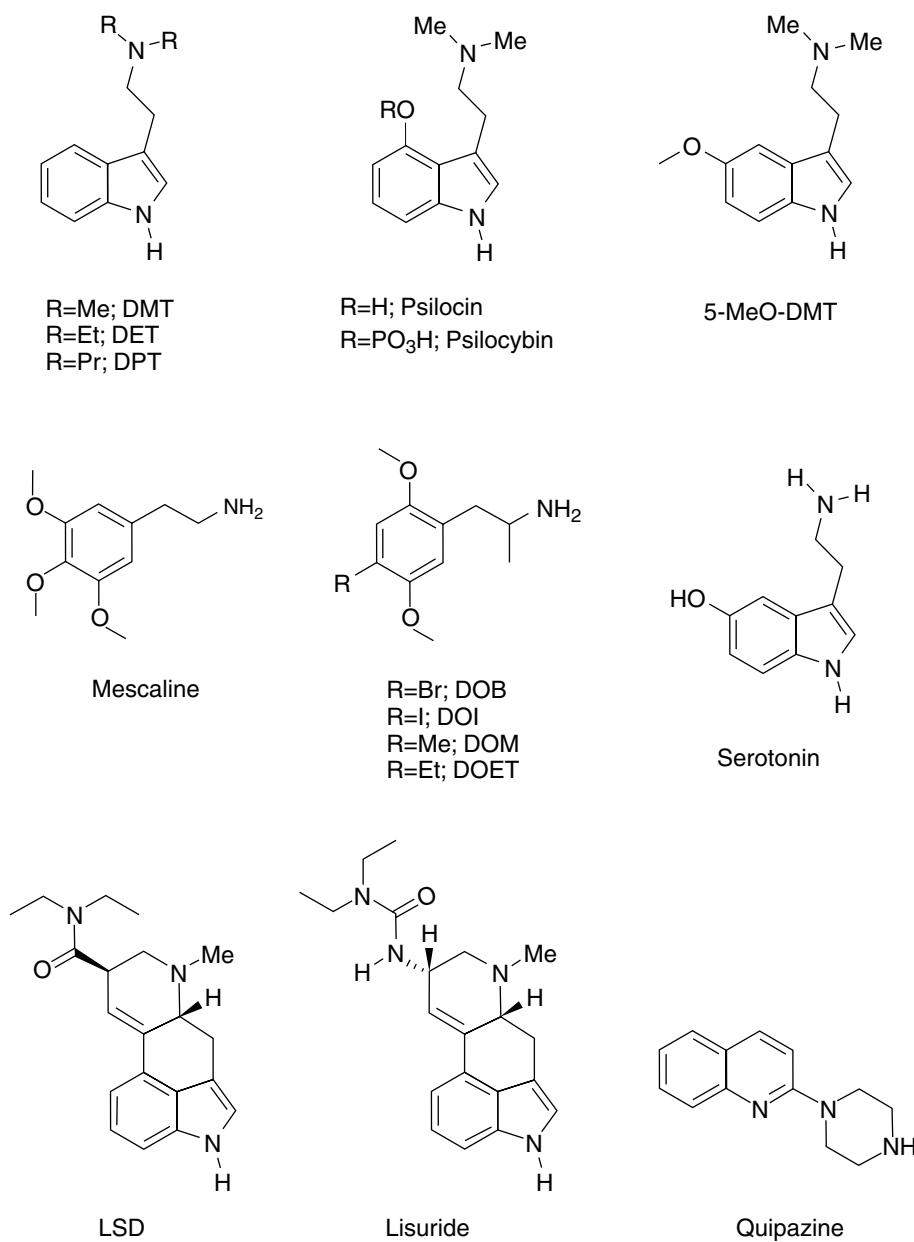

Figure 1 Chemical structures of indoleamine and phenylalkylamine hallucinogens and some related substances.

5-HT_{2C} receptors). LSD binds to a larger population of 5-HT receptors (5-HT_{1A/1B/1D}, 5-HT_{2A/2C}, 5-HT₅, 5-HT₆, and 5-HT₇), but also has high affinity for dopaminergic (DA) and adrenergic receptors. Conversely, phenylalkylamine hallucinogens such as DOM are relatively selective for 5-HT₂ sites, binding to 5-HT_{2A} and 5-HT_{2C} receptors with subnanomolar or nanomolar affinities but interacting with other receptors only at micromolar concentrations. Although the question of whether hallucinogens function as agonists or antagonists at 5-HT₂ receptors was a source of disagreement for many years, it is now widely accepted that these compounds display at least partial agonist efficacy at 5-HT_{2A} and 5-HT_{2C} receptors. Based on the results of behavioral studies in animals, the 5-HT_{2A} receptor is believed to be primarily

responsible for the psychoactive effects of hallucinogens. Importantly, this mechanism has now been confirmed by the finding, in human clinical trials, that the subjective effects of psilocybin are blocked by the administration of the 5-HT_{2A/2C} antagonist ketanserin and the 5-HT_{2A}/DA D₂ antagonist risperidone.

Use of Animal Behavioral Models to Study Hallucinogens

The effects of hallucinogens in humans are highly subjective and are normally assessed using verbal reports. Unfortunately, very few human clinical trials with

hallucinogens have been conducted during the last three decades due to regulatory and ethical considerations. Due to the constraints on human studies, animal behavioral models have become the primary methodology used to study the *in vivo* pharmacology of these drugs. Given the wide variability and the complexity of hallucinogen effects in humans, it has been difficult to define animal behavioral tests for hallucinogenic activity. Nonetheless, numerous animal models have been used over the last four decades to probe the pharmacology of these compounds, yielding a number of important insights.

Types of Animal Models

Animal models used to study the behavioral effects of hallucinogens can be divided into two groups: (1) models that test for behavior(s) that are analogous to hallucinogen effects in humans; and (2) models that test for a behavior that has no human counterpart. One advantage of the first type of model is the existence of a conceptual link to human phenomenology; hence, these models can be used to probe the neural and psychopharmacological mechanisms underlying the human response to hallucinogens. Animal models that belong to the second group are typically robust and have considerable predictive validity. However, with these animal models it is often difficult, if not impossible, to define how the effect(s) being detected relates to the subjective effects of hallucinogens in humans.

Susceptibility to False Positives

One problem associated with animal models used to assess compounds for hallucinogen-like activity is that they cannot always reliably differentiate the behavioral effects of hallucinogens from those of certain closely related compounds that are not hallucinogenic in humans (i.e., hallucinogen false positives). The two most common examples of compounds that generate false-positive results are lisuride and quipazine. Lisuride is an ergot derivative that has been used as a treatment for Parkinson's disease. Lisuride is structurally similar to LSD and is a nonselective agonist at serotonergic, dopaminergic, and adrenergic receptors. Quipazine is an arylpiperazine that acts as a nonselective 5-HT receptor agonist. Neither of these compounds reliably produces LSD-like hallucinogenic effects when tested in human subjects. Nevertheless, many of the behavioral paradigms used to study the effects of hallucinogens identify quipazine and lisuride as being hallucinogen-like. It is not clear why this discrepancy exists. Although the phenomenon of false positives does somewhat limit the predictive validity of these animal models, it is important to consider that the vast majority of agents tested are correctly classified by these paradigms.

Validation of Animal Models

The results obtained with animal models used to study hallucinogen effects should accurately reflect what is known about the pharmacology of these compounds in humans. Valid animal models should reflect the fact that, in humans: (1) tolerance rapidly develops to the behavioral effects of hallucinogens; (2) the action of phenylisopropylamine hallucinogens such as DOM is highly stereoselective; (3) indoleamine and phenylalkylamine hallucinogens produce similar effects; and (4) 5-HT_{2A} receptor antagonists block the subjective effects of hallucinogens.

Animal Models of Hallucinogen Effects

As noted earlier, numerous animal models have been used to study the effects of hallucinogens. The vast majority of these models have, however, fallen into disuse. Some of these models have been invalidated and others were never widely adopted. At present, there are five paradigms commonly used to assess the behavioral effects of hallucinogens. A brief description of each of these behavioral models is provided below. Included in the descriptions are some of the advantages and disadvantages of each model, information about their validation, the receptor mechanisms and neurochemical substrates for the behavioral effect, and the susceptibility of the model to false positives (see [Table 1](#)).

Drug Discrimination

The drug-discrimination paradigm has been widely used to study the pharmacology of hallucinogenic agents and has proven especially useful in structure-activity studies and in mechanistic analyses of these compounds. The paradigm of drug discrimination makes use of the fact that animals can be trained to discriminate the interoceptive stimulus evoked by a training drug from that of the nondrug state. Most commonly, animals are trained to discriminate drug versus vehicle using standard two-lever operant procedures. Once trained, animals can be challenged with novel agents to determine whether these test substances produce stimulus effects similar to those of the training drug (i.e., tests of stimulus generalization). Hirschorn and Winter first demonstrated in 1971 that rats could be trained to discriminate mescaline and LSD from saline. It was subsequently shown that a number of other hallucinogens, including DOM, DOI, DOB, DPT, psilocybin, and 5-MeO-DMT, are capable of serving as training drugs in the drug-discrimination paradigm. Importantly, cross-generalization occurs between these training drugs, suggesting that they evoke similar stimulus cues. The majority of drug-discrimination studies with

? = not yet tested.

Abbreviations: BPM, Behavioral Pattern Monitor; DD, drug discrimination; ESR, mouse ear-scratch response; HTR, head twitch response; PPI, prepulse inhibition of startle.

hallucinogens have used rats, although mice, pigeons, and monkeys have also been studied. The ability of agents to evoke hallucinogen-like responding in the drug-discrimination assay displays pronounced pharmacological specificity in that members of other drug classes (e.g., opioids, depressants, psychostimulants, glutamate NMDA antagonists, cannabinoids, and cholinergic agonists and antagonists) consistently fail to produce substitution in animals trained with classical hallucinogens. The effect of phenylisopropylamine hallucinogens in the drug-discrimination paradigm is stereoselective, with the *R*-(-)-enantiomer being the more potent stereo isomer. Although the drug discrimination paradigm is not an animal model of hallucinogenic activity *per se*, effective dose (ED₅₀) values for stimulus generalization of phenalkylamine and indoleamine hallucinogens are significantly correlated with the potencies of these compounds in humans.

The discriminative stimulus induced by hallucinogens is attenuated to varying degrees by nonselective 5-HT receptor antagonists such as methysergide, metergoline, mianserin, methiothepin, pizotifen (pizotyline or BC-105), and cyproheptadine. The observation that the selective 5-HT_{2A/2C} antagonists pirenperone and ketanserin are potent and highly effective antagonists of the discriminative stimulus properties of DOM and LSD – and of DOM-stimulus generalization to LSD, mescaline, and 5-MeO-DMT – led to the proposal that these drugs may be acting through 5-HT₂ receptors. Subsequent studies have provided evidence that the discriminative stimulus evoked by hallucinogens is mediated by agonist actions at the 5-HT_{2A} receptor subtype. A robust and significant linear correlation exists between the 5-HT_{2A} affinities of various phenylalkylamine hallucinogens and their ED₅₀ values obtained from stimulus-generalization studies using DOM as the training drug. Antagonist correlation analysis has demonstrated that the 5-HT_{2A} binding affinities of a number of structurally diverse 5-HT antagonists is strongly correlated with their potencies for blocking substitution of *R*-(-)-DOM in animals

trained with LSD. Furthermore, the highly selective 5-HT_{2A} antagonist M100907 can block stimulus control evoked by DOI and LSD. Although there has been some controversy over whether interactions with 5-HT_{2C} receptors contribute to the discriminative stimulus effects of hallucinogens, studies in rats demonstrate that the mixed 5-HT_{2C/2B} antagonists SB 200,646A and SB 206,553, and the selective 5-HT_{2C} antagonist SB 242,084, consistently fail to block hallucinogen-induced stimulus control. There is evidence that tolerance can develop to the hallucinogen cue; daily administration of 1.0 mg kg⁻¹ DOI for 8 days to rats trained to discriminate a lower dose of the drug produced a significant decrease in drug-appropriate responding. The decrease in DOI-lever responding was accompanied by a decrease in the number of 5-HT_{2A} receptors but not 5-HT_{2C} receptors. Taken together, these findings indicate that it is unlikely that 5-HT_{2C} receptor activation is essential for the induction of stimulus control by hallucinogens (at least in rats).

Although a preponderance of evidence demonstrates that interactions with 5-HT_{2A} receptors mediate hallucinogen-induced stimulus control, this evidence does not preclude the possibility that interactions with other receptors may contribute to or modify the discriminative stimulus effects of these drugs. Indeed, indoleamine hallucinogens are far less selective for 5-HT_{2A} receptors than the phenylalkylamines and it appears that the former class of agents have more complex stimulus properties than the phenylalkylamines. It is well established that the 5-HT₂ antagonist cinanserin antagonizes the effects of DOM and mescaline much more effectively than it suppresses LSD- and 5-MeO-DMT-appropriate responding. There is evidence that the 5-HT_{1A} subtype contributes to the discriminative effects of LSD. For example, the 5-HT_{1A} agonist ipsapirone produces partial drug-lever responding in LSD-trained animals, and the mixed 5-HT_{1A} agonist/α₂-adrenoceptor antagonist yohimbine has been reported, by several groups of investigators, to

produce LSD-like effects ranging from partial to full substitution. LSD also elicits partial substitution in rats trained with the 5-HT_{1A} agonist 8-OH-DPAT. LSD has high affinity for DA D₁, D₂, D₃, and D₄ receptors. Based on the finding that the 5-HT_{2A}/D₂ antagonist risperidone is much more effective than ritanserin as an antagonist of the LSD cue, it has been proposed that DA mechanisms may also play a role in LSD-induced stimulus control. There have also been reports that the discriminative stimulus effects of LSD occur in two temporal phases, with the first phase mediated by 5-HT_{2A} receptors and the second phase involving interactions with DA D₄ receptors. LSD evokes a compound stimulus; although the most salient component of the LSD stimulus is transduced through the 5-HT_{2A} receptor, ancillary interactions with 5-HT_{1A} and dopaminergic receptors are responsible for secondary nonessential components of the LSD stimulus complex. As with any drug possessing complex stimulus properties, the nature of the LSD stimulus will vary depending upon the training and testing conditions. In addition to LSD, other indoleamines produce stimulus effects that involve 5-HT_{1A}- and 5-HT_{2A}-mediated components. Indeed, the 5-MeO-DMT stimulus cue generalizes not only to DOM, but also to 8-OH-DPAT and ipsapirone. The 5-MeO-DMT discriminative stimulus seems to involve a substantial 5-HT_{1A} receptor-mediated component, as demonstrated by the finding that the 5-HT_{1A} receptor-selective antagonist WAY-100635 and the mixed 5-HT₁/β-adrenergic antagonist pindolol are more effective than pirenperone at blocking stimulus control by 5-MeO-DMT.

It has occasionally been reported that animals trained to discriminate a hallucinogen will generalize to a drug that is not hallucinogenic in humans (i.e., so-called 'false positives'). For example, some (but not all) investigations have found that lisuride can fully substitute for LSD and DOM. Nonetheless, rats can be trained to discriminate between LSD and lisuride using a three-lever drug-discrimination procedure. Thus, although LSD and lisuride have similar stimulus effects, the stimulus cues evoked by these two agents are apparently distinguishable. Quipazine has consistently been found to substitute for LSD and DOM. Substitution of quipazine in rodents trained with hallucinogens is blocked by ketanserin and pirenperone, suggesting it is mediated by 5-HT_{2A} receptors.

The discriminative stimulus effects of hallucinogens are centrally mediated. Systemic administration of xylymidine, a peripheral 5-HT₂ antagonist that does not cross the blood-brain barrier, has no effect on stimulus control induced by mescaline, DOM, or by moderate to high doses of LSD. Central administration of *R*(-)DOM and LSD via the intracerebroventricular route substitutes for the discriminative stimuli produced by systemic injection of those agents. The central neuroanatomical site(s) responsible for mediating the hallucinogen cue have not

been conclusively identified, although a few candidates have been proposed. Intracerebral microinjection studies have suggested that the nucleus accumbens and dorsal raphe nucleus may play a role in the effects of LSD, although very high doses of LSD had to be injected into the latter region in order to produce substitution. A more recent investigation has demonstrated that infusion of LSD directly into the anterior cingulate cortex (ACC) of rats produces full substitution in rats trained to discriminate LSD administered systemically. Importantly, administration of M100907 directly into ACC antagonized the stimulus effects of LSD administered either systemically or via intra-ACC infusion. These findings strongly indicate that the ACC may play a role in stimulus control induced by LSD.

Investigatory and Exploratory Behavior

Locomotor paradigms have frequently been used to assess the behavioral effects of psychoactive drugs. Typically, the amount of unconditioned locomotor activity in rodents is quantified to determine whether a compound acts as a stimulant or a depressant. However, these measures yield only a partial description of the behavioral state (i.e., they reveal nothing about qualitative behavioral changes) and do not address whether alterations in the response to sensory stimuli contribute to the behavioral effect. To address these shortcomings, the rat Behavioral Pattern Monitor (BPM) was developed. The BPM combines features of activity and holeboard chambers and was specifically designed to assess the quantity as well as the quality or patterns of activity by monitoring the temporal and spatial sequence of behavioral responses. In addition to measuring exploratory and investigatory behaviors (rearings and holepokes), the BPM can be used to assess the structure of motor activity. The BPM also enables assessment of the responsiveness of animals to environmental stimuli, including their sensitivity to novelty.

Classical hallucinogens produce a characteristic behavioral profile in the BPM. When tested in a novel environment, phenylalkylamine (mescaline, DOM, DOI, and DOET) and indoleamine (psilocin, DMT, and 5-MeO-DMT) hallucinogens produce the following behavioral effects: (1) reductions in locomotor activity; (2) decreases in investigatory behaviors (rearings and holepokes); and (3) decreased entries into and time spent in the center of the chamber. The effects of hallucinogens in the BPM are significantly reduced when animals are tested in a familiar environment. Based on these findings, it has been suggested that hallucinogens potentiate the neophobia normally exhibited by rats in response to a novel environment. The diminution of the behavioral effects of hallucinogens in a familiar test environment has been interpreted as representing an increased willingness of hallucinogen-treated animals to explore the

test chamber once the stimuli associated with the chamber become less threatening due to habituation. LSD produces a more complex behavioral profile in the BPM. As with other hallucinogens, LSD decreases investigatory behavior and increases avoidance of the center of the chamber, but it has biphasic effects on locomotor behavior, producing an initial reduction in activity followed by an increase as time progresses. The acute effects of LSD and DOI in the BPM are diminished after repeated treatment with the drugs, indicating that hallucinogen-induced tolerance is detectable in this paradigm.

The effects of DOI and DOM in the BPM paradigm are blocked by the nonselective 5-HT antagonist cyproheptadine and by the selective 5-HT₂ antagonists ketanserin and ritanserin. The effects of phenylalkylamine hallucinogens are also blocked by pretreatment with the selective 5-HT_{2A} antagonist M100907 but not with the 5-HT_{2C/2B}-selective antagonist SER-082, and are, therefore, likely solely mediated by 5-HT_{2A} receptors. The mechanistic basis for the effects of indoleamine hallucinogens in the BPM is more complex. For example, the effects of low doses of 5-MeO-DMT are antagonized by the selective 5-HT_{1A} antagonist WAY-100635 but not by M100907 or SER-082. For LSD, experiments have demonstrated that the initial suppression of locomotor activity induced by LSD is blocked by the mixed 5-HT₁/β-adrenergic antagonist propranolol but not by the 5-HT₂ antagonist ritanserin, whereas the delayed increase in locomotor activity is blocked by ritanserin but not by propranolol. More recent studies have demonstrated that the LSD-induced decrease in locomotion is attenuated by WAY-100635, whereas LSD-induced hyperactivity is blocked by M100907. The fact that both 5-HT_{1A} and 5-HT_{2A} receptors appear to contribute to the behavioral effects of LSD in the BPM is supported by the finding that chronic pretreatment with either 8-OH-DPAT or DOI produces cross-tolerance with LSD in this behavioral paradigm.

When tested in a novel environment, selective 5HT_{1A} agonists such as 8-OH-DPAT and ipsapirone produce dose-dependent decreases in investigatory and exploratory behavior, and increase avoidance of the center region. Thus, with regard to these behavioral measures, 5-HT_{1A} agonists induce hallucinogen-like effects. However, whereas the effects of hallucinogens in the BPM depend on the novelty of the testing environment, the effects of 5-HT_{1A} agonists persist in a familiar environment. Based on that finding, it has been concluded that the behaviorally suppressive effects of 5-HT_{1A} are reflective of a generalized sedative effect rather than an alteration in the animal's response to environmental stimuli.

The effects of hallucinogens on investigatory and exploratory behavior in the BPM are distinct from those produced by members of other drug classes (see **Table 2**). Furthermore, it is possible to distinguish the behavioral

Table 2 Drugs that do not reproduce the hallucinogen behavioral profile in the BPM

Drug class	Examples
5-HT _{1A} agonist	8-OH-DPAT Buspirone Gepirone Ipsapirone
5-HT _{1B} agonist	RU 24969
5-HT _{1B} /5-HT _{2C} agonist	mCPP TFMPP
5-HT releaser	Fenfluramine MDA MDMA MDEA MBDB α-Ethyltryptamine p-Chloroamphetamine
SERT inhibitor	Fluoxetine
D ₁ /D ₂ agonist	Apomorphine
DAT inhibitor	Cocaine GBR 12909 Nomifensine
DA/NE releaser	(+)-Amphetamine
α ₂ Agonist	Clonidine
β ₂ Agonist	Clenbuterol
β Antagonist	Nadolol
NET inhibitor	Chlorimipramine
Opioid agonist	Morphine
Adenosine agonist	Caffeine
NMDA antagonist	Phencyclidine MK-801
Muscarinic AChR antagonist	Scopolamine
Nicotinic AChR agonist	Nicotine
MAO inhibitor	Harmaline Clorgyline

Abbreviations: AChR, acetylcholine receptor; DA, dopamine; DAT, dopamine transporter; MAO, monoamine oxidase; NE, norepinephrine; NET, norepinephrine transporter; NMDA, N-methyl-D-aspartate; SERT, serotonin transporter.

effects of lisuride from those induced by LSD and other hallucinogens in the BPM. Low doses of lisuride produce a sedative effect with no evidence of exaggerated avoidance of the center of the chamber. Higher doses of lisuride induce stereotyped patterns of locomotor hyperactivity resembling those produced by the dopamine receptor agonist apomorphine. Conversely, quipazine produces hallucinogen-like effects in the BPM that are blocked by pretreatment with ketanserin and ritanserin.

In summary, the effects of hallucinogens on exploratory and investigatory behavior in the BPM are characteristic and can be used to reliably distinguish these drugs from members of other drug classes. Furthermore, because the BPM includes measures that assess the responsiveness of animals to environmental stimuli, it is possible to relate the effect of hallucinogens in the BPM to the subjective effects of these drugs in humans.

Head-Twitch Response

Corne and colleagues first reported, in 1963, that administration of the 5-HT precursor 5-hydroxytryptophan (5-HTP) to mice evokes the head-twitch response (HTR) – a paroxysmal rotational movement of the head resembling the pinna reflex. It was subsequently shown that hallucinogens such as LSD, DOM, DOI, psilocin, psilocybin, 5-MeO-DMT, and mescaline also induce head twitches in mice. Administration of 5-HTP or hallucinogens to rats induces an analogous behavior that is sometimes referred to as the ‘wet-dog shake’ because it frequently involves the head, neck, and trunk. The HTR induced by phenylisopropylamine hallucinogens is stereoselective, and there is substantial diminution of the response after repeated administration of DOM. The HTR has been widely adopted as a behavioral assay for detecting hallucinogen-like effects because the response is reliably induced by classical hallucinogenic drugs and does not require specialized equipment or training to assess.

The HTR to hallucinogens and to 5-HT precursor loading with 5-HTP can be blocked by administration of nonselective 5-HT receptor agonists such as cyproheptadine, metergoline, mianserin, pizotyline, and methysergide and is thus believed to reflect activation of 5-HT receptors. It was proposed in 1981 that the HTR induced by 5-HTP is mediated by 5-HT_{2A} receptors, based on evidence that the potency of 5-HT antagonists to block the behavior was significantly correlated with their 5-HT_{2A} affinity. Similar findings were later reported for the HTR induced by mescaline and DOI. Additional evidence for a linkage between 5-HT_{2A} receptors and the HTR emerged from studies demonstrating that the effects of 5-HTP and mescaline are blocked by pirenperone and ketanserin. Although those two antagonist ligands bind to both 5-HT_{2A} and 5-HT_{2C} receptors, a specific link between the 5-HT_{2A} receptor and head twitches in rodents is supported by the finding that the HTR to DOI and other hallucinogens is inhibited by the selective 5-HT_{2A} antagonist M100907 but not by the selective 5-HT_{2C} antagonist SB 242,084 or by the mixed 5-HT_{2C/2B} antagonists SB 200,646A and SER-082. The apparent involvement of 5-HT_{2A} receptors in the hallucinogen-induced HTR was confirmed by the recent finding that the ability of LSD and DOI to induce the HTR is abolished in 5-HT_{2A}^{-/-} knockout mice.

Quipazine induces the HTR, an effect that is blocked by ketanserin and pirenperone. Conversely, lisuride fails to provoke the HTR in mice and rats, and can actually antagonize LSD- and 5-HTP-induced head twitching. Although head twitching in rodents is used as a behavioral assay for hallucinogenic drugs, members of other drug classes are also capable of eliciting the HTR. In addition to 5-HTP, phencyclidine, certain benzodiazepines, the cannabinoid CB₁ antagonist SR 141716A, and the 5-HT_{1A} antagonists WAY-100635 and S-(–)-UH 301 have

also been shown to induce the HTR. Importantly, the HTR induced by these compounds is blocked by 5-HT₂ receptor antagonists, indicating that they may also induce the behavior via activation of 5-HT_{2A} receptors. A number of other agents, including [Met]enkephalin, the cholinergic agonist carbachol, and thyrotropin-releasing hormone, are also reported to produce head twitches; however, it is not clear whether the effects of these agents are blocked by 5-HT_{2A} antagonists. Nonetheless, the available evidence indicates that although the HTR cannot be used reliably to assess drugs for potential hallucinogenic activity, it does show utility as an assay for 5-HT_{2A} agonist activity. It is also important to note that the HTR induced by 5-HT_{2A} receptor activation can be modified by drugs acting at a variety of other receptor sites, including 5-HT_{1A}, DA D₁ and D₂, cannabinoid CB₁, μ -opioid, nicotinic cholinergic, α_2 -adrenergic, and ionotropic and metabotropic glutamate receptors. Hence, the HTR has been utilized as a tool to probe the neuronal and circuit interactions between 5-HT_{2A} receptors and other transmitter systems.

Pretreatment with xylamidine has no effect on the HTR induced by 5-HTP. Although this finding indicates that the HTR induced by systemic administration of 5-HT agonists is centrally mediated, there is disagreement in the literature with regard to the neuroanatomical locus that is responsible for mediating this behavioral effect. Bilateral infusion of DOI into the medial prefrontal cortex of rats has been reported to induce the HTR, an effect that was blocked by the systemic administration of ketanserin or M100907 but not SER-082. The conclusion that prefrontal cortical 5-HT_{2A} receptors are involved in the hallucinogen-induced HTR is supported by the finding that selective restoration of 5-HT_{2A} receptors in the cortex of 5-HT_{2A}^{-/-} knockout mice rescues the HTR to LSD. However, other evidence indicates that the frontal cortex is not required for the HTR induced by the systemic administration of 5-HT agonists. For example, removal of the frontal cortex in rats does not alter the HTR induced by quipazine or 5-HTP. Likewise, cutting the rat brain transversely at the level of the anterior commissure did not block the ability of 5-HTP to induce the HTR, whereas transection at the level of the posterior commissure abolished the response to 5-HTP. The latter finding suggests that structures in the caudal diencephalon and medial brainstem mediate the HTR to 5-HT agonists. It has also been reported that infusion of DOI into the region of the brainstem containing the raphe obscurus and inferior olive induces the HTR in rats. Taken together, the available evidence indicates that activation of 5-HT_{2A} receptors in multiple brain regions can elicit the HTR, although it is not clear which brain region(s) are responsible for the HTR induced by systemic administration of 5-HT agonists.

Prepulse Inhibition of Startle

Prepulse inhibition (PPI) of the startle reflex is defined as the response decrement that occurs when a startling acoustic stimulus is preceded immediately by a subthreshold stimulus. PPI serves as an operational measure of sensorimotor gating and has been found to be deficient in patients with schizophrenia. One advantage of this behavioral paradigm is that PPI is a cross-species phenomenon that can be assessed in humans and animals using similar testing procedures. Sipes and Geyer first reported, in 1994, that the hallucinogen DOI disrupts PPI in rats. Additional studies confirmed that other hallucinogens, including LSD, DOB, and 5-MeO-DMT, are capable of disrupting PPI. Ketanserin and risperidone reverse the effect of DOI on PPI. The ability of DOI and LSD to decrease PPI in rats is blocked by the selective 5-HT_{2A} antagonist M100907 but not by the 5-HT_{2C/2B} antagonist SER-082, indicating that the effect is mediated by 5-HT_{2A} receptors. The conclusion that these hallucinogens are not acting through the 5-HT_{2C} receptor to alter PPI is supported by the finding that the preferential 5-HT_{2C} agonist mCPP has no effect on PPI. Compared with DOI and LSD, the mechanism for the effect of 5-MeO-DMT on PPI is more complicated and apparently involves interactions with both 5-HT_{1A} and 5-HT_{2C} receptors.

With regard to the sensitivity of the PPI paradigm to drugs that often generate hallucinogen false-positive results, quipazine has no effect on PPI, whereas there are no published studies of the effect of lisuride on PPI. However, many other nonhallucinogenic agents disrupt PPI in rodents, limiting the predictive validity of the paradigm. Administration of DA agonists such as (+)-amphetamine and apomorphine decreases PPI. Nonhallucinogenic 5-HT-releasing agents such as 3,4-methylenedioxymethamphetamine (MDMA) and fenfluramine also decrease PPI via direct actions at 5-HT_{2A} receptors. Thus, PPI cannot be used to distinguish hallucinogenic from nonhallucinogenic drugs. Nonetheless, PPI continues to serve as a valuable animal paradigm to assess the behavioral effects of hallucinogens because it serves as a model of the effects of these drugs on sensorimotor gating in humans. Indeed, depending on the experimental parameters used, psilocybin has been shown to impair PPI when administered to human volunteers. However, it is not clear whether other hallucinogens such as LSD have similar effects on PPI in humans.

Mouse Ear-Scratch Response

Deegan and Cook reported, in 1958, that administration of mescaline to mice induces stereotypic scratching of the head and ears – an effect that was not observed in other species of animals. It was subsequently confirmed that DOM, DOI, and DOET could also induce the ear-scratch response (ESR). The ESR induced by these agents is stereoselective, with the R-(-)-enantiomers being

significantly more potent than the S-(+)-enantiomers. The ability of mescaline and DOI to induce the ESR is significantly reduced after repeated treatment. DOI-induced ESR is apparently mediated by 5-HT_{2A} receptors, since it is blocked by ketanserin and by spiperone, an antagonist of 5-HT_{1A/2A} and D₂ receptors. It should be noted that the ESR is not predictive of hallucinogenic activity since the behavior is not induced by indoleamine hallucinogens. In fact, LSD and 5-MeO-DMT actually block the ESR induced by mescaline and DOI, respectively. Based on the finding that the DOI-induced ESR is also inhibited by the 5-HT_{1B} agonist RU 24969, it appears that blockade of the ESR by the indoleamine hallucinogens may involve interactions with 5-HT_{1B} receptors. Neither quipazine nor lisuride induces the ESR – a finding that is consistent with the 5-HT_{1B} agonist activity of these compounds. Thus, the ESR has utility to test phenylalkylamines for 5-HT_{2A} agonist activity but cannot be used with indoleamines or other compounds that are nonselective 5-HT receptor agonists.

Conclusion

Animal behavioral models are the predominant methodology used to study the *in vivo* pharmacology of the classical hallucinogens. Although many animal models for hallucinogen effects have been developed, only a few of these paradigms are widely used. One commonality shared by the models described in this article is that they all demonstrate that the behavioral effects of hallucinogens involve interactions with the 5-HT_{2A} receptor. Therefore, although each of these models has certain disadvantages, they have all helped to elucidate the pharmacological interactions that are responsible for the behavioral effects of classical hallucinogens.

Glossary

Baclofen – Prototypic, direct agonist of the GABA_B receptor. Because of its myorelaxant effects, baclofen has been successfully used in the treatment of muscle rigidity from a variety of causes, including multiple sclerosis. More recently, baclofen has been proposed as an anti-addictive therapy. Baclofen and GHB share several psychopharmacological effects.

Conditioned place preference – Behavioral technique widely used to investigate the rewarding properties of psychoactive drugs. Laboratory animals are initially trained to associate the interoceptive cues produced by a drug with the external (neutral) stimuli of a specific environment and the absence of those effects with the stimuli of a different environment. After a number of conditioning sessions, animals are given a choice between the two environments: if the animal increases the time spent in the drug-paired context, it is inferred that the drug possesses rewarding properties.

Drug discrimination – In this behavioral technique, laboratory animals are trained to associate the interoceptive cues of a certain drug (training drug) with a measurable behavior, providing a sort of self-report whether they feel drugged or not. Studies of drug discrimination may provide information on the cellular sites of action of psychotropic drugs, as (1) drugs acting similarly at a given receptor have similar discriminative stimulus effects and (2) receptor antagonists block the discriminative stimulus effects of drugs acting at that specific receptor.

GABA (γ -aminobutyric acid) – Major inhibitory neurotransmitter in the central nervous system. It activates two classes of receptors: ionotropic GABA_A receptors and metabotropic GABA_B receptors. GABA is a precursor of GHB and, at least for a small portion, a product of GHB metabolism.

GABA_A-benzodiazepine receptor complex – Ionotropic receptor whose activation results in an increase of the chloride influx through the associate ion channel and, ultimately, fast inhibition of the excitability of the postsynaptic neuron. The activity of this receptor is potentiated by different positive modulators, including benzodiazepines, barbiturates, and endogenous

neurosteroids. There is evidence that the GABA_A receptor may partially contribute to the mediation of some effects of GHB.

GABA_B receptor – Heterodimer receptor comprised of two 7-transmembrane-spanning units. Its activation decreases adenylyl cyclase activity, increases potassium conductance, and decreases calcium conductance, with the ultimate result of a slow inhibitory action on excitability of the postsynaptic neuron. GHB is a weak agonist at the GABA_B receptor (at pharmacological concentrations).

GHB (γ -hydroxybutyric acid) – A natural constituent of the mammalian brain, likely acting as neurotransmitter or neuromodulator. When exogenously administered, GHB exerts a number of psychopharmacological effects, ranging from euphoria to anesthesia. GHB displays some therapeutic potential (narcolepsy and alcoholism) and abuse liability.

GHB-specific binding site – High- and low-affinity GHB-specific binding sites have been described in neuronal preparations. The high-affinity binding site is displaced only by GHB (at physiological concentrations) and GHB structural analogs, such as NCS-382.

Mesocorticolimbic dopamine system – The mesocorticolimbic dopamine system – composed of neurons originating in the ventral tegmental area and projecting in the nucleus accumbens, amygdala, and frontal and limbic cortex – constitutes the likely neural pathway mediating the reinforcing effects of psychostimulants and the motivational properties of many drugs of abuse (apparently including also GHB). Indeed, virtually all drugs of abuse activate this system, increasing the output of dopamine in the terminal areas.

Narcolepsy – Rare sleep disorder (occurring in <0.15% of the population), it affects the generation and organization of sleep and wakefulness. Narcolepsy is characterized by excessive daytime sleepiness and presence of irresistible daily attacks of refreshing sleep. Other symptoms include cataplexy (a temporary loss of muscle tone while awake), disrupted nighttime sleep, hypnopompic or hypnagogic hallucinations (visual or auditory dream-like hallucinations at the beginning or end of sleep episodes), and sleep paralysis, each

representing a component of rapid eye movement (REM) sleep that abnormally occurs during period of wakefulness.

NCS-382 – Structurally related to GHB, NCS-382 has been initially proposed as an antagonist of both high- and low-affinity GHB-specific binding sites.

Pharmacological experiments however provided contradictory results, as NCS-382 failed – in most instances – to antagonize different effects of GHB, including discriminative stimulus effects, motor-incoordination, and sedation/hypnosis. Conversely, NCS-382 has been often reported to elicit effects qualitatively similar to those of GHB or to potentiate some effects of GHB.

Succinic semialdehyde dehydrogenase deficiency – Also known as GHB aciduria, rare inborn error of GHB and GABA metabolism, resulting in GHB and GABA accumulation in brain and physiologic fluids. This disease is characterized by mental retardation, epilepsy, hypotonia, and electroencephalogram abnormalities.

γ -Hydroxybutyric acid (GHB) is a short-chain fatty acid that occurs naturally in the mammalian brain. Its primary endogenous precursor is the inhibitory neurotransmitter γ -aminobutyric acid (GABA): GABA is converted to succinic semialdehyde by mitochondrial GABA transaminase; succinic semialdehyde is then reduced to GHB by cytosolic succinic semialdehyde reductase. At the same time, GHB is also a precursor of GABA: GHB is indeed initially converted to succinic semialdehyde by GHB dehydrogenase and then succinic semialdehyde is converted to GABA by GABA transaminase. Succinic semialdehyde can also be converted to succinate by succinic semialdehyde dehydrogenase. Congenital defect in succinic semialdehyde dehydrogenase causes GHB and GABA accumulation in brain, liver, blood, and urine, and results in a rare disease – named succinic semialdehyde dehydrogenase deficiency or GHB aciduria – characterized by delayed mental, motor, and language development, epilepsy, hypotonia, and electroencephalogram abnormalities.

Before its discovery as a naturally occurring constituent of the mammalian brain, GHB was synthesized, in the early 1960s, by the French physician and scientist Henri Laborit, while attempting to produce an orally bioavailable GABA analog or precursor capable of easily crossing the blood–brain barrier.

GHB is presently recognized as (1) an endogenous constituent of the mammalian brain, where it likely acts as neurotransmitter or neuromodulator; (2) a medicine, as it exerts a large spectrum of psychopharmacological effects and is currently used for the treatment of narcolepsy and

alcoholism; and (3) a drug of abuse, illicitly used for some of its psychotropic effects. This article is intended to review the body of experimental and clinical evidence sustaining these three features of GHB.

GHB as a Neurotransmitter or a Neuromodulator

Localization of GHB in GABAergic neurons at the synaptic level, existence in brain of GHB-specific receptor sites (high- and low-affinity classes), as well as machinery for GHB synthesis, storage in synaptic terminals, depolarization-evoked and calcium-dependent release, sodium-dependent uptake, and degradation suggest a role for GHB as neurotransmitter or neuromodulator in the central nervous system.

GHB is unevenly distributed in the rat brain, with substantia nigra and hypothalamus showing the highest concentrations (*c.* 45 pmol mg⁻¹ protein), frontal cortex and cerebellum the lowest (4–8 pmol mg⁻¹ protein). High-affinity GHB-specific binding sites have been localized in specific brain structures, including hippocampus, cortex, thalamus, amygdala as well as dopaminergic nuclei (substantia nigra and ventral tegmental area) and regions innervated by dopaminergic terminals (olfactory bulbs and tubercles, nucleus accumbens, and caudate putamen), with comparable density between rat and human preparations. Although still under debate, the GHB-specific binding site has been suggested to be presynaptic and G protein coupled. As described below in greater detail, GHB may bind to the GABA_B receptor as well; however, GHB displays only a weak affinity for this receptor, and the micromolar concentrations of GHB normally present in the mammalian brain tissue are insufficient for its activation (conversely, the GABA_B receptor is more likely activated by the supraphysiological, or millimolar, concentrations of exogenously administered GHB (see below)).

The physiological function of GHB still remains to be clearly defined; data from neurochemical and electrophysiological studies suggest that GHB may (1) alter GABA and glutamate release, (2) increase serotonin and acetylcholine turnover, (3) stimulate the release of various endogenous opioids, (4) increase plasma levels of endogenous neurosteroids, and (5) participate in mechanisms controlling dopamine activity in the nigrostriatal and mesocorticolimbic pathways.

GHB as a Pharmacological Agent

In both laboratory animals and humans, GHB – when exogenously administered – is rapidly absorbed. It crosses the blood–brain barrier with relative ease, penetrates into

the brain, and exerts a number of psychopharmacological effects, including – as the dose is increased, and just to mention a few – euphoria, anxiolysis, amnesia, sedation/hypnosis, and anesthesia. Plasma levels of GHB reach their peak at approximately 40 min after oral ingestion; GHB's half-life is rather short, averaging 20–30 min.

Sites of Actions

GHB-specific binding site

Studies on rat and human brain revealed both high-affinity (K_{d1} 30–500 nM; B_{max} 0.5–1.8 pmol mg⁻¹ protein) and low-affinity (K_{d2} 1–11 μ M; B_{max} 8–46 pmol mg⁻¹ protein) GHB-specific binding-site components. The [³H]GHB-specific binding site is displaced only by GHB and GHB structural analogs, such as the putative GHB antagonist, NCS-382, and not by GABA, baclofen, muscimol, and bicuculline. Although there are contradictory data, it has been hypothesized that the high-affinity GHB-specific binding site is a G-protein-coupled presynaptic receptor whose activation induces a decrease in adenylyl cyclase. Recently, two clones encoding membrane receptors that exhibit pharmacological and functional responses in accordance with a GHB receptor have been isolated from a human frontal cortex cDNA library.

Although most of the pharmacological effects of GHB appear to be secondary to activation of the GABA_B receptor, there is also evidence suggesting that some physiological actions and effects of exogenously administered GHB may be mediated by activation of its own specific binding sites. For example, NCS-382 has been reported to antagonize GHB-induced changes in the functioning of dopaminergic, GABAergic, and glutamatergic neurons in different areas of the rat brain. Data suggesting the capacity of NCS-382 to antagonize GHB-induced sedation, catalepsy, petit mal-like absences, and reinforcement in rodents have also been reported. To date, however, the lack of potent and specific ligands to the GHB-specific binding site has hampered the understanding of the role of this binding site in GHB neurophysiological and pharmacological actions.

GABA_B receptor

Recent experimental evidence suggests that the GABA_B receptor constitutes a second – and likely the major – site of action of GHB. GHB has been found to interact, as a weak agonist, directly with the GABA_B receptor: the reported K_i values of GHB for the inhibition of different GABA_B receptor radioligands are, indeed, approximately 100 μ M. Notably, these concentrations are reached in the brain after exogenous administration of behaviorally active doses of GHB.

Besides the direct action at the GABA_B receptor, GABA_B-ergic activities of GHB may result from alternative mechanisms. First, GHB can influence GABA neurotransmission by serving as a GABA precursor: the conversion of GHB into GABA may form a pool of GABA, which, in turn, binds to GABA_B receptors. Second, moderate-to-high doses of GHB have been reported to stimulate GABA release in some brain areas: again, this GABA pool may bind to GABA_B receptors. Third, GHB – acting at the GABA_B receptor – may oppose the endocytosis of the receptor, with its retention on the cell surface and prolongation of its functionality.

Accordingly, pretreatment with GABA_B receptor antagonists – namely phaclofen, CGP 35348, and SCH 50911 – has been repeatedly reported to block several effects of GHB, including changes in neuronal activity and absence-like seizures in rats, and reinforcement, motor-incoordination, and sedation/hypnosis in mice. Treatment with GABA_B receptor antagonists resulted also in the complete antagonism of GHB-induced lethality in mice. In close agreement with these antagonism data, behavioral effects of GHB (including hypolocomotion and sedation) were virtually absent in mice with genetic deletion of the GABA_B receptor; notably affinity, density, and anatomical distribution of the GHB-specific binding site were identical in GABA_B-knockout and wild-type mice.

In addition, GHB and the prototypic GABA_B receptor agonist, baclofen, have been reported to share several pharmacological properties, including muscle relaxation, hypomotility, catalepsy, proconvulsant activity, and reduction of severity of alcohol withdrawal syndrome, and alcohol and cocaine self-administration. However, although the pharmacological profile of GHB and baclofen is similar in many respects, important differences also exist: for example, electrophysiological experiments found that GHB disinhibited, while baclofen inhibited, ventral tegmental dopamine neurons, providing a likely explanation as to why GHB is abused (see below) while baclofen is not. Possible explanations for these differences are existence of different functional GABA_B receptor subtypes, to which GHB and baclofen may bind differentially; differential activities of GHB and baclofen at GABA_B autoreceptors and heteroreceptors; and differential conformational changes induced by GHB and baclofen on the GABA_B receptor.

Further demonstrations of the contribution of the GABA_B receptor to the mediation of the pharmacological effects of GHB are provided by the results of drug discrimination studies. Indeed, it has been repeatedly observed that baclofen substituted for GHB in rats and pigeons, suggesting that GHB and baclofen have similar discriminative stimulus effects. Some of these studies also suggested that baclofen was more potent in substituting for GHB as the training dose of GHB was increased, in

agreement with the hypothesis that the psychopharmacological effects of moderate-to-high doses of GHB are primarily mediated by the stimulation of the GABA_B receptor. Additional lines of evidence demonstrated that pretreatment with GABA_B receptor antagonists blocked the discriminative stimulus effects of GHB; in some studies, these antagonists resulted in being more effective in blocking high, rather than low, training doses of GHB.

Despite the above-mentioned full substitution of baclofen for the discriminative stimulus effects of GHB, subsequent studies (1) reported solely a partial substitution and (2) demonstrated that rats could be trained to discriminate GHB from baclofen in a three-choice drug discrimination procedure, providing additional evidence that the effects of GHB and baclofen, although similar in many respects, are not identical, and multiple receptor systems may be involved in the mediation of GHB's discriminative stimulus effects.

GABA_A-benzodiazepine receptor complex

Pharmacological data implicate the GABA_A-benzodiazepine receptor complex in the mediation of some effects of GHB. For example, (1) the anxiolytic effect of GHB in rats has been reported to be prevented by the benzodiazepine receptor antagonist, flumazenil, and (2) different GABA_A receptor ligands and GABA_A receptor positive modulators (such as benzodiazepines and barbiturates) substantially substituted for the discriminative stimulus effects of GHB in rats and pigeons.

The interaction between GHB and the function of the GABA_A-benzodiazepine receptor system does not appear to be secondary to the direct activation of either GABA_A or benzodiazepine binding sites. GHB failed, indeed, to bind to both sites as well as to alter the chloride uptake through the associated channel. It is more likely that the GABAergic effects of GHB result from the conversion of GHB into GABA and/or GHB-induced stimulation of GABA release in specific brain regions; both phenomena would give rise to a GABA pool which may bind to the GABA_A-benzodiazepine receptor complex. A possible, third mechanism is the capacity of GHB to effectively increase, in different brain areas, the levels of allopregnanolone and allotetrahydrodeoxycorticosterone, two endogenous neurosteroids with potent positive modulation activity at the GABA_A-benzodiazepine receptor complex.

Interaction with the Mesocorticolimbic Dopamine System

The mesocorticolimbic dopamine system and GABA_B receptors located in the ventral tegmental area constitute the likely neural substrate of GHB's euphorogenic and addictive properties. A recent, elegant *in vitro* study by Cruz and colleagues provides evidence for a cellular

mechanism that may explain the frequently reported, opposite – and somewhat paradoxical – (1) stimulating and inhibitory effects of GHB on dopaminergic neurotransmission and (2) GHB abuse potential and anticraving properties (see below). The premise stands in the finding that the coupling efficacy of GABA_B receptor to potassium GIRK channels is lower in dopaminergic than GABAergic neurons of the ventral tegmental area. Because of its low affinity for the GABA_B receptor, GHB – at concentrations corresponding to those reached after recreational use – activated, preferentially, the GABA_B receptors in GABAergic neurons, decreasing GABA release, and, in turn, disinhibiting dopamine neurons. At higher concentrations, GHB also activated the GABA_B receptors in the dopaminergic neurons, causing their hyperpolarization. This differential action on GABA_B receptors in the ventral tegmental area apparently explains why GHB is a drug of abuse and, in some circumstances, displays anticraving effects. Conversely, baclofen (because of its high affinity for the GABA_B receptor) inhibited both GABAergic and dopaminergic neurons, thus decreasing dopamine release in the target structures; this is consistent with its well-documented anticraving properties.

Therapeutic Uses

Narcolepsy

One of the most important, current therapeutic uses of GHB is represented by the treatment of narcolepsy. The pharmacological treatment of this disorder is primarily aimed at improving the patient's quality of life (increasing alertness, improving daytime performance, and reducing the occurrence of auxiliary symptoms) with the least adverse effects. Although effective in some narcoleptic patients, central stimulants and tricyclic antidepressants often produce intolerable side effects. Conversely, a series of large double-blind studies indicated that modafinil (a stimulant agent characterized by low abuse potential and good safety profile) and sodium oxybate (the sodium salt of GHB; up to 130 mg kg⁻¹, per os, fractioned in multiple doses) are effective and generally well tolerated for the treatment of sleepiness and cataplexy attacks associated with narcolepsy. Accordingly, modafinil is used for the treatment of excessive daytime sleepiness and sodium oxybate for the treatment of cataplexy. Despite the worries for its increasingly widespread recreational use (since March 2000, GHB has been placed in Schedule I, according to the US Controlled Substances Act; see also below), sodium oxybate (known as Xyrem[®]) is currently the only medication approved by the US Food and Drug Administration (FDA) for the treatment of cataplexy associated with narcolepsy. However, it has been reported that modafinil and sodium oxybate provide, at best, only moderate improvement of sleepiness rather than full

restoration (normalization) of alertness in patients with narcolepsy. Despite the progresses in understanding the pathogenesis of narcolepsy, the ideal treatment for sleepiness due to narcolepsy is not yet available. Moreover, to date, no study has been conducted to compare the efficacy of sodium oxybate to that of tricyclic antidepressants.

Alcoholism

Alcohol dependence (a very frequent mental disorder with a lifetime risk in the general population of approximately 15%) is characterized by an obsessive and compulsive desire (craving) for alcohol and inability to control its consumption, resulting in frequent episodes of intoxication. The pharmacological treatment of alcohol dependence is aimed at helping patients to abstain from, or at least to reduce, alcohol consumption. To date, a number of studies have demonstrated some degree of efficacy of two drugs (the opioid receptor antagonist, naltrexone, and the putative GABA_A and NMDA receptor modulator, acamprosate) in reducing alcohol craving and consumption in alcoholic patients, leading to their approval for this indication in several countries.

At preclinical level, acute and/or repeated administration of GHB has been reported to suppress (1) severity of alcohol withdrawal signs in rats made physically dependent on alcohol, (2) voluntary alcohol consumption in alcohol-preferring rats exposed to the two-bottle alcohol-versus-water choice regimen (experimental model of excessive alcohol drinking), and (3) alcohol's motivational properties in alcohol-preferring rats tested in behavioral procedures modeling craving for alcohol. Although there are contradictory data, evidence from drug discrimination studies suggests that GHB and alcohol may possess similar discriminative stimulus effects.

Preliminary open and double-blind clinical surveys indicated that GHB administration reduced alcohol craving and consumption, promoted abstinence, and ameliorated alcohol withdrawal syndrome in alcoholics. Specifically, two small double-blind studies, with less than a total of 100 alcoholic patients, and seven open studies, with a total of approximately 600 alcoholic patients, demonstrated the efficacy of GHB ($50 \text{ mg kg}^{-1} \text{ day}^{-1}$, per os) in the treatment of alcohol dependence. As predictable, because of GHB's abuse potential (see below), 10–15% of the patients under GHB treatment voluntarily increased their daily GHB dosage. Finally, three double-blind studies (with a total of approximately 180 alcoholic patients) and four open studies (with a total of approximately 650 alcoholic subjects) reported that GHB ($50 \text{ mg kg}^{-1} \text{ day}^{-1}$, per os) was also effective in suppressing the symptomatology of alcohol withdrawal syndrome. On the basis of these lines of evidence, GHB is currently marketed in some European countries for the treatment of alcohol dependence and alcohol withdrawal syndrome.

In terms of mechanism of action, the similarity of the pharmacological profile of GHB and alcohol led to hypothesize that the suppressing effects exerted by GHB on alcohol withdrawal syndrome, alcohol consumption, and craving for alcohol may be due to the substitution of alcohol actions, similar to methadone in heroin addiction.

Other Indications

GHB was originally used as an adjuvant in general anesthesia because it exerts a marked hypnotic action at high doses ($75\text{--}100 \text{ mg kg}^{-1}$, per os). Namely it induces a rapid and irresistible sleep, both in healthy and narcoleptic patients, with a profile often reported to be close to that of natural sleep. Despite the positive results obtained by several studies, the use of GHB in anesthesia has never gained widespread acceptance, probably due to reports of its lacking analgesic properties and producing seizure-type EEG activity in animals that resembles petit mal epilepsy.

Over the years, GHB has also been tested for the treatment of a large number of disorders (i.e., heroin dependence, schizophrenia, depression, anxiety, and fibromyalgia), to relieve pain, anxiety, and tension during delivery and to reduce intracranial pressure. However, to date, the total number of clinical studies performed has been relatively small and most have produced contradictory results.

Recent preclinical evidence suggests that GHB may also function as tissue protectant during oxygen restriction: treatment with GHB, up to 2 h after an ischemic episode (temporary occlusion of the carotid arteries), produced indeed a highly significant protection against histological damage in the hippocampus as well as sensory-motor and cognitive impairments in rats. Preliminary studies also indicated the capacity of GHB to suppress the intravenous self-administration of cocaine, as well as acquisition and reinstatement of cocaine-induced conditioned place preference in rodents, leading to hypothesize a possible use of GHB in the treatment of cocaine addiction.

GHB as a Drug of Abuse

Animal Studies

The positive reinforcing properties and abuse potential of a drug are usually assessed in laboratory animals – with high predictive validity for abuse and dependence potential in humans – by determining its capability to be self-administered, to induce conditioned place preference, and to elicit discriminative stimulus effects similar to those produced by abused drugs. In the case of GHB, its anxiolytic, amnestic, and sedative/hypnotic effects seem also to be important, as anxiolysis, feelings of relaxation,

amnesia, sedation, and hypnosis have been reported to be frequently sought by people abusing GHB (see below).

Self-administration studies

Initial studies reported the capacity of GHB to maintain both oral and intravenous self-administration in rodents. Specifically, rats consumed pharmacologically relevant doses of an oral solution of GHB when it was continuously offered, together with water, under the homecage two-bottle free-choice regimen. All rats displayed days of preference for the GHB solution and consumed an average of approximately $700 \text{ mg kg}^{-1} \text{ day}^{-1}$ GHB, distributed in two to three discrete episodes.

In the intravenous self-administration study, mice received infusions of GHB in response to nose-pokes; the number of nose-pokes by mice actively self-administering GHB was significantly higher in comparison to yoked control mice, which passively received the drug solution. As commonly observed in self-administration studies, the amount of self-administered GHB was an inverted U-shaped function of GHB concentration. GHB self-administration was prevented by treatment with the putative antagonist of the GHB-specific binding site, NCS-382, and the GABA_B receptor agonist, baclofen.

Conversely, the few studies that tested GHB self-administration in nonhuman primates generated more equivocal results, with the number of intravenous infusions of GHB exceeding control levels only in some of the tested monkeys. A modest separation between the reinforcing and sedative/hypnotic effects of GHB might have contributed to the difficult unraveling of a more robust GHB self-administration.

Conditioned place preference studies

Two studies reported the capability of GHB to elicit conditioned place preference in laboratory rodents. In the first study, rats were exposed to the repeated pairing of a specific environment with GHB ($87.5\text{--}350 \text{ mg kg}^{-1}$, i.g.). On the test day, the time spent by GHB-treated rats in the GHB-paired compartment was significantly higher than that recorded in the pre-conditioning session. Consistently, the second study demonstrated that 250 mg kg^{-1} GHB (i.p.) induced a robust conditioned place preference in mice.

Drug discrimination studies

The drug discrimination studies conducted to date using rats and pigeons trained to discriminate GHB from vehicle suggested that alcohol and the benzodiazepines, chlordiazepoxide and diazepam, substituted – fully or only partially, depending on the different studies – for GHB. By contrast, neither *d*-amphetamine, cocaine, morphine, the uncompetitive *N*-methyl-*d*-aspartic acid (NMDA) receptor antagonists, phencyclidine, dizolcipine, and ketamine, nor the cannabinoid receptor

agonist, WIN-55,212-2, elicited clear and consistent (among the different studies) GHB-like internal cues.

When GHB was used as a testing drug (i.e., assessing its capacity to elicit discriminative stimulus effects similar to those of some abusive drugs), it failed to substitute for heroin, phencyclidine, cocaine, and Δ^9 -tetrahydrocannabinol in rats and monkeys, and substituted – although not in all studies – for alcohol in rats.

Collectively, these results suggest that GHB may elicit discriminative stimulus effects similar to those produced by alcohol and benzodiazepines, and these alcohol- and benzodiazepine-like effects of GHB may contribute to its abuse potential. This interpretation is consistent with the clinical reports on GHB producing anxiolysis, relaxation, and alcohol-like subjective effects (see below). Recent data suggest that GHB and phencyclidine potentiate reciprocally their discriminative stimulus effects in rats; translated to humans, these results would suggest that two club drugs, such as GHB and ketamine, often co-abused (see below), may potentiate each other's subjective effects.

Studies on the anxiolytic effect of GHB

The anxiolytic effect of GHB has been consistently observed in the few studies addressing this issue. Studies using mice initially kept in isolation and then exposed to contact with nonaggressive, previously group-housed mice – where the defensive responses displayed by the previously isolated mice are recorded as measures of anxiety – indicated that acutely administered GHB ($50\text{--}200 \text{ mg kg}^{-1}$, i.p.) reduced the frequency of defensive behaviors and increased the number of social interactions.

Studies using the elevated plus maze – a validated model of experimental anxiety, based on the natural avoidance and aversion of rodents for open, anxiogenic spaces and their innate preference for closed, more comforting environment; the proportion of the animal's spontaneous explorations in the open and closed spaces of the maze provides a behavioral measure of its anxiety – indicated that acutely administered GHB ($50\text{--}250 \text{ mg kg}^{-1}$, i.p.; 300 mg kg^{-1} , i.g.) exerted a robust anxiolytic effect in rats, as both time spent in and number of entries into the open arms of the maze were dose-dependently increased by GHB administration. In one of these studies, the benzodiazepine receptor antagonist, flumazenil, blocked this anxiolytic effect of GHB, suggesting the involvement of the GABA_A–benzodiazepine receptor complex in this GHB effect.

The above results, showing the capacity of GHB to produce anxiolysis in experimental models of anxiety, are in agreement with clinical observations reporting that GHB exerted anxiolytic effects in healthy subjects as well as with anecdotal reports of anxiolysis, calmness, and relaxation after its recreational use.

Studies on the amnestic effect of GHB

Different lines of experimental evidence suggest that acute or repeated administration of GHB may disrupt learning and memory processes in rodents. As an example, rats treated with 50–100 mg kg⁻¹ GHB (i.p.) and exposed to the Morris water maze took longer and swam greater distances to find the goal platform, hidden under the water surface, than saline-treated (control) rats.

Studies on the sedative/hypnotic effect of GHB

Sedation/hypnosis was historically one of the first pharmacological effects of GHB to be recognized. High doses of GHB result in the loss of the righting reflex in rats and mice, a reliable and widely used index of sedation/hypnosis. Pharmacological investigations of the receptor system(s) mediating GHB-induced sedation/hypnosis found that the putative antagonist of the GHB-specific binding site, NCS-382, increased, rather than decreased, the duration of loss of righting reflex induced by 1000 mg kg⁻¹ GHB (i.p.) in mice. Conversely, the GABA_B receptor antagonists, SCH 50911 and CGP 46381, completely prevented GHB's sedative/hypnotic effect. These results suggest a critical role of the GABA_B receptor in the mediation of GHB-induced sedation/hypnosis. In addition, SCH 50911 was capable of readily reversing the sedative/hypnotic effect of GHB in mice that had already lost the righting reflex. This finding may bear some relevance in terms of the potential therapeutic use of GABA_B receptor antagonists in reversing the episodes of coma, respiratory depression, and loss of consciousness reported to occur in an increasing number of individuals overdosing GHB.

Clinical Studies

In good agreement with the results of some animal investigations, a number of clinical observations and reports from US agencies have shown that GHB is used as a recreational drug, mostly because of its salient feelings of euphoria, disinhibition, anxiolysis, and relaxation (produced by low-to-moderate doses) and of its ability to produce – at higher doses – sedation and hypnosis, resulting in feelings of unusual refreshment on awakening. GHB effects are often described as closely resembling those of alcohol. GHB – together with its precursors, 1,4-butanediol (1,4-BD) and γ -butyrolactone (GBL) – are presently classified as club drugs, that is, recreational drugs ingested in dance clubs, circuit parties, and all-night dance parties (called raves), often in association with other drugs of abuse, most commonly alcohol, methylenedioxymethamphetamine (ecstasy), or cocaine. In the past, GHB gained some popularity among bodybuilders as a steroid alternative, due to its claimed stimulating effect on growth hormone and anabolic action.

Cases of GHB dose escalation and compulsive use, leading to signs of intoxication (i.e., nausea and vomiting,

drowsiness, dream-like state, reduced muscle tone, loss of consciousness, depressed respiration, and seizures), have been reported to occur with increasing frequency and worsened by the narrow margin of safety of the drug (doses of GHB twice those producing euphoria may indeed lead to coma). These effects appear to be exacerbated when GHB is mixed with alcohol, benzodiazepines, barbiturates, and/or other recreational drugs. Acute poisoning from GHB usually resolves within a few hours without sequelae (this rapid and uneventful recovery often creates a false sense of security in GHB users). Currently, there is no antidote to GHB intoxication; pre-clinical data suggest that potential therapies may however come from the GABA_B receptor antagonists. Instances of withdrawal syndrome (similar to that from alcohol and characterized by anxiety, insomnia, muscle cramps, tremors, hallucinations, and delirium) after discontinuation of high and chronic intake of GHB have been also reported, revealing the capacity of GHB to produce physical dependence. Benzodiazepines have been reported to effectively ameliorate GHB withdrawal syndrome.

In spite of the fact that as early as 1990 the FDA declared all GHB-containing products unsafe and banned their public sale, the use and abuse of GHB has dramatically increased. More recently, GHB has gained notoriety as ‘date rape’ drug (its combined amnestic and hypnotic effects make the victim more vulnerable to sexual assault; its solubility and lack of color and odor facilitate the surreptitious addition of GHB to the victim’s drink). The spreading use of GHB has been enhanced by several factors, including presence on the Internet and in underground literature of recipes for the household manufacturing of GHB, to the frequent mispresentation that it may act as a safe and natural sleep aid, mood- and sexually-enhancing substance with attractive names (just to cite a few: liquid ecstasy, liquid X, easy lay, grievous bodily harm, Great Hormones at Bedtime, Georgia Home Boy, liquid loving), and its low price. Further, accumulating lines of evidence suggest that GHB is frequently replaced by its precursors, 1,4-BD and GBL, which are often preferred over GHB because (1) they produce a profile of psychotropic effects similar to that of GHB (with an even shorter onset) and (2) their purchase is not prohibited as they are commonly used as industrial cleaners and solvents.

Korsakoff's Syndrome

H J Markowitsch, University of Bielefeld, Bielefeld, Germany

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Anterograde amnesia – Inability to form new long-term memories. It is usually specified with reference to a certain time point (onset), such as a brain infarct. In Korsakoff's syndrome, however, the appearance is usually more gradual.

Chronosognosia – Impairment or inability to judge the time. It may manifest as a total absence of any time sense, or as a distortion in the perception of time. The distortion may be an acceleration or a prolongation (retardation) of perceived time epochs.

Confabulation – The creation of episodes or stories which have not occurred in reality in their narrated appearance, but which may be based on, or triggered by a stimulus or idea, anchored in reality.

Episodic-autobiographic memory – A memory system, introduced by Endel Tulving, that deals with personal events or episodes, can be traced back by the time (when) and the place (where) they occurred (or may occur in the future), and that is defined by the conjunction of subjective time, autonoetic consciousness, and the experiencing self. Access to this memory system is usually blocked in patients with Korsakoff's syndrome.

False memory syndrome – Self-created or implanted episodes or remembrances of events which frequently have a true core, but are otherwise the product of fantasy or free associations. Nevertheless, the creator of such memories is unable to reflect on their truth value.

Global amnesia – A term used for characterizing patients who manifest major disturbances in both the anterograde and retrograde memory domains. As memory is at present differentiated into several systems (e.g., episodic-autobiographic memory, semantic memory, and procedural memory), some of which are largely preserved in the so-called globally amnesic patients, the term is nowadays used infrequently.

Nonspecific thalamic nuclei – The thalamus is generally divided into specific and nonspecific nuclei. The specific ones have distinct connections to specific areas of the cerebral cortex, while the nonspecific ones project all over the cortex. Furthermore, the axons of specific nuclei usually reach layer IV of the cerebral cortex, while those of the nonspecific nuclei reach layer I (i.e., the top layer).

Perceptual memory – A memory system which relies on judgments of familiarity (on a presemantic level). It

allows us to distinguish between similar items or objects (e.g., apple, pear, and peach) and to identify an item or object that occurs in variations (e.g., red apple and green apple). This memory system is basically preserved in patients with Korsakoff's syndrome.

Priming – A memory system that stands for a higher likelihood to re-identify stimuli which one had perceived (nonconsciously or subconsciously) in the same or a similar way at a previous time point. This memory is preserved in patients with Korsakoff's syndrome. An old example (from 1911) for its intactness in patients with Korsakoff's syndrome is the so-called Claparede phenomenon. The French psychiatrist, Claparede, had hidden a pin in his hand when shaking hands with the patient with the consequence that she later refused to shake hands, but was apparently unaware of a reason for her behavior, or even of the fact that she had met him before.

Procedural memory – A memory system, acting principally at the subconscious or nonconscious level. It largely deals with mechanical or motor-system-related procedures such as driving a car, playing a piano, or riding a bike. This memory system is preserved in Korsakoff's syndrome.

Retrograde amnesia – Inability to retrieve (recall) memories from the past, which are considered to have been stored in the brain. Retrograde amnesia may be due to a decay of memories (usually after major cortical degeneration), to interference effects, or due to a block in recall, that is, an inability to access and activate neuronal storage places due to damage or degeneration of relevant fiber connections and/or trigger regions.

Ribot's law – The French psychiatrist Theodore Ribot formulated in 1881 a law of regression which stated that the more recent a learned information is, the more likely it is lost, while vice versa, the longer it had been stored, the more likely it is retained. In simple words, it means last in, first out – what entered the brain last is lost first and vice versa.

Semantic memory – A memory system that deals with facts (general knowledge) which are consciously available, but lacks relations with time and space. This memory may be partially preserved in patients with Korsakoff's syndrome.

Theory of mind functions – Ability of normal individuals to reflect upon other peoples' intentions or feelings and to show empathic behavior. It is assumed

that theory of mind functions develops over time and is closely related to an appropriate social interaction early in childhood. The brain region most consistently related to these forms of behavior is the medial and inferolateral (orbitofrontal) prefrontal cortex.

History and First Descriptions

The use of the term 'Korsakoff's syndrome' was suggested in 1897 by Friedrich Jolly, director of the psychiatric clinic of the Berlin Charité, at the Moscow International Medical Congress. The syndrome became popular after the appearance of several publications by Sergej S. Korsakoff (1854–1900; usually spelled Korsakow in German-language publications). Korsakoff had written four articles and one book (on alcoholic paralysis) in Russian language initially, but only due to the subsequent appearance of four further articles in German and an additional one in French language his findings and ideas were disseminated in the Western world. These last five articles appeared between 1887 and 1892. While Korsakoff himself subsumed several different etiologies under the heading of *psychosis polyneuritica seu cerebropathia psychica toxæmica*, all of which led to major cognitive and especially memory deteriorations (e.g., the existence of a decaying fetus in the uterus, puerperal septicemia, typhus, tuberculosis, diabetes mellitus, and a decaying tumor), only a few years later the term was generally (though not exclusively) reserved for an alcohol-consumption-related disease resulting – as Karl Bonhoeffer wrote in his German-language monography on the mental illnesses of chronic drinkers – in four cardinal symptoms which can be translated into anterograde amnesia, defects in remembrance, disorientation, and confabulation. Till now, these symptoms describe the core picture of the Korsakoff's symptomatology which, on the other hand (at least in principle), leaves other intellectual functions (e.g., intelligence) unchanged. The syndrome was also named 'amnesic psychosyndrome' and is of hybrid character: though caused by neurological symptoms, the patients are usually referred to psychiatric clinics. In line with the psychiatric classification of Korsakoff's patients is the use of the terms 'Korsakoff's psychosis' or 'polyneuritic psychoses' (which was even the title of a book in 1906). The older literature used the term Korsakoff's syndrome generously so that some researchers favored to speak of the Korsakoff symptom complex and included patients of various etiologies whose core symptoms were a global amnesia.

Prior to the use of the term 'Korsakoff's psychosis', Carl Wernicke in 1881 had introduced a disease

description which he termed 'acute hemorrhagic superior poliencephalitis' and soon which became known as the acute precursor of Korsakoff's disease ('Wernicke encephalopathy'). As alcohol-related diseases were quite frequent at that time, the differentiation between them was important, as some were more prone to treatment and recovery than others. (In fact, Magnus Huss emphasized already in 1852 that alcohol consumption has a major impact on psychic well-being and between his thesis and the descriptions of Wernicke and Korsakoff the use of the term 'multiple alcoholic neuritis' was common. At the beginning of the twentieth century, a 22-year-old medical student was already diagnosed as a Korsakoff's patient; he, for instance, had admitted that he once drank "prophylactically 28 glasses of schnaps against influenza.")

The alcoholic Korsakoff's syndrome is nowadays termed 'alcohol-induced persisting amnesic syndrome' (*The Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision DSM-IV-TR) or 'alcoholic amnesic syndrome' (*International Classification of Diseases-10* (ICD-10)).

Differential Diagnosis and Anatomical Changes

Korsakoff himself justified his labeling of the disease as 'toxic' with his experience that in all cases investigated "the composition of the blood is altered, toxic substances have accumulated, and it is most likely that these poison the nervous system, whereby in a few cases mostly the peripheral, in others the central nervous system, but frequently both are afflicted to the same degree" (the author's translation). We know nowadays that both, the Wernicke encephalopathy and the Korsakoff's psychosis, are due to malabsorption of vitamin B₁ (thiamine) and may also consequently occur in illnesses in which vitamin B₁ deficiency is prevalent as in beriberi disease. The Wernicke encephalopathy constitutes the initial phase of a process, which may later lead to Korsakoff's psychosis or Korsakoff's syndrome. Wernicke encephalopathy is characterized by oculomotor disturbances (due to degeneration of pontine oculomotor nuclei), ataxia and further gait disturbances, dysarthria, and dysphagia; further symptoms (e.g., somnolence, insomnia, and hypothermia) may follow. Besides degeneration of pontine nuclei, the hypothalamic nuclei may also be affected.

For the Korsakoff's syndrome, a polyneuropathy of the legs (weakness due to the degeneration of peripheral axons) was already noted in the old descriptions. Other symptoms, such as fatigue and changed somatosensory perceptions (e.g., coldness), were noted early as well. However, the main symptomatology lies in the diencephalon where degenerations were noted consistently in both the dorsal and ventral diencephalon in the vicinity of

the cerebrospinal fluid (CSF). In particular, the medial portion of the mediodorsal thalamic nucleus and the medially adjacent paratenial nucleus (a nonspecific thalamic nucleus) are degenerated together with the mammillary bodies on the hypothalamic level. Other nonspecific thalamic nuclei such as the nuclei parafascicularis, submedius, and reuniens were frequently damaged as well. Less consistently, degenerations in the basal forebrain area (nucleus basalis of Meynert) and prefrontal cortical regions were found. A minority of studies also suggests some damage in medial temporal regions (e.g., hippocampal formation). Degeneration of cerebellar neurons is observed quite frequently postmortem, and that of brainstem nuclei (locus ceruleus, raphé nuclei) only occasionally.

Certainly, however, the nervous system damage in both Wernicke encephalopathy and Korsakoff's syndrome differs clearly from that of the other two main alcohol-related disease conditions, affecting the nervous system: alcoholic dementia and Marchiafava–Bignami disease. In alcoholic dementia, there is widespread damage to the neocortex, accompanied by ventricular enlargement, with the consequence of a dementic (instead of a pure amnesic) condition. In Marchiafava–Bignami disease, there is principally a degeneration of the corpus callosum fibers (with laminar cortical sclerosis); excessive drinking of specific sorts of red wine are assumed to trigger the degeneration. The condition leads to deterioration of social functioning, and dementia. In comparison to the other three disease conditions, Marchiafava–Bignami disease is very rare and most of the cases originated from Italy. While all alcohol-related disease types may be accompanied by a more general malnutrition, there are certainly several factors, including genetic variations and (related to the genetic predisposition) enzymatic variations which account for the manifestation of the diseases.

Though reduced in frequency of appearance, there is still a significant number of yearly incidences throughout the world with a preponderance of course in those countries, where alcohol (and in particular CSF) is regularly consumed. The disease can break out at any adult age, depending on the history of alcohol consumption, dietary habits of the individual, and genetic factors.

Behavioral Symptomatology

The noted degenerations accompanying Korsakoff's syndrome fit well with the behavioral symptomatology as damage to the mammillary bodies and more so to the mediodorsal thalamus is known to affect anterograde memory in particular. The mediodorsal nucleus in itself is a complex structure which has been subdivided into more than a dozen, but most commonly into three major

portions – the magnocellular, the parvocellular, and the paralamellar subnuclei, each of them projecting to different regions within the prefrontal cortex (**Figure 1**). The magnocellular subnucleus is related to the orbitofrontal cortex and is therefore related to emotional and personality dimensions. Both the mammillary and the mediodorsal nuclei are part of limbic circuits (Papez circuit and basolateral limbic circuit), which are assumed to play crucial roles in the deep encoding and consolidation of autobiographic episodes and consequently of emotional events (**Figure 2**). Already in the 1920s, the German psychiatrist Ewald Gamper emphasized the importance of the mammillary bodies for an integrated action of the brain. He noted that they constitute a center of the vegetative apparatus which controls and regulates the interaction between midbrain, thalamus, and cortex, with respect to psychic behaviors that their damage results in a disturbance or even abolition between consciousness and the experience in the present so that an increase in experience becomes impossible.

Gamper's notion was taken up in later studies and led to the repeated suggestion that the core symptomatology of Korsakoff's disease is the memory impairment, however, in relation to an underlying more basic deficit in consciousness and time perception. Patients with Korsakoff's syndrome become unable to make mental time travels between past, present, and future, and consequently are stuck in time. This basic deficit results in reduced forms of consciousness and self-awareness, together with an emotional flattening. The bases for this deficit may, in fact, not just lie in the damage of a singular structure such as the mammillary nuclei, but may be seen in an interruption of the circuits depicted in **Figure 2** and also in the relation between thalamus and (prefrontal) cortex, as shown in **Figure 1**. For instance, the mediodorsal nucleus of the thalamus certainly represents another center for both consciousness and memory processing, and other structures – such as the amygdaloid nuclei – closely connected to the mediodorsal nucleus (basolateral limbic circuit; cf. **Figure 2**) – provide (together with the septal nuclei in the basal forebrain) further prominent hubs for an integration of emotion, memory, and consciousness. Theory of mind functions, which have been associated to the orbitofrontal cortex (and also in part to the amygdala), have also been found to be impaired in Korsakoff's patients.

The memory deficit in Korsakoff's syndrome consequently is principally one in the domain of (anterograde) episodic-autobiographic memories, and much less so in the domains of the other memory systems currently defined. With respect to semantic retrograde memories, the deficit is less pronounced as can be inferred from a superior retrieval capacity under conditions of recognition compared to free recall.

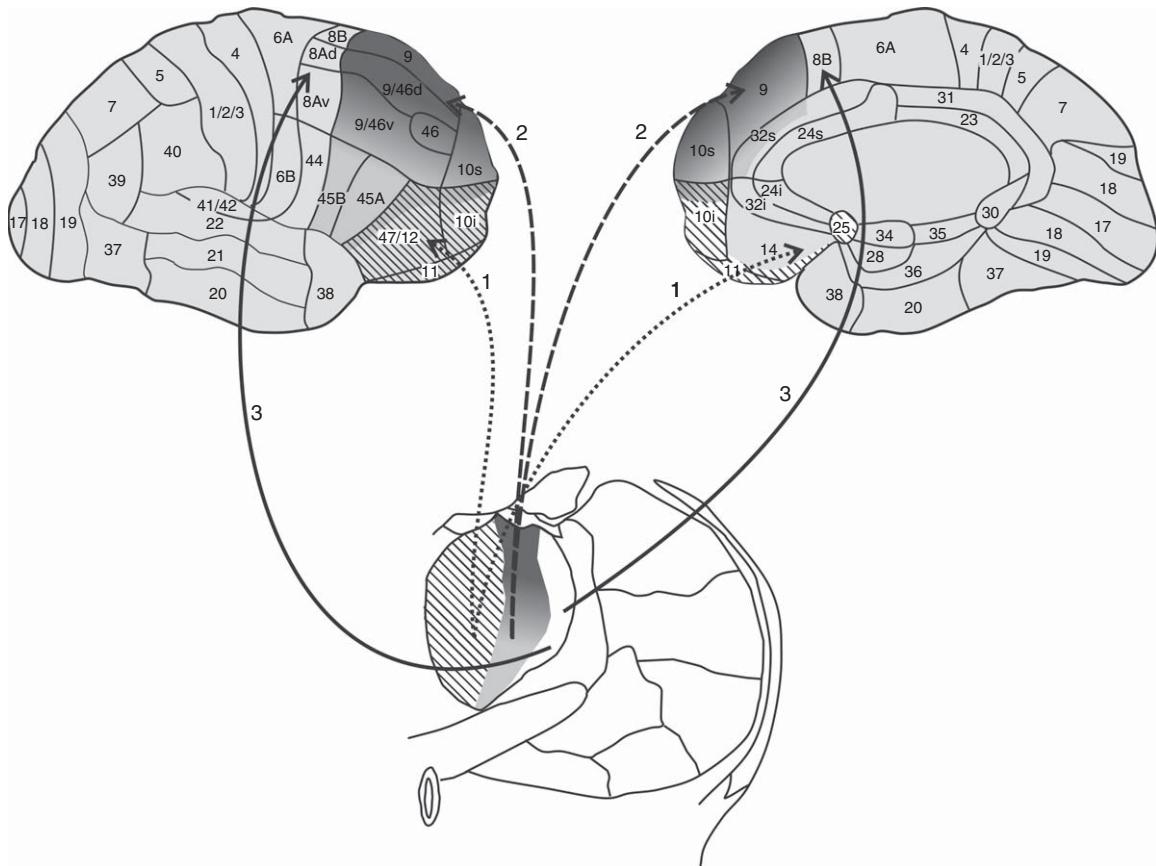

Figure 1 The relations between the mediodorsal thalamus (bottom) and the prefrontal cortex (top). The two top pictures show the lateral and medial cortex with Brodmann areas. Dorsolateral prefrontal regions are darkened, orbitofrontal/ventrofrontal ones are striped. The frontal eye field is composed of areas with the number 8. Within the mediodorsal nucleus of the thalamus the white, lateral area is named parvocellular, the central, gray one parvocellular, and the medial striped one magnocellular. The arrows 1–3 represent corresponding projections of thalamic subnuclei to regions within the prefrontal cortex.

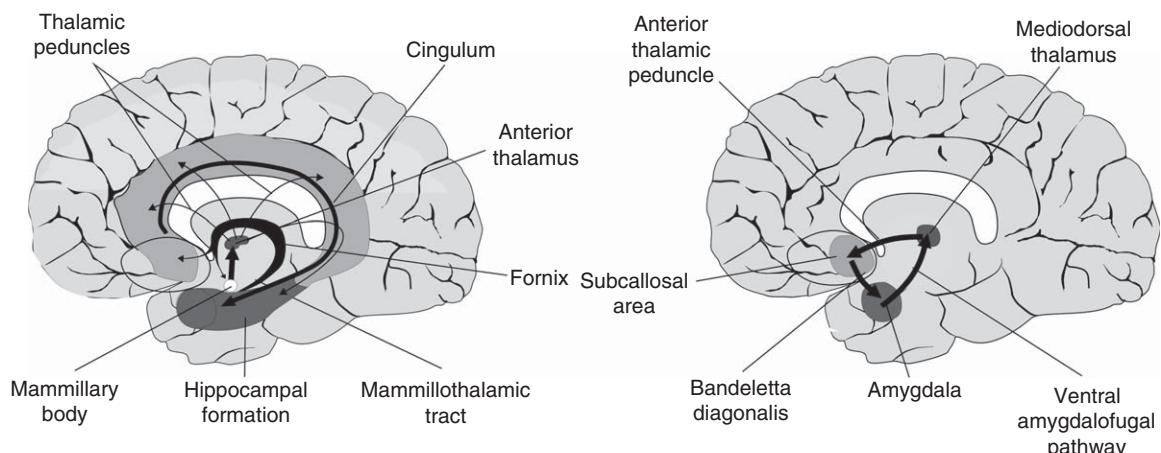

Figure 2 The Papez circuit (left) and the basolateral limbic circuit (right). Both circuits are centrally involved in the processing of conscious information, in particular episodes. They hold information online; associate and synchronize it with the already-existing comparable information and are engaged in the transformation of information for long-term storage.

A case description, given by Korsakoff himself in 1890, clearly demonstrates the differential affection of the various memory systems, showing that procedural memory (chess and card playing) is intact while episodic-autobiographic memory is severely impaired. This case also underlines Korsakoff's excellent power of observation (the author's translation):

At the beginning of a talk the mental disturbance is hardly noticeable; he gives the impression of a person with full mental powers – talking with full reflection, drawing correct deductions on the basis of given premises, playing chess, or a game of cards, in short – he behaves like a mentally healthy subject; only after longer conversation may one notice that he mixes facts quite substantially, and that he is unable to keep in mind anything of what takes place in his environment: he does not remember having eaten, or whether he got up from bed. Sometimes he immediately forgets what has happened to him. Patients of this kind may read for hours one and the same page, because they are unable to keep the contents in mind. They can repeat 20 times the same conversation without realizing the continuous repetition of their stereotyped talk. He does not know persons he met only during the time of his illness, such as the doctor or the nurse, though he sees them consistently; he is always convinced of meeting them for the first time. (Korsakoff, 1890)

Another typical case report referred to a patient with Korsakoff's syndrome who, at the age of 50 years, had retrograde amnesia dating back about three decades, but had a good remembrance of his former school friends, knew Latin syntax, and could name his University professors. He was well educated on questions of political, historical, and moral nature. This and other examples demonstrate that retrograde amnesia in Korsakoff's patients usually follows Ribot's law and that general knowledge (Latin syntax, general education, and social skills), that is, semantic memories are largely preserved. As many other patients with anterograde amnesia, short-term memory, that is, the online holding of information for a few seconds to a few minutes is preserved. An example is a German patient with Korsakoff's syndrome who was able to remember the word *omnipotnekatmehum* (which is not German) for 3 or 4 min.

Korsakoff also referred to 'pseudoreminiscences' or false memories in one of his later studies (in 1891), mentioning that these pseudoreminiscences appear in two forms – as a *déjà vu* feeling and as the appearance of ideas or conceptions which had not occurred in reality. He had noted that most of these pseudoreminiscences had some relation to a true background, and so he hypothesized that they represent a rudimentary form of memory engrams. He furthermore speculated that these rudimentary elements might then combine to constant associative

groups which are first unconscious but at a later stage may come to consciousness and thereby simulate real memories. With these statements, Korsakoff again gave quite modern descriptions of what we currently consider as confabulatory tendencies and false memory syndromes in patients with Korsakoff's syndrome.

When comparing the behavioral disturbances of patients with Korsakoff's syndrome, it becomes apparent that their deficits may vary widely, depending on the particular history of their disease and on a number of personality traits and premorbid intellectual capacities. Aside from memory defects, deficits in executive functions, attention, and emotion/mood can be noted. In most cases, however, at least older retrograde memories are preserved, in particular, when they have some emotional connotation to the patient. For instance, this was observed by Bonhoeffer already in his monography in 1901, where he wrote (the author's translation):

The inability to memorize is complete only exceptionally. Usually it is possible, even in cases with apparent total amnesia, to determine rests of a memory ability. For example, a patient was able to tell me a list of names of familiar distilleries even after a very long time, though he otherwise forgot nearly instantaneously simple, indifferent words, names, or two- or three-figure numbers. (Bonhoeffer, 1901)

With respect to a dissociation of episodic versus procedural memory, it is of interest to note that there are numerous reports of patients who could play chess quite well (e.g., winning against all other occupants of the hospital), or had superior mathematical or calculation abilities, but minutes after finishing their performance had no knowledge of having played a game or calculated. Seen in this way, there is also a disturbance of the patients' ego and of their perception of time – a deficit named 'chronosognosia' or 'amorphism' of the time sense or described as a lost sense of time. Korsakoff's patients may work with pieces of time and points of time, which implies that they may use expressions as weeks and days, but they have lost the ability to experience their duration. The actual comprehension of time and time as a principle of order are disturbed, an observation made already by Wernicke who wrote of a disturbed allopsychic orientation of these patients. In the eyes of other scientists, the principal defect of Korsakoff's patients appears to lie in the inability to relate an actual experience to the total experience of the personality. The patient is fully engaged in the momentaneously experienced situation. The ability of circumspection in the most direct sense of the word is lost. Reasons for this deficit were seen in the passive personality, lacking spontaneity and living in a suspended manner. Such descriptions fit with the neuroanatomical changes in Korsakoff's syndrome, namely the

interrupted Papez and basolateral limbic circuits (cf. [Figure 2](#)), together with an impaired or abolished thalamo-prefrontal mediation (cf. [Figure 1](#)).

Treatment

Treatment of Korsakoff's patients is, of course, based on dietary rules. Nutrition includes strict alcohol abstinence and the application of high doses of thiamine. The doses have to be high, as metabolism of vitamin B₁ is reduced in Korsakoff's patients. Problems may be that some patients may become seriously allergic toward thiamine. As in the majority of Korsakoff's patients the degree of memory loss is not complete and memory training may be helpful, though several authors favor practical work (at least at the beginning of therapeutic interventions). Pharmacological treatment (e.g., with noradrenalin agonists) may be helpful as well. Measuring the glucose metabolism in Korsakoff's patients has shown that their brain metabolism may recover after detoxification.

Glossary

Alcoholism – Alcoholism refers to a drinker's relationship with alcohol and encompasses alcohol abuse and alcohol dependence. Alcohol abuse is defined as repeated use despite recurrent adverse consequences. Alcohol dependence is considered alcohol abuse combined with tolerance, withdrawal, and an uncontrollable drive to drink.

Episodic memory – Episodic memory is currently described as the memory system in charge of the encoding, storage, and retrieval of personally experienced events, associated with a precise spatial and temporal context of encoding. Episodic memory allows the conscious recollection of happenings and events from one's personal past and the mental projection of anticipated events into one's subjective future. Recollection of episodic events includes autonoetic awareness, which is the impression of re-experiencing or reliving the past and mentally traveling back in subjective time.

Perceptual memory – Perceptual memory receives, stores, and makes available to other systems information about perceptual features of physical objects. It is assumed to be involved in perceptual priming in that experience-based changes in perceptual memory may implicitly manifest themselves as enhancement in the perceptual features of objects.

Procedural memory – Procedural memory is defined as the memory system in charge of the encoding, storage, and recovery of the procedures that underlie motor, visuospatial, or cognitive skills.

Semantic memory – Semantic memory refers to the memory of meaning, understanding, general knowledge about the world and other concept-based knowledge unrelated to specific experiences. The level of consciousness associated with semantic memory is noetic because it is independent of context encoding and personal relevance.

Working memory – Working memory is composed of two slave systems and a central executive, sometimes considered as similar to the executive functions. The slave systems are short-term storage systems,

comprising the phonological loop (which processes language-based information) and the visuospatial sketchpad (which processes visuospatial information). The third slave system of working memory is viewed as responsible for maintaining multimodal information and is known as the episodic buffer.

Alcohol dependence is a major public health problem with greater prevalence and severity in developing countries. Acute intoxication alters momentarily brain function while ethanol is still present in the blood but the effects of chronic alcoholism are also discernible in sober alcoholics. Among other medical consequences, chronic alcoholism can indeed lead to more persistent brain damage and attendant functional compromise involving motor, gait and balance and cognitive brain systems. These functional consequences can occur even in uncomplicated alcoholics, that is, those without clinically detectable nutritional deficiencies (e.g., Korsakoff's syndrome) or liver dysfunction often associated with chronic alcoholism. These neuropsychological deficits encompass mainly visuospatial disabilities, executive dysfunctions, and memory impairments. This section focuses on sparing and impairments of memory capacities in uncomplicated alcoholics, within the framework of a memory neostructural intersystemic model (MNESIS; **Figure 1**). Other cognitive functions will be treated only to the extent that they may influence memory functioning.

Episodic Memory

According to MNESIS, of the many components of memory, episodic memory is hierarchically the highest memory system (**Figure 1**): the most sophisticated but also the most sensitive to pathology and toxicity.

Most studies investigating episodic memory in chronic alcoholism examined learning abilities, that is, capacities to improve the level of performance with practice, by means of classical psychometric tasks. These investigations reported a nonspecific nature of learning

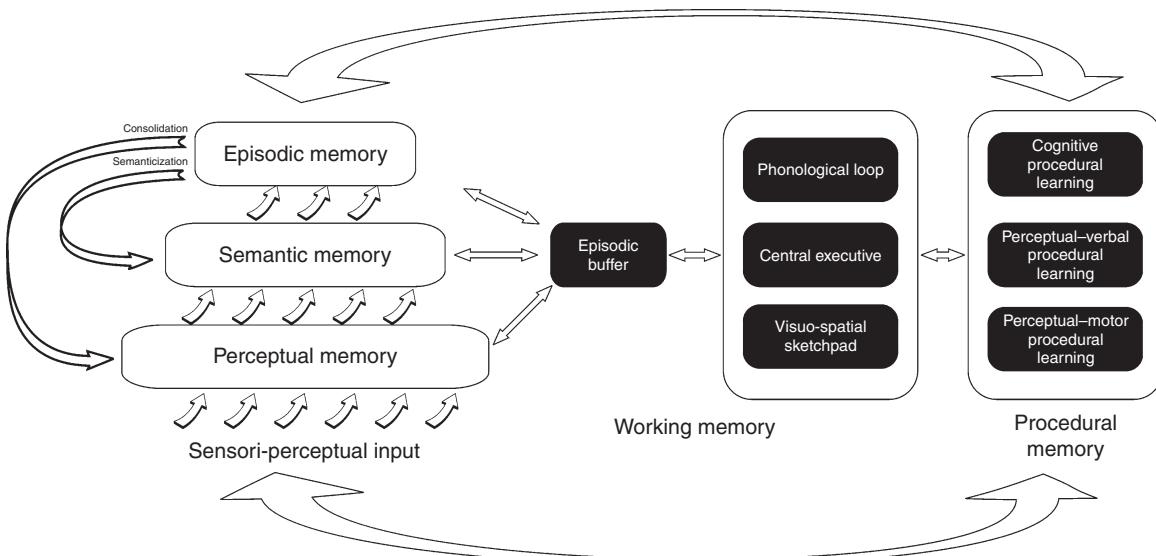

Figure 1 Memory neo-structural inter-systemic model (MNESIS). With permission from Eustache F and Desgranges B (2008) MNESIS: Towards the integration of current multisystem models of memory. *Neuropsychology Review* 18: 53–69.

impairments affecting both verbal (mainly lists of words) and nonverbal information (face-name associations, complex figure, symbols, or visual location). Although sober alcoholics commonly perform below controls, both groups can show evidence of learning over trials. Learning difficulties have sometimes been attributed to an impoverished generation of spontaneous learning strategies, which may also account for the poor performance on free recall tasks. Recently sober alcoholics, however, can show impairment in recognizing test information after spontaneous encoding as well as on a free recall after deep encoding. The timing of these deficits suggests that at alcohol treatment entry, alcoholics present an impairment of both encoding and retrieval abilities.

The spatiotemporal context of encoding is also impaired in alcoholism, affecting both temporal order and spatial context recognition. Moreover, alcoholic subjects tend not to recall complete episodes, that is, correct factual information associated with the correct spatiotemporal context of encoding, indicating that episodic memories are not complete. Source memory, which is the ability to discriminate the origin or source of information, seems also affected by chronic alcoholism. Lastly, alcoholism leads to a deficit of autoetic consciousness and a lack of confidence in the accuracy of one's decisions. Taken together, these findings suggest that most components of episodic memory are impaired in uncomplicated alcoholic subjects.

Because of the connections between episodic memory and working memory, a recent study examined whether executive dysfunctions could explain the episodic memory impairments in alcoholics, that is, whether executive dysfunction could be responsible for the deterioration of certain episodic memory processes. Findings revealed

that the episodic memory impairment observed in uncomplicated alcoholic subjects may not be linked solely to executive dysfunction. One exception was observed for learning abilities, which may draw heavily on strategies to improve performances during repeated presentations of the information. Chronic alcoholism may cause genuine episodic memory deficits and not simply an indirect consequence of executive function deficits.

There may well be a link between the episodic memory disturbance in uncomplicated alcoholic subjects and neuroanatomical abnormalities. For example, postmortem investigations have reported atrophy in the mammillary bodies and dorsomedial nucleus of the thalamus even in uncomplicated alcoholics. *In vivo* imaging studies also reported volume loss in mammillary body, hippocampus and thalamus but failed to show any correlation between gray matter shrinkage and episodic memory impairments. Rather, this memory disorder may be associated with damage of white matter fiber bundles and tracts, in particular, the cingulate bundle and the fornix, which interconnect the hippocampus, thalamus, and mammillary body in the Papez's circuit, thus leading to an interruption of this brain network. This explanation remains hypothetical and requires experimental verification.

Autobiographical memory, which is formed by different types of representation from specific personal events (episodic components) to general knowledge about one-self (semantic component), has been reported impaired in uncomplicated alcoholics. When thoroughly evaluated and compared with nonalcoholic controls, alcoholics were seen to recall specific memories less frequently and general memories more frequently, suggesting

difficulties in strategically accessing episodic autobiographical memory. Nevertheless, when a specific past event was accessed, alcoholic subjects subjectively experienced as many sensory and contextual details associated with the event as controls.

Semantic Memory

In our model of memory processes, episodic memory and semantic memory are connected to each other by two arrows (**Figure 1**). The first one reflects the fact that information is encoded in semantic memory before being encoding in episodic memory, whereas the second one reflects the process of memory semanticization of episodic memories over time.

Early in sobriety, alcoholics present with impairment in novel semantic encoding and more specifically a deficit in acquiring new labels information. Learning new categories and features can be achieved by alcoholics but at a slower rate than controls. Compared with controls, alcoholics invoke different and inefficient cognitive strategies to attempt to compensate for impaired episodic and working memory. Active and strategic learning appears therefore to be not up to par with controls, leading to the shallower (more fragile) encoding of the new information in episodic memory. Alcoholic subjects invoked specific cognitive processes, such as working memory abilities, in addition to those invoked by controls. Compensatory strategies have already been suggested in neuroimaging studies showing that alcoholics recruit higher-level cognitive systems to perform even simple tasks at control levels.

A recent investigation revealed that, in uncomplicated alcoholics, a high level of anxiety was associated with significant difficulties in inhibiting alcohol-related verbal stimuli. The authors interpreted the results as the effect of anxiety that may facilitate the activation of alcohol-related concepts in semantic memory.

Perceptual Memory

Perceptual memory includes both conscious and nonconscious processing of sensori-perceptual information. It can be considered the root of the human memory systems (**Figure 1**), because it is through perceptual memory that information is subsequently and progressively encoded in the different representation memory systems.

While deficits in basic visuospatial abilities have been consistently documented in uncomplicated alcoholic subjects, less is known about implicit perceptual learning processes. One of the implicit perceptual learning tasks is the picture fragment completion stimuli. The ability to identify the stimuli on initial testing requires intact

visuospatial abilities, whereas identification of these stimuli at later testing sessions includes an additional implicit memory component. Given that picture fragment completion tasks can be performed at normal levels by subjects with episodic memory deficits, these tests are assumed to assess implicit memory for perceptual features, that is, perceptual memory.

When using this implicit perceptual learning paradigm, alcoholic subjects were showed to present the commonly reported pattern of impairment in visuoperception but normal levels of perceptual learning, suggesting that they were able to take normal advantage of prior exposure to fragmented line drawings to enhance performance. However, although the alcoholics performed at the same level as the controls on the implicit perceptual learning task, each group used different strategies to perform the task successfully. Alcoholic subjects invoked higher-order executive processes to establish normal learning. This difference in strategy was further indication that alcoholics recruit more cognitively demanding and less efficient neural systems than controls to perform a task at normal levels, possibly because of alcoholism-related dysfunction in optimal neural systems.

Working Memory

In MNESIS (**Figure 1**), working memory is in the center, occupying therefore a strategic position between the three long-term representation systems (episodic memory, semantic memory, and perceptual memory) and procedural memory.

Regarding the nature of the information processed by this memory system, both verbal and nonverbal components can be impaired in uncomplicated alcoholics although nonverbal memory is observed as more severely altered.

The central executive of working memory is compromised in uncomplicated alcoholic subjects. This system is heavily involved in handling novel situations outside the automatic processes. It is regarded as being similar to the executive functions, which are necessary for goal-directed behavior. They include the ability to initiate and stop actions, to monitor and change behavior as needed, and to plan future behavior when faced with novel tasks and situations. Executive functions, therefore, enable us to anticipate outcomes and adapt to changing situations. Inhibition, flexibility, categorization, deduction of rules, organization, updating, and planning have mostly been found to be impaired in uncomplicated alcoholic subjects. The binding of multimodal information, reflecting the episodic buffer, is also impaired in alcoholic subjects, as are the other slave systems of working memory.

Neuroanatomical substrates of the executive dysfunctions are classically associated with compromise of

prefrontal structure or metabolism. Additional substrates of dysfunction involve damage to gray and white matter structure of frontocerebellar circuitry, which may be better predictors of executive dysfunctioning than alterations in prefrontal regions alone. More specifically, smaller white matter volume in the midbrain of alcohol-dependent subjects was related to impaired performance in executive tasks involving flexibility capacities. Uncomplicated alcoholic subjects have fewer white matter fiber tracts coursing between the midbrain and the pons and a smaller pons volume than controls. Furthermore, the number of fibers identified with neuroimaging (diffusion tensor imaging, DTI) was correlated with the alcoholics' performance in the flexibility task. Previous investigations also provided evidence of an association between certain components of executive functions (attention skills and inhibition) and white matter structure in the corpus callosum and between verbal working memory and the medial septal/diagonal band. These later findings suggest therefore a cholinergic mechanism for the working memory impairments in uncomplicated alcoholics.

Functional magnetic resonance imaging (fMRI) provides further information about the status of working memory in uncomplicated alcoholics. Such fMRI studies show that while performing a verbal working memory task, alcoholics exhibit greater activation in the left frontal and right cerebellar regions than controls, suggesting that the articulatory control system of verbal working memory requires a compensatory increase in alcoholics in order to maintain the same level of performance. Such functional reorganization was also revealed in alcoholics engaged in a visual spatial working memory task. In this case, despite equivalence in behavioural performance, uncomplicated alcoholics activated the ventral 'what' stream generally used for encoding of verbal material, whereas controls activated the dorsal 'where' stream appropriately used to encode visuospatial information.

Procedural Memory

Procedural memory is shown on the right-hand side of MNESIS (**Figure 1**). This memory system is connected to both episodic memory and working memory, which are required during encoding of a new procedure, that is, during procedural learning. Procedural learning is a dynamic process involving different phases (cognitive, associative, and autonomous) and resulting in the automation of the procedure. The cognitive stage of such acquisition involves episodic memory and working memory; impairments of these memory systems in uncomplicated alcoholics may therefore hinder cognitive procedural acquisition and hamper its automation. Early in alcohol sobriety, uncomplicated alcoholic subjects

solve cognitive procedural problems more slowly than the controls and make more moves to achieve a new cognitive procedure. Alcoholics are also slower than controls, sacrificing speed for accuracy during learning. By dint of repeating numerous trials, alcoholic subjects manage to catch up with the controls and achieve similar performance. However, alcoholics are typically not at the same stage of learning as controls would be, being still in a problem-solving mode at the end of the learning phase and implementing higher-order cognitive processes to achieve normal learning levels. Their episodic and working memory deficits may prevent them from completing the cognitive and associative stages and thus from automating the cognitive procedure. A recent sober uncomplicated alcoholic may be able to acquire a new cognitive procedure, but it would be more difficult and take longer than nonalcoholic subjects.

In addition to procedural memory, other forms of implicit memory processes have been examined. For example, alcoholism is associated with impairments in conditional responding, especially when the learned response depends on former reactions or the inhibition of the prepotent response patterns. Deficits of associative learning, using eyeblink classical conditioning, are also reported in uncomplicated alcoholics. When using reversal eyeblink classical conditioning, which involves an inversion of the two conditioned stimuli during the task, the alcoholics who learn the initial discrimination are impaired in acquiring the reversed one. These findings suggest that a factor in the maintenance of alcohol dependence is the presence of alcoholic-related associative responses that interfere with the ability to learn new adaptive associations.

Factors Contributing to the Heterogeneity of Memory Disorders in Uncomplicated Alcoholism

Human alcohol consumption is marked by considerable heterogeneity in its consequences on cognition including memory abilities. Potential sources of variability include age, gender, alcohol use pattern, smoking, nutritional status, and psychiatric comorbidity.

Normal aging disproportionately affects some brain regions, and these compromised brain areas in the healthy elderly are also vulnerable to alcohol neurotoxicity. Age and alcoholism interact thereby increasing brain vulnerability to alcohol's neurotoxicity in aging, which, in turn, increases the chances of more severely impaired cognitive capacities in the elderly who abuse alcohol.

Gender may also be a factor influencing the nature and the severity of the memory disorders in uncomplicated alcoholics. Patterns of differences occurring in the

cognitive profiles of healthy men and women may be affected by alcohol use.

The relationships between drinking history and severity of memory disorders are still a matter of debate. Drinking history can be characterized in terms of age at onset (first contact with alcohol or onset of alcoholism), quantity (number of drinks per day), and frequency (number of days drinking per month) of alcohol consumption. Studies yield heterogeneous results, and it remains unknown why some alcoholic subjects exhibit severe impairments, whereas others with measurably similar alcohol consumption levels appear to drink with impunity.

A growing body of evidence suggests chronic cigarette smoking which occurs with high prevalence in alcoholism, itself results in abnormalities in brain morphology, blood flow, neurochemistry, and neurophysiology, leading to cognitive dysfunction. Alcoholism and smoking being frequently associated, the effect of alcoholism *per se* and its interaction with smoking require further examination.

Sustained heavy drinking frequently occurs at the expense of eating, rendering alcoholics at risk for nutritional depletion. In particular, thiamine deficiency appears even in alcoholics without clinically apparent Wernicke encephalopathy and may interact with neurotoxic effects of alcohol *per se*.

Almost 60% of the alcoholics have at least one additional psychiatric (mood or anxiety) or past substance-dependence comorbidity. However, psychiatric comorbidity does not necessarily compound poor cognitive test performance associated with chronic alcohol misuse, suggesting that poorer cognitive performance is more a function of alcoholism *per se* than nonalcoholic comorbidity.

Reversibility

Some cognitive recovery may take place with sustained abstinence from alcohol consumption. The greatest recovery occurs during the first month of drinking cessation, but further improvements are detectable with prolonged abstinence. Indeed, alcoholics have been shown to present memory capacities equivalent to those of control subjects after several years of abstinence. However, some investigations report persistent cognitive impairments in alcoholics 6 months after drinking cessation and even after more than 5 years' abstinence. The lack of accuracy as to the length of abstinence required for normalization may be due to variability in the ability of different cognitive functions to recover, complicating simultaneous analysis of several domains of cognition.

Three main methodological issues inherent to the investigation of cognitive recovery with abstinence from alcohol in alcohol-dependent individuals have to be considered. First, the interaction between age and length of

abstinence may induce a slowdown in the course of recovery in the older alcoholics, notably because of a decrease in brain plasticity in aging. Second, the use of cross-sectional comparisons between groups of alcoholic subjects who are abstinent for two different lengths is not recommended. Even when patient groups are matched in demographic and alcoholism characteristics as closely as possible, cross-sectional comparisons yield less reliable results than longitudinal studies, which monitor recovery in a single sample of subjects, notably because the period of abstinence is variable and represents only a mean or a threshold, leading to an inaccurate picture of the differences between groups. The last factor, which has to be considered when evaluating normalization of abilities, is interim drinking during the follow-up. For example, interim drinking is considered differently according to the investigations, in that alcoholic subjects who have resumed drinking to a modest degree (perhaps just one drink) may be included either in the abstinent or in the relapsed group, whereas some studies consider abstinent subjects as "having not drunk to intoxication." Under conditions of strictly monitored long-term alcohol abstinence, memory capacities have been showed to return to normal in small samples of alcoholics.

Recovery of cognitive function has occasionally been associated with at least partial recovery of alcoholism-related brain shrinkage. This brain recovery may be selective according to the neuropsychological changes observed, and associations were observed between memory improvement and lateral ventricular volume change. In effect, the reduction of alcoholics' brain weight and volume, which is well documented, is largely due to an overall decrease of white matter volume, including demyelination, axonal and glial loss, and dehydration. Recent findings suggested that the reversibility of the brain damage does not only reflect a rehydration but a growth of the white matter volume associated with increased levels of *N*-acetylaspartate (a marker of neuronal integrity) and choline (a marker of cell membrane turnover) and modest increase in cortical gray matter volume. Regarding the hippocampus, a principal neural substrate of episodic memory consolidation, experiments using rodents models of binge drinking indicate that adult neurogenesis in the hippocampus is inhibited during alcohol intoxication but returns to normal with cessation of drinking. Whether substantial and functionally viable neurogenesis occurs in the human hippocampus or other brain structures remains unknown.

Relapse Prediction

Longitudinal studies of alcoholic subjects provide evidence for recovery of cognitive functions with abstinence and provide an opportunity to explore

whether cognitive abilities at initial testing are predictive of abstinence or relapse and therefore the outcome of treatment. For example, are alcoholic subjects with the lower cognitive functions at alcohol treatment entry the most likely to relapse? Conversely, are alcoholics with the highest cognitive functions the most likely to remain abstinent? Even though efficient memory functioning would appear to promote abstinence, the literature is contradictory. Some investigations reported that poor cognitive functioning, and more particularly memory disorders, are predictive of difficulty in maintaining long-term abstinence from alcohol, whereas others have failed to find any such link. Other factors, such as depressed mood, social status, and feeling of self efficacy, may be more relevant predictors than cognitive impairments. Whatever the predictive value of the neuropsychological impairments at alcohol treatment entry, they may be useful indicators when it comes to choosing the best treatment at the best time for each alcoholic subject.

Uncomplicated Alcoholism to Korsakoff's Syndrome: A Graded Effect of Memory Impairments

It was suggested many years ago that alcoholic Korsakoff patients, uncomplicated alcoholics, and heavy social drinkers represent separate points along a single scale of cognitive impairments. Continuity between alcoholic Korsakoff patients and uncomplicated alcoholics has actually been demonstrated in numerous neuropsychological investigations of cognitive functions except memory. Indeed, results of initial studies did not provide strong evidence of continuities in memory processes. Two possible explanations were therefore provided: one was that memory deficits appear when alcoholism is combined

with a thiamine deficiency, and a second was that investigators did not employ tests appropriate to gauge uncomplicated alcoholics' memory disorders and did not distinguish the different component processes of memory, each with the potential of being differentially affected. Recent works showing that the pattern of memory sparing and impairment in uncomplicated alcoholics (**Table 1**) is broadly consistent with that of alcoholic Korsakoff patients challenge the question of the specificity of the memory profile in Korsakoff's syndrome and revive the continuity hypothesis of disordered memory processes.

Most of the memory deficits in alcoholic Korsakoff subjects seem to be already present in uncomplicated alcoholics, either in an equivalent form (working memory) or in a less severe one (episodic memory). Regarding episodic memory, alcoholic Korsakoff subjects may therefore be considered as uncomplicated alcoholics, whose existing deficits due to the neurotoxic effects of ethanol on Papez circuit have been exacerbated by thiamine deficiency, leading to amnesia syndrome. Working memory impairments do not seem to be specific to Korsakoff's syndrome and may simply reflect the effects of chronic alcohol consumption, for example, on frontocerebellar circuitry.

These findings therefore lend weight to a revised continuity theory between uncomplicated alcoholics and alcoholic Korsakoff subjects. Indeed, the continuity theory postulates that alcohol has a neurotoxic effect on brain function and there is therefore a relationship between cognitive performance and drinking history. As we discussed previously, researchers have so far failed to demonstrate any robust or consistent relation between neuropsychological deficits and drinking history, notably because it is difficult to gain an accurate picture of the drinking history of alcoholic patients, let alone alcoholic Korsakoff patients. Even though their drinking history

may not explain the heterogeneity of alcoholics' cognitive abilities, the theory of a continuum between non-Korsakoff alcoholics and alcoholic Korsakoff patients may at least have a heuristic value and extend all the way to alcohol dementia. These neuropsychological findings are corroborated by neuroimaging results indicating graded regional brain volume shrinkage from uncomplicated alcoholics to alcoholic Korsakoff patients.

Clinical Implications

Neuropsychological impairments, and more especially memory disorders, could impede uncomplicated alcoholic subjects from benefiting fully from cognitive and behavioral treatment approaches for alcohol dependence. Indeed, cognitive dysfunctions of alcoholic subjects have been shown to be linked with the outcome of the treatment. Successful alcohol treatment and subsequent abstinence may require high-level cognitive processes and consequently may not be feasible by alcoholic subjects with extensive impaired memory capacities. Because the classic treatment of alcoholism, notably based on cognitive behavioral treatment, may rely on the acquisition of novel semantic information or cognitive procedures, not all alcoholic subjects may be cognitively able to acquire such complex novel knowledge. Consequently, current forms of treatment may not be appropriate for alcoholic subjects with neuropsychological impairments. The assessment of neuropsychological deficits at alcohol treatment entry may prove to be useful for clinical decision making and the choice of the most appropriate treatment. Lastly, repetition of material or procedures to be learned would be a useful strategy with alcoholics who are in educational treatment programs, wherein they are expected to acquire new information that may be relevant in later settings. The neuropsychological screening of these cognitive impairments may prove to be useful at alcohol treatment entry, allowing clinicians to ascertain whether alcoholic subjects are capable of undergoing standard therapy or whether it needs to be adjusted in order to take account of memory disorders. Follow-up testing would document change in memory function that could alter therapeutic programs dynamically.

According to a recent epidemiological survey in the United States (NESARC), only about a quarter of alcoholics ever seek treatment. Some current studies indicate that those alcoholics who remain drinkers are not necessarily affected by alcoholism to a significant extent. These alcoholics may enjoy a special protection, such as relatively safe drinking pattern or safe environment for drinking (such as healthy diet or exercise).

Regarding the graded effect of memory disorders from uncomplicated alcoholics to alcoholic Korsakoff subjects, findings emphasize the need for uncomplicated alcoholics to undergo a neuropsychological assessment, focusing on memory abilities. Those with equivocal episodic memory performances, similar to those of Korsakoff subjects, may be regarded as borderline alcoholics at risk of developing Korsakoff's syndrome and should receive particular attention and preventive action before their memory disorders have harmful repercussions on their daily lives.

Glossary

Chromatin – Material in the cell nucleus composed of DNA, histones, and non-histone proteins. The structure of chromatin (whether its open or closed) around a gene determines the rate at which that gene is transcribed.

Chromatin immunoprecipitation (ChIP) – Experimental procedure in which lightly fixed chromatin is fragmented and then immunoprecipitated with an antibody to a histone modification, transcription factor, or some other nuclear regulatory protein; the level of a given gene in the immunoprecipitate is then quantified.

Dominant-negative antagonist – A protein, which by itself is inactive biologically, inhibits the activity of another endogenous protein.

Gene expression – The process controlling the types and amounts of individual genes expressed (transcribed into mRNA and protein) in a tissue.

Histone – The major protein constituent of chromatin. Covalent modification of histones (e.g., their acetylation, methylation, and phosphorylation) controls the degree to which chromatin is active or inactive.

Histone acetyl transferase – Enzymes that add acetyl groups to histones and thereby generally promote gene expression.

Histone deacetylase – Enzymes that remove acetyl groups to histones and thereby generally inhibit gene expression.

Nucleosome – Unit of chromatin consisting of the DNA double helix wound around an octomeric complex of eight histone proteins.

Protein phosphorylation – A process by which phosphor groups are added to other proteins by enzymes called protein kinases. Phospho groups, because of their large size and charge, alter the activities of proteins, for example, they can activate TFs.

Second messenger – Signals in the cells that are induced by neurotransmitter-receptor interactions and mediate the effect of those interations on virtually all aspects of a nerve cell's function, including the regulation of gene expression.

Transcription – The process by which a gene is transcribed into its encoded mRNA (messenger RNA). mRNA is then translated into protein.

Transcription factor – A class of protein that binds to specific receptor sites present in target genes and thereby increases or decreases the extent to which that gene is expressed.

The Synapse as the Target of Drugs of Abuse

All drugs of abuse initially affect the brain by influencing the amount of a neurotransmitter present at the synapse or by interacting with specific neurotransmitter receptors. **Table 1** lists examples of such acute pharmacological actions of some commonly used drugs of abuse. The fact that drugs of abuse initially influence different neurotransmitter and receptor systems in the brain explains the very different actions produced by these drugs acutely. For example, the presence of high levels of opioid receptors in the brainstem and spinal cord explains why opiates can exert such profound effects on respiration, level of consciousness, and nociception. In contrast, the importance of noradrenergic mechanisms in the regulation of cardiac function explains why cocaine can exert potent cardiotoxic effects.

In contrast to the many disparate acute actions of drugs of abuse, the drugs exert some common behavioral effects: they are all positively reinforcing after short-term exposure and cause a similar behavioral syndrome (addiction) in vulnerable individuals following long-term exposure. This suggests that there are certain regions of the brain where the distinct, acute, pharmacological actions of these drugs converge. Indeed, we now know that activation of opioid receptors (by opiates), inhibition of monoamine reuptake (by cocaine), or facilitation of γ -aminobutyric acid (GABA)-ergic and inhibition of N-methyl-D-aspartate (NMDA) glutamatergic neurotransmission (by ethanol) elicit some common neurobiological responses – in the brain's reward circuitry – that mediate their reinforcing and addicting properties. The best-established components of the reward circuitry, as discussed elsewhere in this encyclopedia, include dopamine (DA)ergic neurons in the ventral tegmental area (VTA) of the midbrain and their projections to the nucleus accumbens (NAcc) and several other limbic forebrain regions.

Transcriptional Mechanisms of Addiction

The acute pharmacological actions of a drug of abuse *per se* do not explain the long-term effects of repeated drug exposure. To understand such long-term effects, it is

Table 1 Examples of acute pharmacologic actions of drugs of abuse

Drug	Action
Opiates	Agonist at μ , δ , and κ opioid receptors ^a
Cocaine	Inhibits monoamine reuptake transporters
Amphetamine	Stimulates monoamine release
Ethanol	Facilitates GABA _A receptor function and inhibits NMDA glutamate receptor function ^b
Nicotine	Agonist at nicotinic acetylcholine receptors
Cannabinoids	Agonist at CB ₁ cannabinoid receptors ^c
Hallucinogens	Partial agonist at 5HT _{2A} serotonin receptors
Phencyclidine (PCP)	Antagonist at NMDA glutamate receptors

^aActivity at μ and δ receptors is thought to mediate the reinforcing actions of opiates.

^bThe mechanism by which ethanol produces these effects has not been established. In addition, ethanol affects many other neurotransmitter systems in brain.

^cSeveral lipid-related molecules have been implicated as endogenous ligands for this receptor, such as anandamide.

GABA_A, γ -aminobutyric acid A; NMDA, *N*-methyl-D-aspartate; 5HT₂, 5-hydroxytryptamine (serotonin) 2.

necessary to understand adaptive mechanisms in neurons, which involve the ability of neurotransmitter–receptor interactions to regulate virtually every process in a neuron over a longer timescale. Such effects are mediated by altering the functional activity of proteins that are already present in the neuron or by regulating the amount of the proteins through the regulation of gene expression. The remainder of this article provides an overview of the mechanisms by which repeated exposure to a drug of abuse regulates gene expression in brain reward regions.

The activation or repression of specific transcriptional patterns is part of a neuron's response to virtually every cellular signal. Accordingly, transcriptional regulation can be viewed as the ultimate target of signal transduction cascades, and is a critical mediator of a wide range of neuroadaptations in neural structure, connectivity, and function, which occur in response to environmental stimuli, such as drugs of abuse.

Considering the importance placed on alterations in gene expression in addiction, it is surprising that only a small number of transcription factors have, to date, been directly implicated in addictive disorders. Moreover, even less is known about the target genes that are regulated by these transcription factors to mediate stable behavioral change. This article focuses on those transcription factors which have been shown to regulate the activity of the brain's reward pathways in animal models of drug addiction.

CREB–CREM–ATF Family

The cyclic adenosine monophosphate (cAMP) response-element-binding protein (CREB) family of transcription factors, in addition to CREB itself, include cAMP

response-element modulator (CREM) and activators of transcription (ATFs). These proteins are bZip transcription factors; bZip refers to the basic domain (b) of the proteins that binds a specific consensus sequence (cAMP response element (CRE)) in gene promoter regions, and the leucine zipper domain (Zip) which allows homo- or heterodimerization of two bZip transcription factors necessary for the transcriptional activity of these proteins. Although most proteins of this family heterodimerize selectively with other CREB–CREM–ATF transcription factors, some family members (specifically ATF2) can dimerize with bZips of other families and act on distinct response elements. To complicate matters further, there are many splice variants of these transcription factors that can act as potent repressors of transcription due to the absence of activation domains in the proteins. An example is inducible cAMP early repressor (ICER) – a product of the CREM gene, which represses CRE-mediated transcription.

Most evidence for a role of the CREB–CREM–ATF family in brain reward regions in addiction models has focused on CREB itself. CREB is activated both in the NAcc and VTA in response to acute and chronic administration of certain drugs of abuse (cocaine, amphetamine, opiates, etc.). This has been shown by direct demonstration of increases in the phosphorylation of CREB at ser133, which is required for its transcriptional activation. It has also been demonstrated by use of CRE-LacZ transgenic mice, in which CRE transcriptional activity is induced in brain reward regions under these conditions.

There is now a large body of evidence to support the view that CREB activation in the NAcc by drugs of abuse mediates a form of tolerance and dependence to drug exposure. Viral-mediated overexpression of CREB in the NAcc decreases an animal's sensitivity to the rewarding effects of several drugs of abuse, whereas blockade of CREB function in this region, via overexpression of a dominant-negative antagonist of CREB, causes the opposite effect. Studies of bitransgenic mice – in which CREB or its dominant negative is inducibly expressed in the NAcc of adult animals – as well as studies of CREB knockdown mice, generally support these conclusions. Interestingly, increased CREB activity in the NAcc also reduces an animal's sensitivity to natural rewards and induces depression-like behavior in several rodent assays. Thus, CREB activation in the NAcc by drugs of abuse could mediate some of the negative emotional symptoms seen in many drug addicts during early phases of withdrawal.

CREB activity in the VTA is more complex. Here, CREB can either decrease or increase an animal's sensitivity to a drug of abuse depending on the subregion of the VTA involved. Further work is needed to better understand these actions of CREB, as well as the influence of several other members of the CREB–CREM–ATF family in regulating responses to drugs of

abuse. There is recent evidence, for example, that drugs of abuse – in addition to activating CREB – also activate ICER as well as ATF2, ATF3, and ATF4 in the NAcc. Consequently, the net effect of drug exposure on the expression of CRE-containing target genes is likely to be very complex. For example, activation of ICER – a transcriptional repressor – may serve to dampen the functional consequences of CREB (and of some of the ATFs) induced during the course of drug exposure.

The effects of CREB and related transcription factors on NAcc function and behavior are mediated in part by the opioid peptide dynorphin, which is increased by CREB and decreased upon inactivation of CREB. Dynorphin acts on κ -opioid receptors within the NAcc and VTA to produce aversive effects by reducing DA release from presynaptic dopaminergic terminals (**Figure 1**). Thus, activation of CREB, and the resulting induction of dynorphin, in response to long-term drug exposure represents a mechanism of tolerance to drug reward as well as dysphoria during drug withdrawal (dependence).

AP1 Family

Fos and Jun proteins, like CREB proteins, are bZip transcription factors. Fos family members dimerize with Jun family members to form active AP1 complexes, which then bind to AP1 sites in gene promoters. Genes encoding Fos and Jun family proteins are immediate early genes, which means that they are induced very rapidly in

response to an acute stimulus. Accordingly, acute administration of virtually any drug of abuse induces many Fos and Jun family members in the NAcc. Not only is the induction very rapid, but it is also very transient, because the Fos and Jun mRNA's and proteins are all highly unstable.

Δ FosB is a C-terminal truncated splice variant of the FosB gene. It, too, is induced rapidly in response to acute drug exposures. However, unlike all other Fos and Jun family proteins, Δ FosB is a relatively stable protein. This stability is mediated partly by the loss of the C-terminus – which contains degron domains that are conserved in all other Fos family proteins – and by its phosphorylation. As a result, in response to repeated drug administration, levels of Δ FosB accumulate and eventually become the predominant Fos family protein in NAcc neurons. This pattern of induction is illustrated in **Figure 2**. Induction of Δ FosB occurs as a common response to many classes of addictive drugs, including cocaine, amphetamine, methamphetamine, opiates, nicotine, phencyclidine (PCP), cannabinoids, and alcohol. Δ FosB is also induced in the NAcc after repeated consumption of natural rewards, like wheel running, sucrose intake, or sexual behavior.

Studies with inducible bitransgenic mice and viral vectors show that induction of Δ FosB in the NAcc increases an animal's sensitivity to the rewarding effects of drugs of abuse, and also seems to increase incentive motivation, or drive, for the drugs. In addition, Δ FosB increases an animal's drive for natural rewards. Thus, Δ FosB may function as a sustained molecular switch,

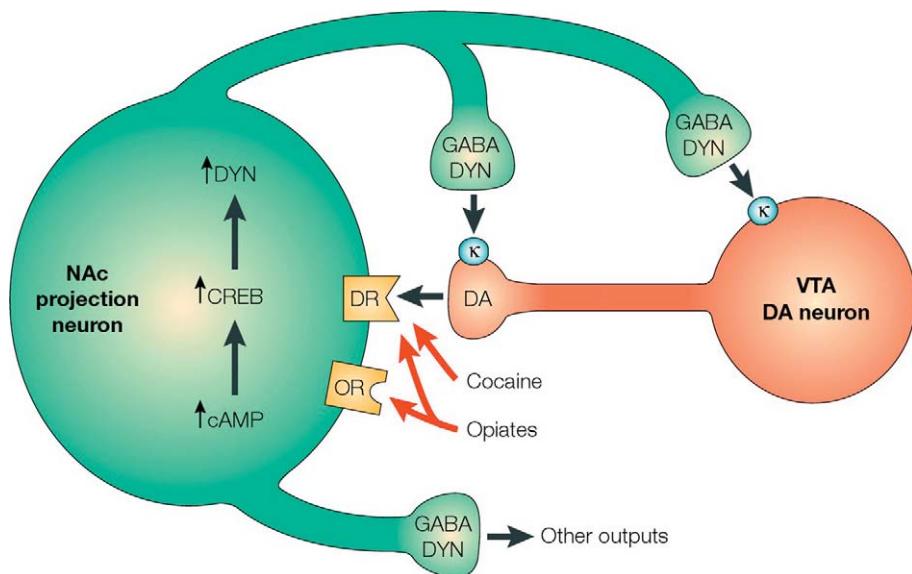

Figure 1 Feedback between the NAc and VTA via CREB activation. Cocaine and amphetamine have been shown to activate *prodynorphin* gene expression in the NAc via D₁ dopamine receptor stimulation, the cyclic adenosine monophosphate (cAMP) pathway, and the phosphorylation of CREB. The resulting dynorphin peptides are transported to presynaptic terminals including terminals that feed back on VTA dopaminergic neurons. Dynorphin peptides are agonists at inhibitory κ -opioid receptors, resulting in decreased dopamine release. From Nestler EJ (2001) Molecular basis of long-term plasticity underlying addiction. *Nature Reviews Neuroscience* 2: 119–128.

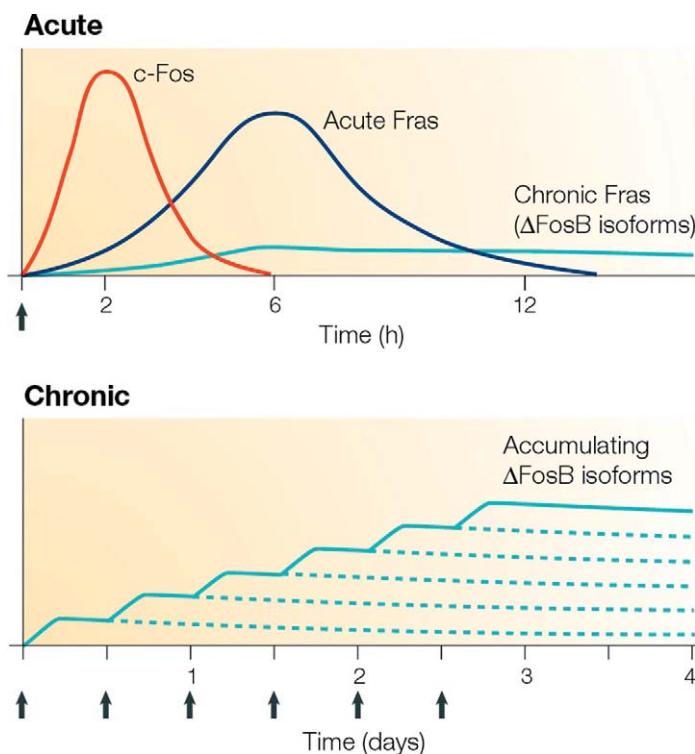

Figure 2 Regulation of Δ FosB by drugs of abuse. The figure shows the several waves of induction of Fos family proteins in the NAc after a single exposure to a drug of abuse. These proteins include c-Fos and several other Fos family proteins (FosB, Fra-1, Fra-2, etc.). Unlike all of these Fos family proteins, which are highly unstable, isoforms of Δ FosB are highly stable and, therefore, persist in the brain long after drug exposure. Because of this stability, Δ FosB accumulates uniquely with repeated drug exposures. From Nestler EJ (2001) Molecular basis of long-term plasticity underlying addiction. *Nature Reviews Neuroscience* 2: 119–128.

which first helps initiate and then maintains a state of addiction for many types of rewards for a relatively prolonged period of time.

There is early evidence that induction of Δ FosB in the NAcc may mediate the ability of a drug of abuse to increase the dendritic branching, and the number of spines on distal dendrites, in NAcc neurons. Although the precise functional role played by these morphological changes is not known, the changes have been shown to persist for at least several months after the last drug exposure, and are hypothesized to mediate the near-permanent sensitization in drug responsiveness seen in certain animal models of addiction. Δ FosB is one mediator of these drug-induced changes in dendritic structure via its regulation of several target genes. For example, chronic cocaine administration induces cyclin-dependent kinase 5 (Cdk5) and nuclear factor κ B (NF κ B) in the NAcc, effects mediated via Δ FosB, and infusion of an inhibitor of either Cdk5 or NF κ B into the NAcc prevents the ability of cocaine to increase dendritic spine density in this region. The implication of these findings is that structural changes caused by repeated cocaine administration may be mediated, in part, via induction of Δ FosB and may persist long after the Δ FosB signal itself

dissipates. While Δ FosB is the longest-lasting known molecular change in the brain seen in the context of drug exposure, and perhaps to any other perturbation of the adult brain, it nevertheless undergoes proteolysis at some finite rate: Δ FosB dissipates to normal levels within a month or two of drug withdrawal. This means that Δ FosB cannot *per se* mediate the extremely long-lived changes in brain and behavior associated with addiction and depression. One possibility is that Δ FosB causes other changes in the brain, such as the changes described in dendritic structure, which themselves are more permanent.

Other Transcription Factors that Regulate Brain Reward Pathways

Recent work has shown that several other transcription factors are also regulated in brain reward regions by drugs of abuse, although in general much less is known about the behavioral consequences of their induction compared with CREB and Δ FosB. As stated above, the transcription factor, NF κ B, has recently been shown to be induced in the NAcc by chronic cocaine. NF κ B has been the subject

of intense investigation for its widespread involvement in a multitude of disease states and for its inducible pattern of gene expression. Several types of cellular stress, including cytokines, growth factors, viruses, and environmental hazards, induce NF κ B in peripheral cells. Under normal conditions, NF κ B, which is composed of a dimer of any of several subunits, termed p50, p52, p65, c-Rel, and RelB (most abundantly p50 and p65), remains sequestered in the cytoplasm by inhibitory- κ B (I κ B). Upon phosphorylation by I- κ kinase (I κ K), I κ B releases the inactive NF κ B dimer, which can then be phosphorylated and transported to the nucleus where it undergoes further posttranslational modifications to initiate transcription of a range of genes involved in cell survival. In the brain, NF κ B has received considerably less attention, however, it has been implicated in certain forms of learning-related plasticity. Although the involvement of NF κ B in addiction and depression models is not well studied, NF κ B has been implicated in the neurotoxic effects of amphetamine and amphetamine-like drugs. Furthermore, chronic cocaine administration upregulates the NF κ B subunits p65, p105 (precursor to p50), and I κ B γ and thereby increases NF κ B-dependent transcription in the NAcc where it serves to enhance dendritic arborizations. As already mentioned, cocaine induction of the NF κ B subunits is mediated by Δ FosB. Studies are underway to better understand the target genes downstream of NF κ B upregulation in drug-addiction models.

Clock and other members of the basic helix-loop-helix-PAS (PER-ARNT-SIM) transcription factor family are best known for their control of circadian rhythms. The first evidence that this gene family may be involved in reward came from studies of *Drosophila*, where loss of Clock dramatically altered the flies' responses to cocaine. More recent work has demonstrated a role for Clock and other circadian genes in mammalian models of addiction. Thus, mice lacking Clock show dramatically increased activity of VTA DA neurons and increased behavioral responses to cocaine. Mice lacking the Clock homolog, NPAS2, or the Clock-NPAS2 target genes, Per (period), also show abnormal responses to the rewarding effects of cocaine. Current research is focused on defining the target genes through which these circadian genes act to regulate the VTA-NAcc pathway in addiction models.

Several drugs of abuse induce the release of systemic glucocorticoids, which activate glucocorticoid receptors expressed throughout the brain. These receptors, which are members of the nuclear receptor family of transcription factors, are expressed in the VTA and NAcc. As glucocorticoids are released in response to stress, they may provide one important mechanism by which stress regulates the reward pathway and addiction behavior. Estrogen and progesterone receptors, members of the nuclear receptor family as well, are also expressed in the

VTA-NAcc pathway and have been found to regulate drug-reward mechanisms. Such effects may contribute to gender differences observed in behavioral responses to drugs of abuse and stress. However, the target genes for glucocorticoid, estrogen, and progesterone receptors in the VTA and NAcc, through which steroid hormones regulate reward mechanisms, have not yet been established.

Regulation of Chromatin Remodeling in Brain Reward Pathways

Binding of transcription factors to their target genes regulates transcription via chromatin-remodeling events, which are becoming increasingly well understood. Interest in chromatin remodeling in the context of drug addiction comes from two sources. First, studies of chromatin remodeling make it possible to delineate the detailed molecular events by which drug-regulated transcription factors activate or repress target genes in the VTA and NAcc *in vivo*. Second, such changes in chromatin structure provide a novel mechanism by which exposure to a drug of abuse may cause lasting changes in gene expression that outlive changes in the transcription factors themselves.

The rate of expression of a particular gene is controlled by its location within nucleosomes and by the activity of the cell's transcriptional machinery. A nucleosome is a short span of DNA that is wound around a complex of histones and other nuclear proteins. Transcription of a gene requires the unwinding of a nucleosome, which makes the gene accessible to the basal transcription complex, comprised of RNA polymerase (which transcribes the new RNA strand) and numerous regulatory proteins (which unwind the nucleosomes). Transcription factors act by enhancing (or inhibiting) the activity of the basal transcription complex; this is achieved by altering nucleosomal structure through changes in histone acetylation, effects mediated by histone acetyltransferases (HAT) or histone deacetylases (HDAC), as well as through many other modifications of histones or the DNA directly. Transcription factors also recruit other regulatory proteins to the complex, which further modify chromatin structure. For example, chromatin remodeling involves enzymes (e.g., SWItch/Sucrose NonFermentable (SWI-SNF; mating switching and sucrose nonfermenting) complex) that reposition nucleosomes, in an adenosine triphosphate (ATP)-dependent manner, and thereby further make genes accessible for transcription.

Recent evidence has demonstrated the relevance of chromatin remodeling to drug-induced neuroadaptations within the brain's reward pathway. This work is made possible by use of chromatin immunoprecipitation (ChIP)

assays, in which brain tissue (under control or drug-treated conditions) is lightly fixed in formaldehyde to cross-link DNA to nearby histones and other proteins. The fixed chromatin is then sheared into smaller fragments, immunoprecipitated using an antibody directed against a protein of interest, the immunoprecipitate is un-cross-linked, and then individual genes of interest are analyzed by quantitative real-time polymerase chain reaction (PCR). Alternatively, the immunoprecipitated DNA is amplified and analyzed on a promoter chip, or sequenced, to obtain a genome-wide assessment of regulated genes. This approach makes it possible to identify changes that occur genome-wide within the brain reward circuit as a consequence of drug exposure.

Using ChIP assays, differential chromatin-remodeling events (such as histone acetylation and deacetylation) have been observed at various cocaine-regulated genes. For example, it was found that chronic, but not acute, cocaine administration induces histone acetylation at the Cdk5 gene promoter in the NAcc. This is consistent with earlier observations that cocaine induces Cdk5 expression in this brain region, but provides the first direct evidence that this induction is mediated via activation of the Cdk5 gene *per se*. Moreover, after chronic cocaine use, ChIP assays revealed increased binding of ΔFosB to the Cdk5

gene promoter, while inducible overexpression of ΔFosB in the NAcc of adult bitransgenic mice, which is sufficient for induction of Cdk5 expression *in vivo*, caused increased binding of ΔFosB to the Cdk5 gene. Chronic cocaine administration, or inducible overexpression of ΔFosB, also causes increased binding of Brg1 (a component of the SWI-SNF complex) to the Cdk5 gene. Together, these results support a scheme whereby the gradual accumulation of ΔFosB, in response to chronic cocaine administration, recruits chromatin-remodeling factors, such as specific HATs to induce histone acetylation as well as Brg1-containing chromatin-remodeling complexes to its target genes such as Cdk5 (**Figure 3**).

Importantly, recent work has established the behavioral relevance of histone acetylation in the NAcc. First, viral-mediated overexpression of particular HDACs in the NAcc dramatically blocked the rewarding effects of cocaine. Conversely, treatment of animals with structurally distinct HDAC inhibitors caused the opposite effect and increased an animal's sensitivity to the behavioral effects of cocaine. These HDAC inhibitors were also found to interact synergistically with cocaine to induce histone acetylation at responsive gene promoters. One of the important HDACs involved in these phenomena is HDAC5, whose function is downregulated in the NAcc

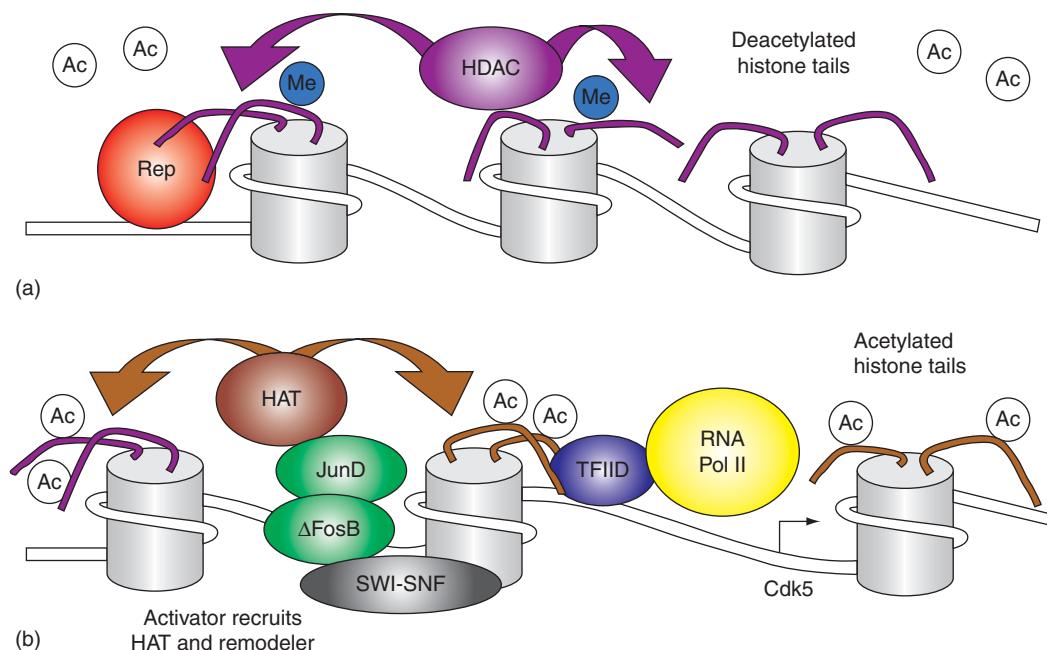

Figure 3 Scheme of proposed chromatin-remodeling events at a cocaine-activated gene. (a) shows the repressed state of chromatin, where a site-specific repressor (Rep) recruits an HDAC complex, which removes acetyl groups (Ac) from histone N-terminal tails. Gene inactivation likely involves other modifications, such as methylation (Me) of histone tails. (b) shows the active state of chromatin around a cocaine-activated gene (e.g., Cdk5), where a cocaine-induced transcriptional activator (e.g., ΔFosB-JunD) recruits a HAT and chromatin-remodeling complex (SWI-SNF), which induce acetylation (and presumably demethylation and other modifications) of histone tails and repositioning of nucleosomes. These actions facilitate the binding of general transcription factors and the basal transcriptional apparatus (e.g., TFIID and RNA polymerase II (PolII)) to the promoter. From Kumar A, Green TA, Russo SJ, Renthal W, and Nestler EJ (2009) Transcription and reward systems. In: Squire LR (ed.) *Encyclopedia of Neuroscience*, ch 195, vol. 9, pp. 1063–1070. Oxford: Academic Press.

by chronic cocaine and which normally serves to dampen cocaine's effects on gene expression and behavior. These findings demonstrate directly that histone acetylation can modify both biochemical and behavioral responses to cocaine, and implicate chromatin remodeling as a key mechanism underlying the molecular control of the brain's reward regions by drugs of abuse.

Future Research

Progress has been made in identifying transcription factors, for example, CREB, ΔFosB, NF κ B, Clock, and steroid hormone receptors, among others, that mediate the effects of drugs of abuse on reward circuits in brain. Future research is needed to better understand how drugs, presumably via regulation of DA and other receptors and of downstream intracellular signaling cascades in the reward circuitry, lead to the regulation of these transcription factors, and how these factors induce chromatin-remodeling events at particular target genes. ChIP assays now make it possible for the first time to identify the precise steps by which different transcriptional complexes are formed at each of the genes regulated in addiction models, and ChIP-chip or ChIP-seq (sequence) assays will help identify the complex gene-regulatory networks affected by these transcription factors to regulate the reward circuitry. This new dimension of molecular research will dramatically expand our understanding of the regulatory control of brain reward regions, and provide fundamentally new paths for the discovery of novel treatments for drug addiction and related conditions.

Glossary

Amygdala (nucleus amygdala) – Almond-shaped nuclei within the medial temporal lobes involved in emotional processing and memory.

c-Fos – A proto-oncogene member of the immediate early-gene family of transcription factors used as an index of neuronal activity.

cAMP response-element binding (CREB) – A transcription factor involved in the regulation of expression of several genes including brain-derived neurotrophic factor (BDNF), c-fos, neuropeptides, and tyrosine hydroxylase.

Conditioned place preference (CPP) – An experimental model based on the concept of classical conditioning to study the conditioned rewarding or aversive effects of drug or non-drug treatments. Animals learn to associate one part of a test chamber with a drug and another part with vehicle by repeated pairings. Later, the animal is allowed to choose between the two environments. An increase or decrease in preference toward the drug-paired context is interpreted as reinforcing versus aversive effects of the drug, respectively.

Craving (psychological dependence) – Intense desire or urge to re-use a substance. Craving is thought to cause relapse following abstinence/withdrawal.

Dependence (physical dependence) – A new equilibrium state that develops to compensate adaptations induced by persistent drug use. The dependant subject requires repeated drug administration in order to maintain normal function, and cessation of drug use causes withdrawal syndrome.

Drug self-administration – An animal model with high face and construct validity based on operant conditioning in which laboratory animals learn to lever-press or nose-poke for drug injections.

Dysphoria – A negative emotional state usually in association with depression and/or anxiety.

Extinction – A type of learning that happens when conditioned stimuli that were previously paired with reinforcing stimulus (food, drug, etc.) are presented in the absence of the reinforcing stimuli. In the drug self-administration procedure, extinction refers to lever pressing in the absence of the drug and/or cues that had previously been paired with drug injections. This leads to a decline in a previously established conditioned response.

Hippocampus – A part of the three-layer archicortex inside the medial temporal lobe that is related to the limbic system and plays important roles in long-term memory formation and spatial navigation.

Locus ceruleus – A brainstem nucleus which is the main source of brain noradrenaline.

Long-term potentiation (LTP) – A form of synaptic plasticity that is thought to be involved in learning and memory processes. In this process, high-frequency, patterned stimulation of cells results in prolonged increase in synaptic transmission efficacy.

Mesocorticolimbic pathway – A major dopamine pathway of the brain connecting the ventral tegmental area to limbic areas (such as the nucleus accumbens, amygdala, and hippocampus) and the cerebral cortex (especially the frontal cortex). It is known to be involved in motivational processing and cognitive performance and the pathogenesis of mental disorders such as addiction, depression, and schizophrenia.

Neuroplasticity – Change in morphology and connections of neurons by external stimuli that cause long-lasting alterations in neural function.

Nucleus accumbens (NAcc) – A pair of forebrain nuclei composed of core and shell parts with distinct morphology and function. Nucleus accumbens is important in reward processing and addictive processes.

Orexin (hypocretin) – A neurotransmitter (made of two neuropeptides – Orexin-A and B) produced exclusively by hypothalamic neurons that send projections throughout the brain. The orexin peptides bind to two G-protein-coupled receptors, OX₁R and OX₂R, and play roles in awareness and reward.

Prefrontal cortex – The anterior part of the frontal lobes involved in higher cognitive and executive functions, such as decision making, goal-directed behavior planning, personality, and social behavior.

Priming – In the drug self-administration paradigm, it refers to re-exposure to a previously experienced drug which usually results in resumption of drug seeking/taking.

Reinstatement – A process that refers to the retrieval of an extinguished memory and, thereby, recovery of a previously learnt response. In the drug-seeking context, mostly refers to the resumption of drug seeking/taking following extinction induced by drugs, drug-associated cues, or stress.

Relapse – A clinical term that refers to the resumption of drug administration following abstinence.

Reward – A stimulus that is interpreted as intrinsically positive by the brain and, therefore, is worked for.

Tolerance – Reduction in subject's responsiveness to a drug with repeated exposure in a way that higher doses are required to achieve the same effect.

Ventral tegmental area (VTA; ventral tegmentum) – A midbrain nucleus that plays an important role in reward processing and the development of many mental disorders.

Withdrawal syndrome – A collection of signs and symptoms associated with the discontinuation of drug intake (or blockage of drug actions by antagonist). Symptoms are usually the opposite of acute drug actions. Withdrawal is thought to play an important role in relapse to addiction.

Among the remedies which it has pleased Almighty God to give to man to relieve his sufferings, none is so universal and so efficacious as opium.

Thomas Sydenham, 17th Century

Definition

Opioids (substance with a morphine-like effect; synonymous here with opiates) include the natural drug opium and its derivatives (such as morphine and codeine), semi-synthetic compounds made of morphine (such as heroin, oxycodone, and oxymorphone), and synthetic drugs (such as fentanyl, levorphanol, meperidine, and methadone), in addition to endogenous opioids that are the naturally occurring ligands for opioid receptors (such as endorphins and enkephalins). Opium is traditionally made by drying the juice produced by lacerating the immature seed capsule of the plant *Papaver somniferum* (opium poppies). Opioids have been the mainstay of pain treatment for thousands of years, and they remain so today. The term narcotic refers to the sleep-producing effects of opioids, although it is not their major therapeutic use today.

Opioids: Past to Present

History

Opium has been used since prehistoric times. Cultivation of opium dates back to the Neolithic Age (4th millennium BC). The first undisputed reference to opium is found in the writings of Theophrastus (third century BC). Physicians of ancient civilizations used opium for the treatment of pain, sedation of crying children, anesthesia, euthanasia,

diarrhea, and melancholy. Opium has been mentioned in important medical texts of the ancient world (such as the writings of Galen and Canon of Avicenna). Sometime between AD 400 and 1200, opium was introduced to the Far East and Europe from the Middle East. Opium lost popularity in inquisitional Europe (AD 1300–1500), when it was believed to be a tool of the devil. Paracelsus reintroduced opium to Western medicine in 1527. In 1680, laudanum (a compound containing opium, sherry wine, and herbs) was introduced by Thomas Sydenham to treat pain, insomnia, and diarrhea. The smoking of pure opium became popular in the eighteenth century and it was brought to North American cities by Chinese workers. Morphine (named after Morpheus, the god of dreams) was isolated from opium in 1806, and was followed by the isolation of other alkaloids. By the middle of the nineteenth century, the use of pure alkaloids in place of crude opium preparations began to spread throughout the medical world. Heroin, the first semi-synthetic opioid, was synthesized in 1874. From 1898 to 1910, heroin was marketed as a nonaddictive morphine substitute and cough medicine for children. Soon, however, it became apparent that it caused profound dependence.

Abuse Potential

To avoid confusion with physical dependence, the term addiction used in this article refers specifically to drug craving and compulsive use. In contrast to physical dependence (a natural consequence of chronic drug exposure), addiction is a chronic mental illness characterized by drug craving and impaired control over compulsive drug taking despite obvious harm to self and society. Hence, addiction and physical dependence can exist independent of each other and, although opioid addicts often show evidence of physical dependence, this is neither sufficient nor necessary to make a diagnosis for addiction. Importantly, the brain areas responsible for physical dependence and withdrawal are, to a considerable extent, anatomically distinct from the neural circuitry that underlies the habit-forming effects of drugs.

Theories of addiction

Different theories based on neurobiological data have been proposed to explain addiction. In the opponent-process theory, chronic drug use produces disequilibrium in brain reward systems causing a vicious cycle of altered hedonic set-point changes. This transition results in compulsive drug use and vulnerability to relapse. Alternatively, in the incentive sensitization theory of addiction, it is postulated that continuous drug exposure alters brain areas involved in incentive motivation for reward, resulting in hypersensitivity to the drug and drug-associated cues and, thereby, a shift from drug liking to drug wanting. Learning-based theories of addiction

propose that repeated drug exposure is associated with particularly strong memories, mediated by drug-induced changes in brain reward regions. Accordingly, drug taking is a learned response to conditioned stimuli, such as drug-associated cues. It has been proposed that impaired decision making due to prefrontal cortex dysfunction contributes to compulsive drug use. Different theories of addiction overlap in some aspects and are not mutually exclusive. None of them alone fully explains all aspects of addiction. It is likely that a combination of factors proposed in each of these theories contributes to the neural and behavioral pathology that underlies addiction.

Abuse vulnerability

Opioids are highly addictive and addiction to opioid drugs is a serious clinical and social problem. Opioids are one of the most commonly prescribed analgesics. It is noteworthy that only a small proportion of individuals who use opioids progress to addiction. The rate of addiction is higher among illicit users than patients using opioids for clinical purposes. Interactions among several internal (i.e., genes) and external (i.e., drug and environment) factors contribute to the transition from abuse to addiction and relapse following abstinence.

Genetic variations have been shown to affect an individual's response to drugs of abuse, vulnerability to addiction, relapse, and treatment outcome for opioid addiction. For instance, specific polymorphisms in genes encoding the cytochrome P450 system, catechol-*O*-methyl-transferase (COMT; an enzyme involved in dopamine (DA) catabolism), DA and serotonin transporters, DA D₂-like receptor, and especially opioid receptors have been related to amounts of heroin use, development of heroin addiction, and craving and relapse to heroin seeking. In addition, the genetic background of an individual is linked to impulsivity, risk-taking and novelty-seeking behaviors, response to stress, as well as other comorbid disorders (such as schizophrenia, mood disorders, and attention-deficit hyperactivity disorder (ADHD)). These factors may increase the risk of abuse and addiction and are associated with an unfavorable prognosis. Abuse of other illicit drugs is common among opioid addicts. Pharmacological properties of drugs are also important. For instance, heroin is more addictive than morphine because it is more potent, has a faster onset of action (due to its higher lipid-solubility), and produces more abrupt and intense syndromes of withdrawal (due to its short half-life).

Epidemiology

Addiction to opioids is a major health problem in the world. Heroin is the most commonly abused opioid. The prevalence of opioid addiction in many developed

countries is less than that of addiction to stimulants or other illicit drugs (the lifetime rate of heroin use in the US is less than 2%). However, the percentage of people addicted to heroin out of those who ever used is much higher (23.1%) than for other drugs of abuse (except tobacco). Heroin addiction occurs most commonly in low socioeconomic populations. Heroin is widely available on the illicit market with a continual decline in price and increase in purity over the last decade. This may be relevant to the doubling of heroin use observed in high school students. Opioid-associated mortality (especially due to heroin overdose, drug-related violence, or human immunodeficiency virus (HIV) infection) is also higher compared to other drugs of abuse such as cocaine. Infection with HIV or viral hepatitis is a very common comorbidity among heroin addicts. Although there are no statistics that provide an accurate number of heroin addicts, it is estimated that over 3.5 million Americans have used heroin and from 800 000 to 1 million heroin addicts reside in the United States of America. The prevalence of heroin use has increased among youths in the last decade. Heroin addiction is seen more commonly in males (male/female ratio: 3:1) in the age range of 30–50 years of age. The advent of newer prescription opioid analgesics (such as oxycontin and other oxycodone derivatives, methadone, fentanyl, and buprenorphine) has led to the abuse of these agents consequent to medical treatment with opioids.

Physiological Effects and Medical Uses of Opioids

Opioid Receptors

Opioids act by binding to and activating specific membrane receptor proteins. Three main subtypes of opioid receptors have been recognized: μ , δ , and κ . These receptors couple to G proteins and thereby modulate the activity of adenylyl cyclase (AC), voltage-gated calcium ion (Ca^{2+}) channels and G-protein-gated inwardly rectifying potassium ion (K^+) (GIRK) currents. Opioid receptors can also couple to other second-messenger systems such as mitogen-activated protein (MAP) kinases and the phospholipase C (PLC). More recently, a fourth subtype, the nociceptin/orphanin FQ (N/OFQ) receptor, has been cloned – based on extensive sequence homology, but not function. Opioid receptors are widely distributed throughout the body and brain including reward-related areas, and each subtype has a unique anatomical distribution in the nervous system. Actions of different subtypes of opioid receptors are summarized in **Table 1**. Most of the clinically used opioids work mainly through μ -opioid receptors (MORs).

Table 1 Physiological actions of opioid receptors

Receptor subtype	Location in CNS	Major Actions	Agonists	Antagonists
μ	Amygdala, caudate, cortex, nucleus accumbens (NAcc), periaqueductal gray (PAG), spinal cord, thalamus	analgesia, ↓ cough, euphoria, ↑ feeding, ↓ gastrointestinal motility, ↑ prolactin and GH release, ↓ immune function, miosis, physical dependence, respiratory depression, sedation	DAMGO Morphine Methadone Endomorphin Met-enkephalin β -endorphin Levorphanol	CTOP CTAP Naloxonazine Naloxone naltrexone
κ	Claustrum, cortex, hypothalamus, NAcc, PAG, spinal cord	analgesia, ↓ antidiuretic hormone release, ↑ feeding, ↓ gastrointestinal motility, miosis, muscle rigidity, sedation	Dynorphin U50,488 Fentanyl Butorphanol	Nor-BNI Naloxone Naltrexone
δ	amygdala, caudate, cortex, NAcc, olfactory bulb, Pontine nucleus	Analgesia, ↑ feeding	DPDPE Deltorphin Leu-enkephalin Etorphine	Naltrindole Naloxone naltrexone

Clinical Effects and Uses

In clinics, opioids are widely used as relatively selective painkillers without affecting other sensory modalities. They are more effective in the relief of nociceptive than neuropathic pain. Agonists acting at μ - and κ -receptors cause miosis (constriction of the pupils) – an effect that is more resistant to development of tolerance than other physical responses. Opioids depress respiration and the cough reflex by directly affecting respiratory and cough centers of the brainstem, and cause nausea and vomiting by stimulation of chemoreceptors in the medulla. Opioids can act in the hypothalamus to change the set point for body temperature, inhibit the release of pituitary trophic hormones, increase prolactin release, and decrease plasma levels of testosterone and cortisol. However, with chronic use, tolerance develops to these hormonal effects of opioids. In the gastrointestinal tract, morphine and other μ -agonists decrease acid secretion, gastric motility, biliary and pancreatic secretions, peristalsis of the large bowel, and increase the tone of the anal sphincter and sphincter of Oddi. These effects may lead to gastroesophageal reflux, epigastric pain, delay in absorption of food and drugs taken orally, biliary colic, increase in plasma levels of amylase and lipase, and, more commonly, constipation. Morphine can normalize the oxytocin-induced contractions of the uterus. In the skin, morphine causes flushing and pruritus. Nearly all of these opioid effects can be reversed by the MOR antagonist, naloxone. In general, opioids suppress the immune system; therefore, the drugs increase the risk of infections and spread of malignancies. Morphine-like drugs may also cause catalepsy, seizures, muscle rigidity, and stereotypical behavior especially at higher doses. Death from opioid overdose is almost always due to respiratory arrest and may occur when purity or potency of the supply is unexpectedly high or after recent abstinence (due to reduced tolerance).

Transition from Abuse to Addiction

Acute Rewarding Properties of Opioids

Subjective effects depend on the drug, dose, route, and rate of administration. In the human, acute intravenous heroin administration induces an intense pleasurable effect or euphoria (rush) in a few seconds that has been described as a total-body orgasm. The heroin rush lasts for a few minutes. The opioid-induced sense of well-being (high) lasts for a few hours after the rush and is, sometimes, followed by a state of de-realization and inattention to the external world. The acute rewarding effects of heroin disappear after a few hours, leading addicts to inject several times a day. Therefore, addicts typically oscillate between a euphoric high (during which they are relatively calm) and early withdrawal symptoms (which make them irritable and sometimes aggressive). In laboratory animals, opioids induce conditioned place preference (CPP) and are readily self-administered.

Accumulating evidence indicates that the acute rewarding properties of opioids are, at least in part, mediated by the mesocorticolimbic DA system. This system has two parts that work in parallel. The mesolimbic pathway consists of DA projections from neurons of the ventral tegmental area (VTA) to limbic structures such as the nucleus accumbens (NAcc), ventral pallidum (VP), amygdala, and hippocampus. These target areas of the mesolimbic pathway are involved in the primary reinforcing properties of drugs, memory formation, and conditioned and contextual learning. The mesocortical pathway is made of DA projections from VTA to cortical regions such as the prefrontal cortex (PFC), orbitofrontal cortex, and anterior cingulate cortex, and is thought to mediate the cognitive aspects of the drug experience, craving, altered executive function, and loss of control

over compulsive drug use. Additionally, DA has been proposed to be involved in reward anticipation and associative learning. Opioid agonists acting at MORs inhibit γ -aminobutyric acid (GABA)-ergic inhibitory interneurons in VTA, resulting in disinhibition of DA neurons and increased DA release in terminal regions. Accordingly, self-administration of MOR agonists into the VTA and NAcc increases DA in the shell subregion of the NAcc, and lesions of the NAcc, VTA, and VP impair heroin self-administration. However, animals will continue intra-NAcc self-administration of opioids despite DA blockade in the NAcc, indicating the presence of DA-independent mechanisms in the acute rewarding effects of opioids.

The endogenous opioid system (especially the MOR) is also implicated in the mediation of opioid reward. In fact, although DA neurotransmission plays a role in the rewarding properties of many drugs of abuse, MORs are central to the rewarding effects of opioids and DA has only a modest role. The opioid system is also important in the reinforcing effects of other drugs of abuse such as cannabinoids, alcohol, and nicotine. Involvement of other pathways in opioid reward has also been suggested. For instance, opioid self-administration and CPP is abolished in cannabinoid CB₁-receptor knock-out mice or by cannabinoid antagonist administration.

Tolerance and Withdrawal

With repeated exposure to opioids, adaptations occur that lead to chronic and endurable changes at the level of cells and circuits.

Tolerance

Tolerance is defined as a reduced response to a drug for a desired effect after repeated administration. Therefore, increasing doses and/or frequency of drug use are required to achieve the same effect. Tolerance develops rapidly to some effects of opioids such as analgesia and reward and the dose can even increase hundreds of folds. However, tolerance to opioid-induced miosis and constipation develops slowly. Development of tolerance depends on the dose and pattern of drug administration. In addition, tolerance is affected by conditioned cues (such as context) and the administration of the usual dose in a different context may lead to overdose (conditioned tolerance). Different types of tolerance by various mechanisms exist. Tolerance may be innate (genetic sensitivity to a drug) or acquired (pharmacokinetic, pharmacodynamic, or learned tolerance). Pharmacokinetic tolerance is mostly due to increased metabolism rate of a drug. Pharmacodynamic tolerance is related to adaptive changes that occur within target systems of a drug that decrease the response to it. Learned tolerance is a decline in the effects of a drug made by previous learned mechanisms. Situation-specific (conditioned) tolerance may occur

if drug taking is always paired with distinct environmental cues. Hence, cues predict the effects of the drug and less effect of drug is observed when environmental cues are available.

Adaptive mechanisms underlying tolerance may occur at any level, from MORs (receptor tolerance) to neurons (cellular tolerance) to networks (system tolerance). Tolerance may develop acutely upon a single exposure to opioids (acute tolerance); however, this is different from the classical tolerance seen after chronic administration of opioids. Desensitization and internalization of MORs are considered to be involved in the development of receptor tolerance. It has been proposed that activation by agonist induces phosphorylation of MORs and increases their affinity for binding to arrestin proteins (β -arrestin2), which eventually uncouples MORs from G-protein signaling and starts the process of internalization. Accordingly, β -arrestin2 knock-out blocks the development of tolerance to antinociceptive effects of acute and chronic morphine. However, the importance of these mechanisms for the development of tolerance is still uncertain. Desensitization is a distinct process that precedes internalization. Morphine, unlike more potent agonists, has low efficacy for desensitization and a very low efficacy for internalization of MOR in most neurons. Therefore, it seems that the reduced coupling of MOR to its intracellular effectors over time (desensitization) is a more potent mechanism for tolerance than decreased cell-surface expression of MOR, although it is unlikely that these mechanisms can fully account for the greater magnitude of tolerance observed at behavioral levels. Possibly, tolerance to the effects of morphine results, in part, from ineffective desensitization, which causes prolonged receptor activation leading to further downstream cellular adaptations that increase development of tolerance. The importance of interactions of different neurotransmitters (such as the glutamatergic system) with opioid pathways in the development of tolerance to morphine has been demonstrated.

Withdrawal

A prototypical withdrawal syndrome occurs when drug administration is withheld after dependence has developed with chronic exposure. Signs and symptoms of opioid withdrawal are very unpleasant but are not life threatening, and are often opposite to the original effects produced by the drug before the development of tolerance. They include: yawning, lacrimation, mydriasis (dilated pupils), rhinorrhea, perspiration, gooseflesh, muscle spasm, hot and cold flashes, tremor, anorexia, nausea, emesis, diarrhea, restlessness, insomnia, weight loss, dehydration, hyperglycemia, hyperpyrexia, and hypertension, as well as dysphoria (a negative emotional state containing depression and anxiety-like symptoms). The symptoms of withdrawal depend on the last dose and

type of drug. For long-acting agents (such as methadone) withdrawal occurs more slowly, is less intense, and is more prolonged than for short-acting drugs (heroin). Although avoidance of withdrawal seems to be an important motivation to take drug, considerable evidence indicates that the rewarding properties of drugs play the major role in the continuation of drug seeking and administration.

The locus ceruleus (LC) – the major noradrenergic (NA) nucleus of the brain – has been studied extensively in opioid withdrawal. Acute administration of opioids inhibits AC (subtypes I and VII) and the production of cyclic adenosine monophosphate (cAMP) levels in LC neurons and also decreases the firing rate of LC neurons. However, with continued administration of opioids the inhibition of AC and firing rate recovers to normal as a homeostatic compensatory response, and they increase several times above normal levels during withdrawal. Evidence indicates that enhanced excitatory inputs and intrinsic unregulated excitability lead to the observed hyperactivity of LC neurons during opioid withdrawal. More recently, it has been shown that withdrawal symptoms as well as the spontaneous firing activity of LC neurons are highly attenuated in GIRK knock-out mice. However, the causal relationship between this LC hyperactivity and behavioral symptoms of withdrawal is still unclear. Although surgical lesion of the LC area or decreased expression of transcription factor cAMP response-element-binding protein (CREB) in the LC attenuates the withdrawal syndrome, pharmacological ablation of noradrenergic LC function does not prevent the expression of withdrawal behavior.

Evidence indicates that the dysphoria associated with opioid withdrawal can be dissociated from the physical symptoms listed above. For example, studies in our laboratory found that blockade of β -NA receptors in the ventrolateral bed nucleus of stria terminalis (vBNST), or lesion of the ventral NA bundle which originates in the caudal medullary NA cell groups, strongly attenuates the aversion associated with morphine withdrawal but has very little effect on the physical withdrawal syndrome. Thus, different circuits may be involved in the affective and somatic responses to withdrawal. These results also point to the caudal NA cell groups, rather than the LC, as an important site mediating the affective response to withdrawal (**Figure 1**).

Chronic opioid exposure also upregulates the cAMP pathway in regions outside the LC, including the NAcc. One target for CREB in the NAcc is the opioid peptide dynorphin. During withdrawal, dynorphin released from neurons of the NAcc binds to κ -opioid receptors on VTA dopaminergic neurons, inhibits their activity and decreases DA release in the NAcc. This phenomenon seems to contribute to the dysphoria seen during acute withdrawal. Consistently, mutations of the CREB gene

decrease morphine withdrawal symptoms, and increased CREB expression decreases the rewarding effects of opioids. Drug withdrawal activates stress systems other than Norepinephrine (NE) neurons, and increased levels of corticotropin-releasing factor (CRF) in the amygdala have been observed. In addition, blockade of the CRF₁ receptor blocks the development of place aversion for precipitated opiate withdrawal.

Protracted withdrawal/abstinence

Prolonged exposure to drugs causes neuronal adaptations that continue long after symptoms of acute withdrawal have dissipated. These adaptations cause anhedonia, depression, dysphoria, anxiety, and decreased interest in natural rewards during protracted withdrawal (weeks or longer). Our knowledge with regard to changes in the brain during protracted withdrawal is limited. However, it seems that plasticity in the extended amygdala results in prolonged elevated anxiety as well as altered hedonic processing during this period that may contribute to increased vulnerability to drug seeking and relapse. In a series of studies in our laboratory, morphine-dependent or naive rats were subjected to abstinence withdrawal for 2–5 weeks, followed by training for morphine or food CPP. Postdependent animals showed enhanced morphine preference and attenuated food preference, compared to nondependent animals. This altered hedonic processing (decreased valence for natural rewards in addition to enhanced incentive value of drugs) was correlated with Fos activation in some stress-related areas such as ventral BNST and central amygdala (CeA), and their major NA afferent in the nucleus tractus solitarius (NTS). These alterations and the resulting changes in hedonic analysis could be attributed to changes in afferents from these areas to the VTA, or to plasticity within the VTA. Postdependent rats also exhibited more anxiety and increased sensitivity to stress during the protracted withdrawal (**Figure 2**).

Other brain changes were observed that may contribute to altered hedonic processing during protracted withdrawal. For example, Fos induction in the BLA, NAcc, and lateral hypothalamus (LH) mirrored the changes in preference in postdependent animals – being increased for increased morphine preference but decreased with decreased food preference. These changes in the LH were determined to occur in orexin (hypocretin) neurons; the role of the orexin system in opioid abuse will be discussed further in this article. Changes in the NAcc shell may be particularly involved, as FosB expression in this region (but not in other areas examined) 5 weeks after withdrawal correlated with increased drug preference.

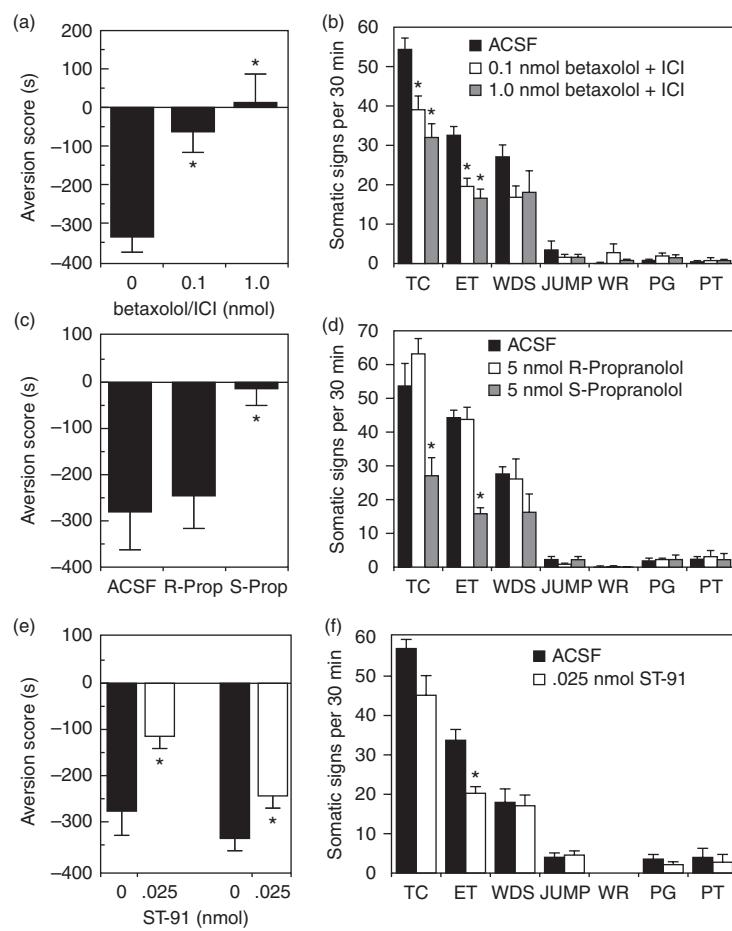

Figure 1 Effects of the β -antagonists betaxolol + ICI 118,551 ((a) and (b)), propranolol ((c) and (d)) or the α_2 agonist ST-91 ((e) and (f)) on aversion scores and somatic withdrawal. Infusion of noradrenergic drugs into the BNST blocked conditioned place aversion but had minimal effects on somatic signs of acute opioid withdrawal. TC = teeth chattering; ET = eye twitch; WDS = wet dog shakes; JUMP = jumping; WR = writhing; PG = penile grooming; PT = paw tremor. Aversion score for the withdrawal-paired environment is the mean time in seconds spent in the withdrawal side minus the nonwithdrawal side on test day. * $P < 0.05$. With permission from Delfs et al. (2000) Noradrenaline in the ventral forebrain is critical for opiate withdrawal induced aversion. *Nature* 403: 430–434.

Neural Plasticity

Neural plasticity (the brain's ability to change over time) is thought to contribute to normal learning and memory, as well as to the development of psychiatric diseases. Evidence suggests that long-term adaptations that are induced by chronic exposure to drugs in reward-related areas of the brain are the neural basis of the transition from social drug use to compulsive intake and relapse. In particular, adaptations in the VTA and the NAcc have been studied extensively and are thought to be relevant to long-lasting drug-induced plasticity. The behavioral relevance for many of these changes is yet to be determined.

Acutely, opioids increase the firing rate of DA neurons in the VTA by hyperpolarizing inhibitory GABAergic synapses onto these cells. This phosphorylates the transcription factor CREB which, in turn, increases the expression of the GluR1 subunit of the α -amino-3-hydroxy-5-methyl-4-isoxazole-propionate

(AMPA) glutamatergic receptor. It has been shown that even a single injection of morphine is capable of inducing long-term potentiation (LTP)-like enhancement of glutamatergic responses in the VTA DA neurons. For cocaine, such VTA plasticity has been shown to be dependent on orexin neurons originating from the hypothalamus. The orexin system has been shown to affect the addictive properties of morphine in several studies. For example, Fos induction in LH orexin cells correlates strongly with morphine preference. In addition, application of the orexin A peptide in the VTA, or stimulation of LH orexin neurons, induces reinstatement of extinguished morphine CPP; 'this reinstatement' is blocked by an orexin 1 receptor antagonist.

Neurotrophic factors also seem to play a role in opioid addiction. The VTA DA neurons express neurotrophic factors such as the brain-derived neurotrophic factor (BDNF). Serum BDNF is altered in human opioid addicts; and in the rat, morphine acutely increases expression of

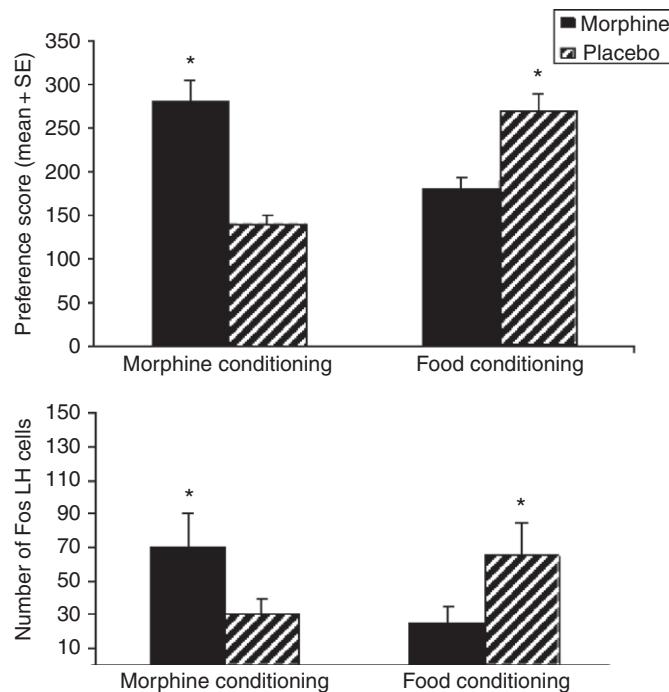

Figure 2 Upper panel: Previously morphine-dependent animals showed decreased preference for the environment associated with food but increased morphine CPP after 5 weeks of abstinence, as compared to nondependent animals (placebo). Preference for food- or morphine-paired environments was measured as the difference in times spent in the rewarded side minus the nonrewarded side on test day. Lower panel: More Fos+ neurons were found in the LH of morphine-abstinent, than placebo-pretreated, rats that underwent morphine CPP, and conversely significant – more Fos+ neurons were found in the LH for placebo than abstinent animals that underwent food conditioning. Other studies from our laboratory show that many of these Fos+ LH neurons contain the neuropeptide orexin. Modified with permission from Aston-Jones and Harris (2004) Brain substrates for increased drug seeking during protracted withdrawal. *Neuropharmacology* 47: 167–179.

BDNF in the VTA, NAcc, and frontal cortex. Chronic exposure to escalating doses of morphine (but not subcutaneous implants) downregulates BDNF function in the VTA. In addition, chronic morphine differentially modulates the downstream signaling pathways from BDNF in the VTA. The effect of chronic morphine exposure on the extracellular signal-regulated kinase (ERK) pathway is not clear, and both decreased and increased activity of this pathway have been reported. However, IRS-PI3K-Akt signaling is decreased by chronic opioid exposure in both VTA and NAcc, which could be related to the decreased size of DA cells (in the VTA) or decreased arborization and dendritic spine density (in the NAcc). The PLC γ pathway is activated by chronic morphine. In addition to BDNF, another neurotrophic factor called glial cell line-derived neurotrophic factor (GDNF) is increased in the VTA following chronic opioid use.

In the NAcc, acute administration of opioids rapidly increases the expression of the Fos family of transcription factors which lasts for a few hours. Δ -FosB is a member of Fos family that is extremely stable; and, therefore, chronic drug use leads to gradual accumulation of Δ -FosB in NAcc over time. Overexpression of Δ -FosB in the NAcc has been associated with increased rewarding

properties of morphine. However, the levels of Δ -FosB return to normal values after 8 weeks of abstinence, and so these alone cannot explain relapse to addiction after longer periods of abstinence (months or years). Nonetheless, Δ -FosB or similar proteins can possibly act as a molecular switch between transient acute effects of drugs and persistent long-lasting features of addiction (such as prolonged changes in gene expression and synaptic remodeling).

Morphologically, chronic morphine decreases the size of the VTA DA neurons – an effect that can be prevented by intra-VTA infusion of BDNF. In addition, both contingent and noncontingent chronic administration of opioids decrease the arborization of dendrites and the spine density of medium spiny neurons of the NAcc in rats. Fewer studies have shown the effect of chronic opioid use in other areas of the brain. For instance, it is known that chronic exposure to opioids diminishes the number and complexity of dendritic spines (mPFC and the hippocampus) and neurogenesis (hippocampus). In human opioid addicts, metabolism and blood flow is decreased in the PFC and this hypofrontality is thought to be involved in relapse to addiction.

Craving and Relapse

Long-term exposure to exogenous opioids induces adaptive changes in the brain that disrupts natural reward seeking and increases drug craving and vulnerability to relapse. The major problem in opioid addiction is return to drug seeking and taking, even years after detoxification. The relapse rate for heroin addicts is about 75–85% in the first year of abstinence and is still 25% after 15 years of abstinence.

During abstinence, craving and relapse to drug seeking can be induced by re-exposure to the drug or cues previously associated with drug use, or by stressors. In the last few decades, several laboratories have been using animal reinstatement models to study the underlying neural mechanisms of relapse. The most commonly used methods are reinstatement of self-administration and CPP. Animals are trained to press a lever for drug infusion (self-administration) or to associate a distinct environment with the drug experience (CPP), and are then subjected to abstinence or extinction training during which the drug is not available. Reinstatement of lever pressing or preference is then tested upon exposure to a noncontingent priming injection of the drug, cues associated with drug intake, or stress. The neural basis of relapse to opioid seeking has not been studied extensively, compared to studies on stimulant seeking. Recent findings indicate that, although there are many commonalities in the brain areas mediating reinstatement of cocaine and heroin seeking, a more diffuse neurocircuitry seems to underlie heroin seeking.

Drug Priming

A wide range of areas is engaged in drug-induced reinstatement. Inactivation of the VTA, NAcc (both shell and core), BLA and CeA, PFC (both dorsomedial (dmPFC) and ventromedial (vmPFC)), BNST, and even the dorsolateral caudate-putamen (dlCP), substantia nigra (SN), and ventral pallidum (VP) attenuate heroin-primed reinstatement of drug seeking in rats. Several neurotransmitter pathways are involved. For instance, systemic or intra-VTA injection of MOR agonists, systemic or intra-NAcc application of indirect DA agonists, and systemic D₂ – but not D₁ – agonists reinstate heroin seeking. On the other hand, neurochemically specific lesions of DA neurons and terminals in the VTA or NAcc block morphine-primed reinstatement of CPP, and D₂ antagonists block heroin-induced reinstatement. Both heroin- and intra-VTA morphine-induced reinstatement of heroin seeking are blocked by naltrexone. In addition, it has been shown that NA depletion in the PFC blocks morphine-primed CPP reinstatement.

More recently, it has been suggested that glutamatergic input to the NAcc core from the PFC or amygdala contributes to the reinstatement of heroin seeking. Heroin- (and cue-)induced reinstatement increases glutamate in the NAcc core, and inhibition of PFC or amygdala afferents attenuate heroin-induced reinstatement. The stimulation of presynaptic group II metabotropic glutamate (mGluR2/3) receptors, or cystine–glutamate exchange, can inhibit synaptic release of glutamate and also attenuate reinstatement of heroin seeking. A role for the endocannabinoid system in relapse to heroin seeking has also been shown, for example, CB₁ receptor agonists can trigger reinstatement of heroin self-administration. In addition, CRF₁ – but not CRF₂ – receptor antagonists attenuate reactivation of morphine CPP.

Cues

Afferents from the medial PFC and amygdala to the NAcc core play a major role in the reinstatement of heroin seeking upon exposure to cues previously associated with heroin. In addition, inactivation of several other areas have been shown to impair cue-induced reinstatement of heroin seeking in the rat, including the medio-posterior parts of the BNST, dlCP, SN, and VP. Dopaminergic and glutamatergic neurotransmission in the NAcc are known to contribute to cue-induced reinstatement of heroin seeking and inhibiting either glutamate or DA receptors blocks both cue- and drug-induced reinstatement of heroin seeking. Importantly, the NAcc core mediates discrete cue-induced reinstatement while the shell subregion is involved in context-induced reinstatement. Akin to heroin-primed reinstatement, stimulation of the mGluR2/3 receptors (systemic or intra-VTA and NAcc shell), which decreases synaptic glutamate release, attenuates context-induced reinstatement of heroin seeking. In addition, chronic administration of *N*-acetyl-cysteine – which increases cystine–glutamate exchanger activity – has been shown to block cue (and heroin-)induced reinstatement of heroin seeking. Cholinergic transmission in the VTA versus the NAcc has been shown to provoke and block reinstatement of heroin seeking upon exposure to heroin-associated cues, respectively. A role for cannabinoid receptors (in the PFC and NAcc) in cue-induced reinstatement has also been proposed. In addition, as mentioned above, activation of orexin neurons in the LH, or intra-VTA administration of the orexin A peptide, can reinstate morphine CPP (Figure 3), an effect that may mimic stimulus-induced reinstatement as drug-associated stimuli stimulate orexin neurons. This orexin-driven reinstatement is completely blocked by pretreatment with an orexin 1 receptor antagonist, as is cue-induced reinstatement of cocaine-seeking behavior.

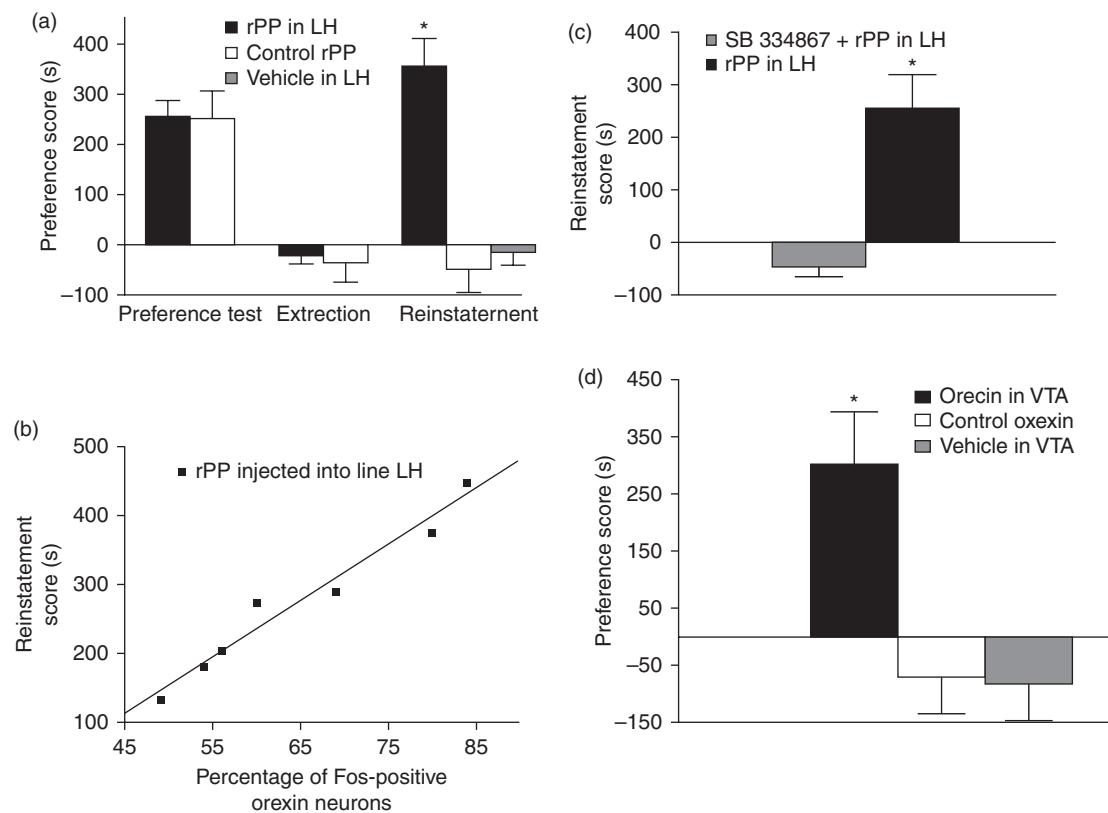

Figure 3 Activation of lateral hypothalamus orexin neurons by rPP reinstated an extinguished preference for morphine.

(a) Preference scores were measured as the difference in time spent in the morphine-paired side minus that spent in the saline-paired side. (b) The selective orexin A antagonist, SB 334867 ($20\text{--}30\text{ mg kg}^{-1}$), blocked reinstatement induced by rPP injected into the lateral hypothalamus. (c) Correlation between reinstatement scores and percentages of lateral hypothalamus orexin neurons that were Fos activated in rPP-reinstated animals. (d) Administration of orexin (140 nM) into the VTA reinstated an extinguished morphine place preference. Modified with permission from Harris *et al.* (2005) A role for lateral hypothalamic orexin neurons in reward seeking. *Nature* 437: 556–559.

Stress

Stressors are important factors in relapse to drug seeking and taking both in the human and animal models. The most commonly used stressors in laboratory animals are footshock, food-deprivation, and pharmacological blockade of α_2 -adrenoceptors. The CeA and BNST are major areas involved in this regard. It has been suggested that unlike drug- and cue-induced reinstatement, the dopaminergic system plays an indirect role in footshock-induced reinstatement of heroin seeking; this reinstatement is attenuated by the chronic administration of nonselective DA receptor antagonists (but not selective D₁ or D₂ antagonists). However, CRF and central noradrenergic pathways are critically involved in stress-induced reinstatement of heroin seeking. For instance, antagonists of CRF receptors (especially the CRF₁ receptor) and α_2 -adrenergic agonists have been shown to attenuate footshock-induced reinstatement of heroin seeking. It appears that NA neurons in the lateral tegmental area and their projections through the ventral noradrenergic bundle, but not LC neurons, are involved in the effects of

the NA system on stress-induced reinstatement of heroin seeking, similar to the findings for stress-induced reinstatement of cocaine seeking. Leptin is involved in heroin seeking reinstated by food deprivation.

Glossary

Action potential – Also known as a nerve impulse, spike, or firing, it is a change in neuronal membrane potential that is propagated down the length of the axon. Membrane potential refers to the difference in electrical charge across the neuronal membrane, between the inside of the cell and the extracellular fluid surrounding the neuron. In order for a neuron to generate an action potential, the membrane potential must change from resting (-70 mV) to the threshold for firing (-50 mV). The change in membrane potential from resting threshold depends on neurochemical actions at membrane receptor proteins located on the neuron soma and dendrites, which lead to the opening of ion channels and the influx of positive ions into the neuron.

Electrophysiology – It is the study of the electrical properties of biological cells and tissues. It involves measurements of voltage change or electrical current on a wide variety of scales from single ion channel proteins to whole organs such as the heart. In neuroscience, it includes measurements of the electrical activity of neurons, and particularly action potential activity.

Extracellular single-neuron recording – It is an electrophysiological method. The technique is used to measure changes in current that occur in the extracellular fluid caused by movement of ions across the membrane of a single neuron in association with the occurrence of action potentials.

Neurophysiology – It refers to neuronal electrical properties and events that underlie biological functions regulated by the brain. These functions are diverse in nature (e.g., breathing, heart rate, movement, sensory perception, goal-oriented behavior, and emotion).

Neuroplasticity – Also referred to as neuroadaptations, it is the changing of neurons and the organization of neuronal networks and hence the function of the neurons and networks. Neuroplasticity can be induced by various experiential events, such as those associated with learning (e.g., repeated stimulation of particular synapses during repeated exposure to particular environmental stimuli and behavioral events). It can also be caused by exposing the neuron to pharmacological agents that affect neural function via actions at either membrane or intracellular receptors. Examples of drug-

induced neuroplasticity include neuronal changes that underlie drug tolerance and sensitization.

Operant behavior – Also referred to as goal-directed or reward-directed behavior, it is a term used in reference to operant (instrumental) conditioning (i.e., learning). The operant is a behavior upon which a biologically significant event (i.e., reward) is contingent. Rewards that are contingent upon the occurrence of a particular behavior are referred to as reinforcers if the behavior-reward contingency is associated with an increase in the probability of the operant behavior.

Overview

A reward is a biologically significant event, such as food or a receptive mate. Through Pavlovian and instrumental conditioning, an individual can learn predictive relationships between rewards, stimuli, and instrumental behavior. These associations evoke, maintain, and direct behavior, which lead organisms to contact rewards. Certain drugs, particularly those having abuse potential, share properties of natural rewards. However, given adequate drug exposure, drug-directed behaviors can become compulsive and uncontrollable. Understanding the mechanisms that mediate instrumental behavior directed toward drug reward is not only relevant to understanding the mechanisms that contribute to reward-directed behavior generally but is also relevant to understanding mechanisms that contribute to drug addiction.

Neuropsychopharmacological studies show that the acquisition and expression of instrumental behavior directed toward natural rewards and drug rewards are mediated by overlapping neural circuitry. Electrophysiological recordings of single-neuron activity in behaving animals have refined our understanding of the functional contribution of particular brain regions to natural reward-directed behavior. The recordings have also identified underlying neurophysiological mechanisms. During the late 1980s, researchers began to conduct similar studies of drug-directed behavior. The present article reviews some of this latter work. The article also compares studies of drug-directed behavior to similar investigations of natural reward-directed behavior.

The reviewed research shows that some of the neurophysiological correlates of drug-directed behavior are comparable to those of natural reward-directed behavior. The research has also led to the discovery of novel patterns of neural activity, some of which are unique to drug-directed behavior and which may be relevant to drug addiction.

Investigations of Drug-Directed Behavior: Research Method

Drug Self-Administration Paradigm

To conduct electrophysiological studies of drug-directed behavior, researchers have integrated chronic extracellular recording methods with the intravenous drug self-administration model. The intravenous drug self-administration model is a well-validated model of human drug self-administration. In the simplest case, animals (e.g., rats or nonhuman primates) are implanted with an intravenous catheter and then trained to engage in operant behavior, typically a lever press response, according to a fixed-ratio 1 (FR1) schedule of reinforcement. Each press of the lever is followed by a single drug infusion, which is typically paired with a conditioned reinforcer such as a light or a tone. Although the experimenter controls the drug concentration and volume of each infusion, animals control the timing of infusions. The patterns of drug taking exhibited by animals in the self-administration paradigm are quite similar to those observed in humans.

If exposed to short daily sessions (i.e., 1–2 h per day) and moderate drug doses, animals exhibit stable rates of intake across many days. In this circumstance, the drug-directed behavior is sensitive to the same associative variables as is natural reward-directed behavior. However, if animals are exposed to high doses of drug and/or long daily sessions, animals exhibit escalation of drug intake across repeated self-administration sessions and exhibit other behavioral changes reminiscent of drug addiction symptoms, such as a decreased ability to withhold drug-directed behavior despite adverse consequences. The paradigm is thus used to study both drug reward and drug addiction.

Chronic Extracellular Recording

To conduct electrophysiological recordings of single neurons during drug self-administration, animals are chronically implanted with either a bundle or an array of insulated microwires (e.g., 50 µm diameter stainless steel wires with Teflon coating). After surgery, extracellular recording procedures are used to record the activity of individual neurons. To conduct these recordings, a connector cemented to the skull, which contains electrical contacts to the microwires is connected through a flexible cable to a computer-controlled amplification and filtering

system. Animals can move freely and exhibit typical operant behavior. During recording sessions, the occurrence of action potentials can be tracked with a 1-ms resolution. The recordings are highly stable such that the activity of a single neuron can be followed for many hours and sometimes for multiple days. Given the temporal resolution and stability of the recording procedure, it is possible to characterize changes in neuronal firing that occur time locked to rapid discrete events, such as the cocaine-reinforced operant response. One can also concurrently evaluate slow and long-lasting changes in firing that might be associated with changes in either drug exposure or the motivational state of the animal (i.e., time frame of minutes to hours). With histological procedures, the location of recording wires can be identified with a resolution of $\approx 100\text{ }\mu\text{m}$.

Focus of Most Research Studies of Drug-Directed Behavior

Brain areas implicated in mediating self-administration of addictive drugs in animals are consistent with regions implicated in drug self-administration and addiction in humans. These brain areas include the ventral tegmentum, and regions in the prefrontal cortex, striatum, particularly the nucleus accumbens, and limbic regions such as the amygdala. As noted already, these regions also overlap with those implicated in natural reward-directed behavior. Most of the electrophysiological studies of drug self-administration have thus far focused on characterizing the activity of individual neurons in the nucleus accumbens during periods in which rats self-administer cocaine. However, there have also been characterizations of accumbal activity during ethanol and heroin self-administration, and studies of neural activity in the prefrontal cortex and amygdala. Many of these investigations involve a characterization of the topography and behavioral correlates of single-neuron firing patterns during the drug self-administration session. A smaller but growing number of studies have investigated the changes in neural firing patterns that occur across repeated days of drug self-administration and subsequent periods of abstinence. Both types of studies are relevant to understanding drug reward. The latter type of study is also relevant in identifying lasting neuroadaptations that contribute to drug addiction.

Firing Patterns of Individual Neurons during Drug Self-Administration Sessions

Overview

One focus of recording studies of cocaine-directed behavior has involved the cataloguing of firing patterns that occur during FR1 cocaine self-administration sessions.

Another has been investigating the nonpharmacological factors that contribute to those firing patterns. This section reviews some of this research.

Short-Duration Changes in NAcc Firing Time Locked to Cocaine-Reinforced Behavior

The firing patterns

Some of the first extracellular recordings conducted during FR1 cocaine self-administration sessions characterized phasic firing patterns time locked to the operant behavior. These studies showed that at a cocaine dose of 0.75 mg kg^{-1} per infusion (inf), approximately 25–40% of NAcc neurons exhibit rapid phasic changes in firing during the seconds which bracket the cocaine-reinforced

lever presses (referred to herein as lever-press firing patterns) (Figure 1(a)). The firing patterns have been subtyped into three main groups: (1) prepress, (2) post-press, and (3) prepost press. A small subset of additional neurons exhibit similar changes in firing with a slightly longer duration (e.g., 30–60 s). The broad range of firing-pattern time courses suggests that, during cocaine self-administration, NAcc neurons track multiple variables or combinations thereof during the seconds that precede and follow the reinforced operant response.

Lever-press firing patterns have been observed under a range of experimental conditions but have been consistently reported as predominantly excitatory. There is evidence that the firing patterns are more prevalent in the core subterritory of the NAcc than in the shell

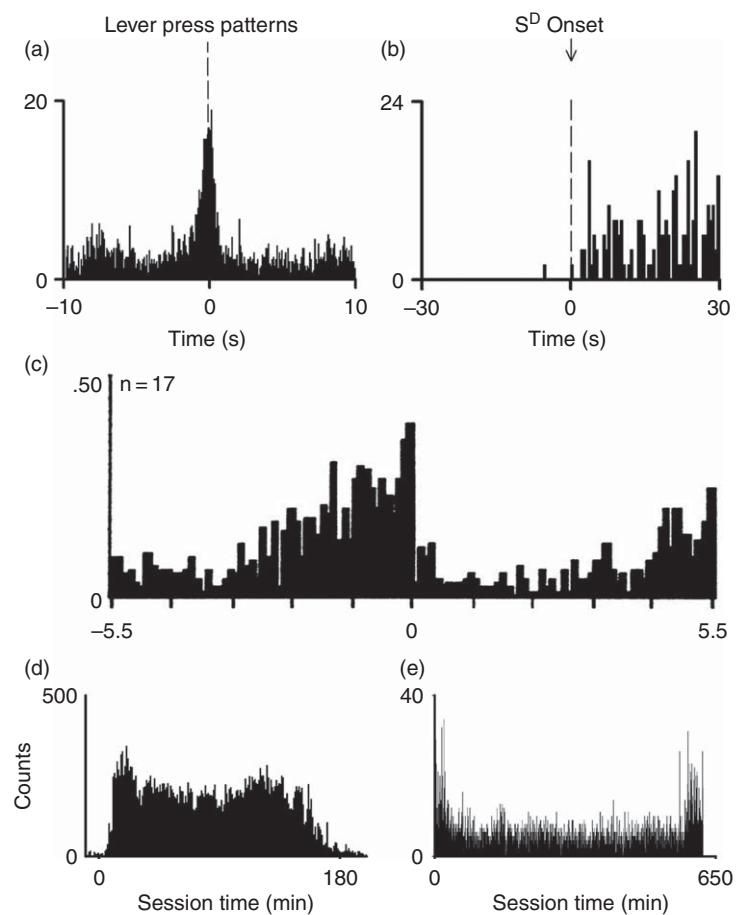

Figure 1 Single-neuron firing patterns during FR1 cocaine self-administration sessions. (a) Average phasic change in firing time locked to the cocaine-reinforced lever press. Average firing rate (Hz per 0.1-s bin) is plotted during the 12 s before and after presses made during the maintenance phase of a self-administration session (i.e., 10th to 27th reinforced lever presses). (b) Change in firing time locked to presentation of cues that signaled the onset of an FR1 cocaine self-administration session (firing pattern referred to as an S^D response). Firing rate (counts per 0.5-s bin) is plotted for the 30 s before and after onset of the cue. Cue onset is shown at Time 0 on the abscissa. (c) Average change in firing time locked to the cocaine-reinforced press (firing pattern referred to as progressive-reversal firing patterns). Average firing rate (Hz per 0.6-s bin) is plotted during minutes before and after press (i.e., all presses excluding the first 10 of the session). The time base of the histogram corresponds to the average inter-infusion interval exhibited by the individual animal from which the neural activity was recorded. (d, e) Session-long changes in firing during a FR1 cocaine self-administration session. In each histogram, firing (Hz per 30-s bin) is plotted during an entire FR1 cocaine self-administration session, as well as during a pre- and postsession baseline period. Beginning and end of self-administration is indicated by arrows at top of histograms.

subterritory of the NAcc (i.e., particularly posterior shell), though this anatomical difference has not always been observed.

Correlates of the firing patterns

The offset of the short-duration lever-press firing patterns precedes the expected latency for pharmacological actions post-infusion. There are numerous nonpharmacological events that occur within the seconds, which lead up to and follow the reinforced lever press during typical FR1 cocaine self-administration sessions. These include, but are not limited to, the following: approach to the lever, the lever-press operant, the conditioned reinforcer cues, and delivery of the primary reinforcer. To isolate the event(s) to which the firing is correlated, researchers recorded responses of lever-press responsive neurons to individual events in isolation of other events. These studies showed that, for all neurons, the prepress firing is associated with the occurrence of the operant behavior, though not the movements which make up the lever-press response *per se*. For about half the neurons showing postpress activity (i.e., for prepost neurons and post neurons), the neurons consistently showed a response to the occurrence of a lever press, even when it occurred in the absence of either a cocaine infusion or the cues normally paired with delivery of the infusion. However, the same neurons did not respond to the infusion or cues when they occurred in the absence of the operant behavior. These data indicate that for about half of the neurons showing postpress activity, the neural response is specifically associated with the operant behavior, though again, not with the execution of the movements required to make the lever press. For most of the remaining neurons that showed postpress activity, the firing is associated with both the operant and the conditioned cues typically paired with delivery of the cocaine infusion.

Several studies showed that the lever-press firing patterns are specific for the expected reward. In these studies, NAcc activity was recorded during multiphase sessions in which the reinforcer varied between phases and was either a natural reward (water or food) or cocaine. During these sessions, most neurons that showed a phasic response time locked to cocaine-reinforced lever presses did not show a phasic response time locked to lever presses reinforced by the natural reward. Similarly, other neurons that exhibited responses time locked to lever presses reinforced by the natural reward rarely did the same when the operant was cocaine reinforced. In some of these experiments, the animals pressed the same lever during both phases so the between-phase difference in firing could not have reflected the movements associated with either the operant or the spatial location of the lever. These findings are consistent with the interpretation that the lever-press firing patterns are related in some

way to expectation of a particular reward. Additional studies are required to further specify the information encoded by the phasic firing patterns.

Electrophysiological studies of natural reward-directed behavior have progressed farther than studies of drug-directed behavior. The natural reward studies have shown that NAcc neurons exhibit phasic firing patterns in association with reward-predictive stimuli and behavior. The majority of the firing patterns involve a short-duration increase in firing. The firing patterns are dissociable from both specific movements and the physical properties of the stimuli, and can reflect various characteristics of the expected reward, including the following: (1) the reward predicted by the cue; (2) the magnitude of the predicted reward; and (3) the temporal proximity of the reward. Based on available data, NAcc firing patterns during drug self-administration will be shown to share similar characteristics.

Studies of natural rewards have also shown that NAcc neurons exhibit changes in firing during reward consumption. In contrast to the phasic activity time locked to reward-predictive cues and operant behavior, the majority of the changes in firing during reward consumption are inhibitory. Though cocaine self-administration is not associated with specific consummatory behaviors, a high percentage (50%) of neurons show an inhibition in firing during the minute(s) that follow each cocaine infusion. The nature of these decreases is not yet understood; however, it is possible that the change in firing is analogous to the inhibitory response exhibited by NAcc neurons during consumption of natural rewards. These findings suggest that increases in NAcc neural activity are associated with instrumental events, which lead animals to contact reward (referred to as preparatory behavior), whereas decreases are predominantly associated with reward consumption.

NAcc Firing Patterns during Cocaine Seeking

In addition to characterizing firing patterns during FR1 drug self-administration sessions, researchers have begun to document and investigate firing patterns during periods in which animals engage in drug-directed behavior under drug-free conditions. There are a number of reasons for conducting these types of studies. First, neuropharmacological studies show that the mechanisms that mediate drug-directed behavior under drug-free and drug-exposed conditions are not identical. Second, drug-directed behavior under drug-free conditions (referred to as drug seeking) is thought to better model conditions associated with relapse in humans, which is a primary therapeutic target. Third, the research also represents an opportunity to compare patterns of firing during drug-directed and natural reward-directed behavior in the absence of pharmacological effects, which can sometimes complicate comparisons of neural firing patterns associated with natural reward-directed versus drug-directed behavior.

These studies have been conducted in a number of ways, though all the studies thus far have focused on NAcc neural activity in animals with a history of cocaine self-administration. Several studies have characterized the response of neurons to cocaine-predictive cues (e.g., cues typically paired with cocaine infusions) in the absence of operant behavior in drug-free animals. Studies have additionally or alternatively characterized NAcc activity during periods in which operant behavior is sustained for a period by response-contingent presentation of only conditioned cues, which have previously been paired with cocaine delivery. The findings of the various experiments are quite consistent in showing that a portion of NAcc neurons (e.g., 25%) exhibit changes in firing in response to the presentation of cocaine-predictive cues (**Figure 1(b)**). The NAcc responses are predominantly excitatory. If operant responding occurs, the cue-evoked neural responses are typically maintained during the period of drug-directed behavior. In cases in which drug is ultimately delivered, some neurons show a significant decrease in average firing relative to firing during a presession baseline period that preceded the operant session (see session-long changes described below). Similar findings have been obtained in other experiments in which animals were exposed to a priming infusion of cocaine concurrently with the conditioned cue. The functional correlates of NAcc firing patterns during drug seeking have not yet been characterized. However, given the partial overlap between neurons which are responsive during drug seeking and drug self-administration, it is likely that there are at least some shared functional characteristics of NAcc firing patterns during drug-directed behavior in drug-free and drug-exposed situations.

Long-Duration Changes in Firing Time Locked to Operant Behavior during Cocaine Self-Administration Sessions

The firing patterns

NAcc neurons exhibit another category of firing pattern time locked to the cocaine-reinforced lever-press. At a cocaine dose of $0.75 \text{ mg kg}^{-1} \text{ inf}^{-1}$, approximately 65% of all neurons show a change in firing that occurs slowly across the interval between successive self-infusions. For most neurons (i.e., 50% of all recorded neurons), firing rate decreases during the first-minute postpress and then progressively increases until the time of the next lever press (i.e., decrease + progressive reversal) (**Figure 1(c)**). For the remaining neurons, firing rate increases postpress and progressively decreases until the time of the next press. Interestingly, the majority of the neurons that show a lever-press firing pattern also show a decrease + progressive reversal firing pattern. Consistent with this

observation, the progressive reversal firing patterns are significantly more prevalent in the rostral and lateral regions of the core than in the posterior parts of the shell.

Determinants of the firing patterns

In considering possible reward-related determinants of the decrease + progressive reversal firing pattern, it is relevant to note that the firing pattern mirrors changes in drug and DA levels in the NAcc during the cocaine self-administration session. The changes in drug level that occur between successive self-infusions are expected to engender interoceptive cues, including those that develop progressively over the course of the interval, in conjunction with drug metabolism. These interoceptive cues could include or become associated with changes in the motivational state of the animal that occur with changes in drug level. It is possible that the progressive increase in firing reflects excitatory afferent input related to the cues and motivational state of the animal and that the rapid decrease in firing that occurs following the press reflects the cessation of that afferent input. An alternative, but not mutually exclusive, interpretation of the firing pattern is that it reflects more direct and acute actions of cocaine in the NAcc. The relative contribution of pharmacological and nonpharmacological variables to the decrease + progressive reversal firing patterns remains to be further delineated.

Similar firing patterns do not appear to occur in either the amygdala or prefrontal cortical regions. The firing patterns were also not observed in a study of accumbal neural activity during nicotine self-administration. The patterns may thus be relatively specific to accumbens and psychomotor stimulants, though further research is required to evaluate this possibility.

Session-Long Changes in Average NAcc Firing Rate during Cocaine Self-Administration Sessions

The firing patterns

Extracellular recordings during intravenous FR1 cocaine self-administration ($0.75 \text{ mg kg}^{-1} \text{ inf}^{-1}$) sessions have shown that most ($\approx 90\%$) NAcc neurons exhibit a change in average firing rate during the self-administration session relative to pre- and postsession baseline periods. These firing patterns have been referred to as session-long changes or session changes (**Figures 1(d)** and **1(e)**). The session changes in firing are exhibited by neurons that exhibit a phasic lever-press firing pattern, a progressive reversal firing pattern, or both. However, the patterns are also exhibited by neurons that show no other change in firing. At the dose of $0.75 \text{ mg kg}^{-1} \text{ inf}^{-1}$, the majority of the session-long changes in firing (i.e., 60% of all recorded neurons) are decreases.

Correlates of the firing pattern

The session-change firing pattern is defined by a sustained change in average firing during the self-administration session relative to the drug-free baseline period. It thus involves a difference in firing between a drug-free period and the entire period of drug exposure and potentially reflects an acute drug effect. Though the firing pattern has a time course consistent with a potential pharmacological origin, it is also possible that the firing patterns reflect NAcc encoding of nonpharmacological events. Available data are indicative of a combined role of pharmacological and nonpharmacological events in mediating the firing patterns.

Two lines of evidence are consistent with the hypothesis that at least some portion of the session-long changes in firing are nonpharmacological. First, the onset of some of the changes in firing precedes the delivery of the first drug infusion and occurs in association with the cues that signal the onset of drug availability and the onset of the first operant response. Second, NAcc neurons exhibit session-long changes in firing during FR1 sucrose-reinforced operant behavior. In considering possible nonpharmacological determinants of the firing patterns, researchers tested the hypothesis that the patterns reflect primarily an effect of particular behaviors (e.g., locomotion and operant response), which are present during the self-administration session, but not during baseline periods, when animals are typically at rest. Several lines of evidence led to the rejection of this hypothesis.

An alternative nonpharmacological determinant of the firing patterns could include reward-related events or states that are maintained throughout the operant session. Investigations of sucrose-directed behavior are consistent with this idea. In these studies, average firing of NAcc neurons was characterized across alternating phases of operant behavior reinforced on an FR1 schedule of conditioned reinforcer presentation and an FR1 schedule of sucrose plus conditioned reinforcement. Of the neurons that showed a session-long change in firing during one type of phase, approximately two-thirds showed session-long changes that were unique to the particular phases. Behavior during the two phases was comparable, except for the differential presence of consummatory behavior. Control studies showed that this behavioral difference could not explain the change in firing between the conditioned and primary reinforcement phases. These data suggest that the phase-specific session-long changes in firing reflect the response-reinforcer contingency (i.e., different expectations related to reward), which was stable throughout the particular phases but differed between the phases. These NAcc data are comparable with findings of a similar experiment, which recorded the activity of orbitofrontal cortex neurons during sucrose-directed behavior and with preliminary findings of an ongoing study of NAcc neurons during cocaine self-administration (Figure 2).

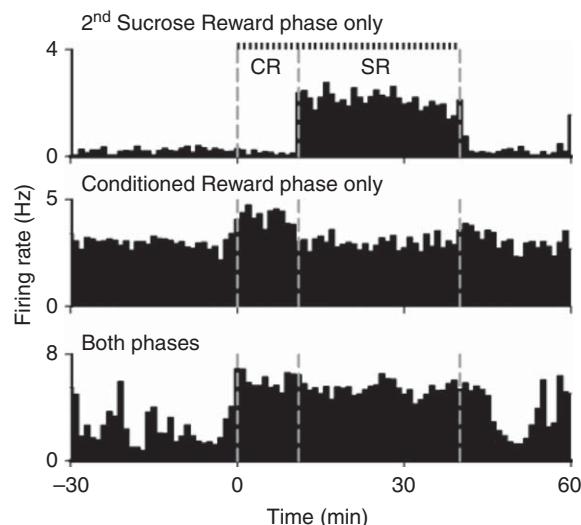

Figure 2 Individual-neuron examples of firing patterns during conditioned reinforcement (CR) and sucrose reinforcement (SR). Vertical dashed lines represent (from left to right) the start of conditioned reward phase, the start of the sucrose reward phase, and the end of the sucrose reward phase. Tick marks above the top histogram represent lever presses. Each row corresponds to the firing of a single neuron. Reproduced with permission from Kravitz AV and Peoples LL (2008) Background firing rates of orbitofrontal neurons reflect specific characteristics of operant sessions and modulate phasic responses to reward-associated cues and behavior. *Journal of Neuroscience* 28: 1009–1018.

Several lines of evidence suggest that during cocaine self-administration, some of the session-long changes in firing additionally reflect an influence of acute inhibitory pharmacological actions of cocaine. First, session-long decreases are the predominant change in average firing during cocaine self-administration sessions and are significantly more prevalent during cocaine self-administration sessions than during sucrose self-administration sessions. By contrast, the prevalence of session-long increases in firing is comparable between the two rewards. Second, decreases in average firing are dose dependent, increasing in prevalence, and in some cases magnitude, as drug level increases (Figure 3). Average firing of NAcc neurons does not show a similar concentration dependence when animals are trained to self-administer different concentrations of sucrose (Figure 3). Third, electrophysiological recordings in slice and anesthetized animal preparations show that experimenter-delivered cocaine inhibits spontaneous and glutamate-evoked firing of NAcc neurons.

Further investigations of the cocaine-induced inhibition in behaving animals showed that the acute inhibition induced by self-administered cocaine is activity dependent. Specifically, as a group, neurons that show a phasic increase in firing time-locked to the cocaine-reinforced lever-press show significantly less inhibition in firing

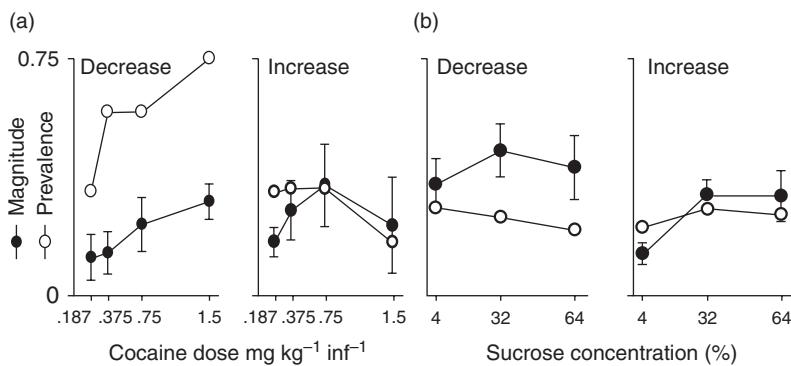

Figure 3 Changes in average firing of NAcc neurons during exposure to either different doses of cocaine or different concentrations of sucrose. (a) Animals trained to self-administered cocaine (FR1 to 60 s; 0.75 mg kg⁻¹) were exposed to one of three cocaine doses (0.75, 1.5, or 3.0 mg kg⁻¹ inf⁻¹). Prevalence and average magnitude of session-decrease firing patterns and session-increase firing patterns are plotted as a function of infusion type. Average magnitude of change in firing rate during the 2–6 min post-infusion relative to baseline. Index is defined as $|A - B|/(A + B)$, where A and B = average firing rate (Hz) during the self-administration session and the presession baseline, respectively. (b) Separate groups of rats were trained to self-administer sucrose on an FR1 schedule of reinforcement. The sucrose concentration varied across the groups. Prevalence and average magnitude of session-decrease firing patterns and session-increase firing patterns are plotted as a function of infusion type.

during the self-administration session than do neurons which show no change in firing time-locked to the behavior. The differential inhibition can be observed not only in the overall average firing rate during self-administration but also across multiple specific behaviors (e.g., stereotypy or locomotion), which occur during the self-administration session. This latter finding indicates that the differential change in firing rate reflects a general differential susceptibility of the neurons to cocaine-induced inhibition. The differential inhibition causes a net strengthening of firing during drug-directed behavior exhibited by the phasically active neurons (i.e., signal) relative to average background of all neurons (i.e., firing during periods in which animals are not engaged in drug-directed behavior). The differential inhibition and increases in signal:background ratio are not observed in animals trained to self-administer sucrose. It is hypothesized that the drug-induced increase in signal:background ratio may strengthen drug-directed behavior during periods of drug exposure.

Changes in NAcc Firing Patterns, Which Occur Across Repeated Cocaine Self-Administration Sessions, Drug Abstinence, and Reexposure to Cocaine Self-Administration

Multiple electrophysiological studies conducted in slice and anesthetized animal preparations have shown that a history of repeated experimenter-delivered cocaine exposure induces NAcc neuronal hypoactivity. Consistent with this observation, researchers have shown that a history of repeated cocaine self-administration is associated with decreases in average firing of NAcc neurons. These

decreases in firing are observed across multiple behavioral and pharmacological conditions and thus appear to reflect a general hypoactivity (e.g., reduced neuronal excitability). A similar decrease in average firing does not occur in animals exposed to a history of sucrose self-administration, which has been matched to the cocaine self-administration history (i.e., same number of reinforcers per session and same number of training sessions). The decrease in average firing is correlated with increases in the propensity of animals to seek and take cocaine, and thus potentially contribute to the change in behavior.

Interestingly, the decreases in average firing that occur in cocaine-exposed animals are only observed in a subset of accumbal neurons. Specifically, lever-press nonresponsive neurons (i.e., neurons that do not show a phasic change in firing time-locked to the operant) show an emergent hypoactivity. Lever-press responsive neurons do not exhibit this change in average firing. The differential change in average firing between the two groups of neurons may reflect a net increase in NAcc signaling related to drug-directed behavior and a corresponding NAcc-mediated facilitation of drug-directed behavior. The differential neuron susceptibility to the hypoactivity which develops across repeated drug self-administration sessions parallels the differential acute inhibition of NAcc neurons during daily self-administration sessions. It is hypothesized that the acute cocaine-induced activity-dependent inhibition of NAcc neurons during daily self-administration sessions alters the susceptibility of neurons to certain types of drug-induced plasticity, which in turn contributes to the activity-dependent changes in firing that occur after repeated exposure to cocaine self-administration.

A number of other studies have tested for changes in NAcc firing patterns that occur in animals that have a history of cocaine self-administration and an extended period of drug abstinence. Comparisons of firing before versus after abstinence show that phasic firing patterns time locked to cocaine-predictive cues, and cocaine-directed operant behavior are significantly increased after a 30-day period of abstinence relative to before the abstinence period. This increase in phasic responses to events which are predictive of cocaine persists when animals are reexposed to repeated daily cocaine self-administration sessions. In addition, the hypoactivity of the task-non-activated neurons which develops across initial pre-abstinence self-administration sessions is absent after 30 days of abstinence but quickly reemerges after only 3 days of reexposure to daily periods of self-administration training. Importantly, none of the changes in average or phasic firing that have been observed in cocaine-trained animals has been observed in similarly treated control animals trained to self-administer sucrose. This observation suggests that the changes in firing observed in cocaine-trained animals reflect cocaine-induced neuroadaptations.

The plasticity studies show that NAcc neurons undergo drug-induced adaptations which are stage dependent (i.e., ongoing periods of drug taking versus abstinence) and activity dependent (e.g., occur depending on whether neurons are lever-press responsive vs. lever-press nonresponsive). The adaptations in firing are associated with a progressive increase in the difference and ratio between average firing at the time of the drug-directed operant and average background firing (i.e., firing during periods in which animals are not engaged in drug-directed behavior). This type of change could potentially contribute to the progressive and chronic increases in drug-directed behavior and the decreased interest in nondrug rewards, which are associated with the development of drug addiction. Finally, the pattern of plasticity observed in behaving animals, which have a history of self-administered cocaine, is more complicated in several respects relative to that detected in electrophysiological slice and anesthetized animals studies, which have been primarily conducted in animals with a history of experimenter-delivered cocaine. This observation suggests that certain cocaine-induced adaptations depend on behavioral conditions present during periods of drug exposure and/or during electrophysiological studies.

Other Brain Regions and Other Addictive Drugs

Operant-locked phasic firing patterns during FR1 drug self-administration sessions have been observed during nicotine, ethanol, and heroin self-administration. The

firing patterns also occur in multiple regions connected with the NAcc, including the orbitofrontal cortex, medial prefrontal cortex, and the amygdala. The subtypes of firing patterns are similar across drugs and brain regions, though some differences in prevalence and functional characteristics of the firing patterns have been observed.

Session-long changes are exhibited by NAcc neurons during nicotine and heroin self-administration sessions. The firing patterns are also observed in the medial prefrontal cortex during cocaine and heroin self-administration, and in the orbitofrontal cortex and insula cortex during both cocaine and sucrose self-administration. The prevalence of the firing patterns differs across brain regions and drugs but available evidence indicates that in all cases session-long changes in firing during drug self-administration reflect a combined effect of pharmacological actions and normal afferent input associated with simple FR1 operant sessions. The inverse relationship between the direction and magnitude of session-long changes and phasic responses time locked to the operant behavior is observable in orbitofrontal cortex as well as the NAcc, suggesting that the pattern of activity may reflect a general mechanism associated with reward-directed operant behavior.

The studies of changes in neural activity across repeated self-administration sessions and abstinence are particularly challenging experiments, and as of yet few such studies have been completed. Only one study has characterized a drug other than cocaine. Interestingly, the adaptations in firing were identical to those observed in cocaine-trained animals.

Summary

Available evidence shows that there are similarities between NAcc firing patterns exhibited during individual sessions of cocaine- and natural reward-directed instrumental behavior. Some of the similarities include the following: (1) the predominance of excitatory changes in firing time locked to predictive cues and instrumental behavior, (2) evidence that the firing patterns reflect reward-related expectations, and (3) the occurrence of session-long changes in firing.

At least one similarity between drug and natural rewards is unexpected, which is the occurrence of session-long changes in average, background firing, and the relationship between these changes in background and phasic responses of neurons to discrete reward-predictive events such as the reinforced operant. Historically, electrophysiological studies of natural reward and reward-directed behavior have focused on short duration changes in firing time-locked to discrete events such as conditioned cues, operant behavior, and reward delivery. Many variables (e.g., context or motivation), which

influence reward-directed behavior are sustained over extended periods of time and can be critical to directing and maintaining behavior toward rewards, which are often distal in space and time and can require a long sequence of instrumental behavior. It is difficult to see how the short-duration phasic responses to discrete events could track or mediate the effects of the longer-duration determinants of reward-directed behavior. Instead, the session-long changes in firing could quite plausibly contribute to coding and mediating sustained influences on reward-directed behavior, such as the influence of context and motivation on behavioral responses to particular reward-predictive stimuli. The firing patterns could also potentially contribute to the persistence of behavior directed toward distal rewards.

The accumbal recording studies of cocaine-directed behavior have also demonstrated differences between the neurophysiological events associated with drug-directed and natural reward-directed behavior. Thus far, the most prominent differences in firing of NAcc neurons during cocaine versus food sessions include a greater prevalence of session-long decreases in firing during cocaine sessions than during sucrose sessions and a dissociation between neurons that are lever-press responsive during cocaine-directed versus natural reward-directed behavior. Comparisons of firing patterns across repeated self-administration sessions and periods of extended abstinence and reexposure also show that NAcc firing patterns in cocaine-trained animals exhibit a number of adaptations that are not observed in sucrose-trained animals. The majority of the differences in firing patterns between natural rewards and cocaine appear to reflect the differential presence of acute and chronic pharmacological actions of cocaine and are relevant to the search for mechanisms that contribute to drug addiction.

Studies of drugs other than cocaine and regions other than the NAcc have shown that firing patterns time locked to conditioned cues and operant behavior, as well as session-long changes in firing are general characteristics of neural activity during periods of drug-directed behavior. The presence of similar types of firing patterns between drugs and natural rewards is consistent with the evidence that drug-directed behavior of animals exposed to a limited history of drug self-administration is sensitive to many of the same variables that have an impact on natural reward-directed behavior. Moreover, the neural circuitry that contributes to both drug- and natural reward-directed behavior are similar. Continued studies

of drug reward and comparisons to natural reward are likely to further enhance our understanding of natural reward as well as drug reward and drug addiction.

Glossary

Abstinence/withdrawal – A syndrome of uncomfortable psychological and biological effects that result when the use of an addictive drug is discontinued.

Cigarette – French for small cigar (cigar + -ette). A manufactured product consisting of cured tobacco leaf and other additives that are rolled into a paper cylinder that may have a filter at one end. The product is ignited at the nonfiltered end and smoke is inhaled through the filtered end.

Cotinine – The primary chemical byproduct ($C_{10}H_{12}N_2O$) of nicotine metabolism that is often used as a marker of tobacco use because of its long half-life.

Drug addiction – A behavior pattern of psychoactive drug use that involves overwhelming involvement with use of the drug, securing its supply, and a high likelihood to relapse to drug use after abstaining from use. Addiction often is accompanied by tolerance and withdrawal effects.

Drug dependence – The highly controlled or compulsive use of a psychoactive drug that is reinforced by the effects of that drug. Drug dependence often is accompanied by drug tolerance and withdrawal.

Negative reinforcement – The increased likelihood that a behavior will be repeated when that behavior is followed by the removal of an unpleasant or aversive state.

Nicotiana tabacum – Genus and species name for the cultivated tobacco plant most commonly used to make commercial tobacco products.

Nicotine – A chemical alkaloid ($C_{10}H_{14}N_2$) that is found naturally in tobacco.

Nicotine replacement therapy (NRT) – Any of several medicinal nicotine-containing products intended to help a person abstain from tobacco use by offsetting withdrawal symptoms.

Nicotinic acetylcholine receptors (nAChRs) – Ligand-gated ion channels found in the cell membranes of various cell types, including neurons and muscles that open in response to the endogenous neurotransmitter acetylcholine and to nicotine.

Passive administration/involuntary smoking/second-hand smoking – A mixture of the side-stream smoke from a burning cigarette, cigar, or pipe, and the smoke exhaled by a smoker, that is inhaled by a nonsmoker.

Positive reinforcement – The increased likelihood that a behavior will be repeated when that behavior is followed by a pleasant or rewarding consequence.

Sympathomimetic – The activation of the sympathetic nervous system branch of the autonomic nervous system.

Tobacco – An herbaceous plant native to North and South America, Australia, southwest Africa, and the South Pacific that contains nicotine, and is used to make consumer products such as cigarettes, cigars, pipe tobacco, chewing tobacco, and snuff.

Nicotine is a fascinating drug with a long history. It is highly addictive, can be arousing, as well as calming, but is usually self-administered through deadly tobacco products. The study of nicotine has revealed important information about receptor biology underlying drug actions in the body, neurochemical pathways in the brain, and mechanisms of positive and negative reinforcement. This primary drug of addiction in tobacco products also may be used or may inspire the development of new medications to treat anxiety, mood, thought, and skeletal muscle disorders.

History of Tobacco and Nicotine

Historical Use

Tobacco use and the self-administration of nicotine through tobacco products date back centuries. Mayan stone carvings (c. 600–900 AD) indicate tobacco use in the New World and other archeological evidence indicates tobacco use dating back several millennia earlier. European explorers to the New World in the late fifteenth and sixteenth centuries discovered native people of the American and Caribbean islands smoking or chewing dried tobacco leaves in spiritual practices, for medicinal reasons, and to achieve desired effects, including appetite regulation, energy enhancement, and relaxation. The word tobacco is derived from the Y-shaped tube (called a taboca or tobago) that was used to smoke tobacco leaves in the Caribbean islands. Several species of wild tobacco plant grew indigenously in North and South America, including *Nicotiana petunoides*, *Nicotiana rustica*, and *Nicotiana tabacum*. The tall,

broad-leaved *N. tabacum* became the tobacco species that is primarily cultivated and sold for commercial use throughout the world. Today, tobacco is grown in over 100 countries worldwide, including the United States. In every country and culture where tobacco has been introduced, self-administration of tobacco products has become common and persistent.

Isolation and Synthesis

As tobacco use spread to Europe, interest in the plant and its actions grew. In the early 1800s, Cerioli and Vauquelin discovered that the major active ingredient in tobacco was an oily material which was named ‘nicotianine’ after Jean Nicot de Villemain, the French ambassador to Portugal who introduced tobacco to the French court as a universal cure-all herb. Several decades later, Posselt and Reimann at the University of Heidelberg isolated nicotianine from *N. tabacum* and changed the name to ‘nikotin.’ In the mid-1800s, Melsens determined the chemical formula for nikotin ($C_{10}H_{14}N_2$), and Schloesing determined its molecular weight (162.23 g mol⁻¹). In the late 1800s, Pinner discovered the structure of what became known as ‘nicotine,’ an Anglicized spelling of the German word. Also in the late 1800s, Langley and Dickinson discovered that nicotine acted to stimulate autonomic ganglia and investigations of these actions led to the idea that chemicals (including nicotine) act at specific sites or receptors on cells which, in turn, release chemicals that transmit information between neurons. Pharmacological study of nicotine became active in the mid-twentieth century and continues to the present day.

Physical Chemistry

Nicotine (3-(1-methyl-2-pyrrolidinyl)-pyridine) is a highly toxic liquid alkaloid found naturally in several plant species, including *N. tabacum*, and is the key addictive component of tobacco products. Nicotine is a bicyclic compound with pyridine and pyrrolidine rings. The compound possesses one asymmetric carbon and can exist in two enantiomeric forms. In nature, nicotine exists in the S-shape, or levorotary form. Nicotine is a colorless and odorless base, with a dissociation constant (pK_a) of approximately 8.0. It forms water-soluble solid salts when mixed with acids. Nicotine is hydrophilic and lipophilic and readily distributes throughout the body because it is absorbed through the skin, mucous membranes, lungs, and gastrointestinal tract. Free-base nicotine combusts at approximately 35 °C (95 °F), so much of the nicotine in a cigarette burns off when the cigarette is lit but the amount that is inhaled exerts powerful effects in the brain, nervous system, and at other sites in the body.

Forms of Nicotine and Their Use

Not only is nicotine most commonly self-administered through tobacco products, but it also is self-administered in an ever-increasing variety of nicotine replacement products.

Tobacco Products

Tobacco cigarettes are the most common nicotine-containing products. Most cigarettes are commercially produced, but some people continue to roll their own cigarettes. Smoking cigarettes is the most common way to self-administer nicotine and it is the most effective way to get nicotine to the brain. Tobacco also is smoked in pipes, cigars, flavored cigarettes, bidis, kreteks, and hookahs. Pipe and cigar smoking is more common among men than women, but cigar smoking is increasing in popularity among women. Flavored cigarettes are most common among teenage and young adult smokers. Flavored cigarettes usually have lower nicotine contents than conventional cigarettes, and have distinctive flavors such as cherry, mocha, or vanilla. Bidis are small, hand-rolled cigarettes primarily smoked in or imported from India and Southeastern Asian countries. Bidis may or may not be flavored. Kreteks are made from a mixture of tobacco, cloves, and other herbs. Bidis and kreteks deliver more nicotine than the standard tobacco cigarette. Hookah (also known as water pipe, nargeela, arghileh, and nargile) is a traditional Middle Eastern or Asian device that operates by water filtration and indirect heat to cool the tobacco smoke as it is inhaled by the smoker. Nicotine-containing tobacco products also include smokeless products, including chewing tobacco and snuff. Chewing tobacco is usually kept under the lip or in the cheek. Snuff can be inhaled through the nasal cavity.

Nicotine Replacement Products

In addition to tobacco products, nicotine is now available in various nicotine replacement products or nicotine replacement therapy (NRT). Nicotine polacrilex gum was developed by Ove Ferno and colleagues in Sweden in the 1970s to help people quit smoking tobacco cigarettes. Nicotine gum became available in the United States as a prescription medication in the 1980s to help alleviate withdrawal symptoms in abstinent smokers. By the twenty-first century several dosages and flavors of nicotine gum became available over the counter (OTC) and no longer required a prescription. Currently, nicotine is available in several other forms, including nicotine transdermal patches, nicotine vapor inhaler, nicotine lozenges, nicotine microtabs (small sublingual tablets that slowly dissolve under the tongue), nicotine nasal spray, and nicotine in water.

Epidemiology

Approximately 20% of adults (1.3 billion people) smoke cigarettes worldwide and more men than women smoke. Similarly, in the United States, 20.8% of adults (45.3 million people) currently smoke tobacco cigarettes, and prevalence is higher among men (23.9%) than among women (18.0%). In the United States, tobacco use by numbers and by percentage of the population has decreased over the past 20 years, but global numbers of smokers have increased. In the United States, it is estimated that 4000 children under the age of 18 try smoking each day, that about 2000 of them continue to smoke, and that almost 20% of high school students smoke cigarettes everyday.

Prevalence of smokeless tobacco use among adults in the US is about 3% (6% of men vs. 0.4% of women). About 8% of high school students in the US use smokeless tobacco (13.6% of males vs. 2.2% of females). Worldwide 11% of children use tobacco products other than cigarettes.

Administration, Absorption, and Distribution

The chemical and physical properties of nicotine allow it to be readily absorbed through the skin, mucous membranes, and the respiratory tract. These multiple sites of absorption and ready passage of nicotine allow it to be self-administered or administered medically through several different methods.

Self-Administration of Nicotine-Containing Tobacco Products

The most common way to self-administer nicotine is by smoking tobacco products, primarily commercially made cigarettes. When a person smokes a tobacco product, the inhaled smoke travels through the respiratory tract and is absorbed by the alveoli in the lungs. The absorbed nicotine passes from the alveoli through the capillary walls and into the bloodstream. The pulmonary circuit of the cardiovascular system carries nicotine directly to the brain within seconds of inhalation and the nicotine rapidly crosses the blood-brain barrier through passive diffusion because of its small size and lipophilicity and through active transport by the choroid plexus. As a result, the smoker receives a bolus of nicotine into the brain soon after taking a puff on the cigarette. That bolus infusion of nicotine sets off a cascade of neurochemical and neurophysiological events (discussed below under the section titled 'Actions') which result in reward, dependence, and other reinforcing effects.

Nicotine also is self-administered through smokeless tobacco products, but the time course for nicotine to reach the brain is much slower than with smoked tobacco products. Nicotine from smokeless tobacco either is absorbed in blood vessels in the mucous membranes of the mouth or travels to the stomach with saliva and enters the bloodstream through the digestive system. The amount of nicotine that reaches the brain from smokeless tobacco products is relatively small and some of it is metabolized in the liver before reaching the nervous system. The addiction liability to smokeless tobacco products is markedly less than the addiction liability to smoked tobacco products because of the slower time course and reduced quantities of nicotine that reach the brain.

Self-administration of Nicotine-Containing Medications

Nicotine is available in several products that are used as medications (NRT) to help smokers abstain from tobacco use and to attenuate withdrawal symptoms that accompany abstinence from regular tobacco self-administration. NRTs use several different routes of administration.

Nicotine polacrilex gum, or simply nicotine gum, was the first nicotine replacement product. Nicotine gum became available in Europe in the 1970s and seemed to be a valuable adjunctive pharmacological therapy to behavioral smoking cessation approaches. It was hailed as a new effective treatment to aid in smoking cessation but subsequent studies in the United States in the 1980s showed modest efficacy. Later in the 1980s and 1990s as nicotine addiction became better understood, comparison of nicotine gum clinical trials revealed that higher dosages were being used in the European versus American clinical trials. Now several dosages and flavors of nicotine gum are available. These gums are, indeed, useful ways to administer small amounts of nicotine and are valuable adjunctive therapies to behavioral and cognitive smoking cessation techniques.

Similar to nicotine gum, nicotine lozenges and nicotine microtabs administer nicotine orally. Some nicotine crosses the mucous membranes in the mouth and some nicotine travels through the gastrointestinal tract and is absorbed into the circulation. Much of this nicotine is metabolized in the liver, so reduced amounts of the drug reach the brain.

Nicotine can also be inhaled using an NRT vapor inhaler. Although the administration device is called a nicotine inhaler, most of the nicotine actually stays within the oral cavity and is absorbed through the oral mucosa rather than through the lungs. Similar to the gum, lozenge, and microtab, much lower plasma concentrations of nicotine are achieved from the NRT vapor inhaler than by smoking cigarettes, so many doses are necessary

throughout the day to satisfy the smoker and to attenuate withdrawal.

Nicotine patches and nicotine nasal spray deliver nicotine through different routes than the other products. Nicotine skin patches are now available in several dosages and from several manufacturers. Nicotine is slowly absorbed across the skin over many hours (up to 24 h per patch). The nicotine nasal spray administers the drug intranasally and it is absorbed through the blood vessels in the mucous membrane of the nose. As with the other NRTs, dosages of nicotine are much lower and follow a slower time course than smoking tobacco products, which is why these products have a low addiction liability compared with smoking nicotine-containing tobacco.

Passive Administration

It is important to realize that nicotine can be administered unknowingly. Environmental tobacco smoke (also known as ETS, second-hand smoke, involuntary smoking, or passive smoking) from side-stream smoke of burning tobacco products and from exhaled smoke from tobacco smokers is absorbed by inhalation and transdermally by nonsmokers who are in the proximity of smokers. In fact, a nonsmoker who lives with a two-pack-a-day smoker can have urinary levels of cotinine (the primary metabolite of nicotine) equivalent to smoking several cigarettes per day. The amount of ETS exposure increases in spaces that are enclosed, poorly ventilated, or where the air is recirculated. That is why airplanes and many restaurants and enclosed public places have banned tobacco smoking. Children are at particular risk to develop smoking-related pulmonary health problems as a result of ETS.

Distribution

Following absorption, nicotine is rapidly distributed in many tissues and organs throughout the body because it is lipophilic and readily passes through cell membranes. In

cigarette smokers and other tobacco users, nicotine reaches its peak plasma concentration within 30 min of administration, and then slowly declines during the next several hours. Smoking cigarettes delivers nicotine to the brain within seconds of inhalation. NRTs have different time courses for distribution of nicotine based on the specific route of administration. Nicotine nasal spray, gum, and lozenges deliver and distribute nicotine quickly to the peripheral bloodstream, but nicotine levels also decline quickly using these methods. In contrast, nicotine is delivered slowly by the nicotine transdermal patch. For the 24-h patch, plasma concentrations of nicotine rise slowly during the first 6–10 h, plateau after 8–12 h, and then decline slowly during the subsequent 6 h. The slow distribution and clearance of the patch allow for its once daily use, as opposed to the high dosing frequency of other NRTs.

Actions

Table 1 presents a summary of neural substrates underlying key actions of nicotine.

Nicotine Receptor Biology

Nicotine acts at chemical receptors located throughout the body which partially explains its wide-ranging biological and psychological effects. Nicotine is an agonist at nicotinic acetylcholine receptors (nAChRs) in the central and peripheral nervous systems (nAChR_N), but has little or no effect at similar nicotinic acetylcholine receptors in the muscle (nAChR_M). The receptors are presynaptic ligand-gated ion channels which are composed of five subunits. There are several classes of subunits found in the nervous system (including α and β), each of which has several different subtypes (e.g., $\alpha 2-10$ and $\beta 2-4$). α -Subunits are differentiated from the β -subunits because they have two adjacent cysteine residues that are necessary for the binding of acetylcholine. There is

Table 1 Summary of neural substrates underlying key actions of nicotine

<i>Nicotine action</i>	<i>Neural substrate</i>
Reinforcing and rewarding effects	Mesocorticolimbic dopamine pathway (including PFC, NAcc and VTA) via $\alpha 4\beta 2$
Increase attention, alertness, vigilance, and arousal	Decreased slow-wave EEG, increased fast-wave EEG
Enhance memory	Hippocampus via $\alpha 7$
Enhance movement	SNC
Sympathomimetic effects (including effects on respiration, heart rate, and blood pressure)	Sympathetic and parasympathetic branches of the autonomic nervous system
Mood modulator	Via increased serotonin release
Maintenance of self-administration and conscious urges	Insula and mesocorticolimbic dopamine pathway
Induce nausea and vomiting	Emetic trigger zone in area postrema
Induce vasopressin secretion	Supraoptic nucleus of hypothalamus

growing evidence that the various effects of nicotine (e.g., addiction, appetite regulation, mood modulation, and attention effects) in humans and animals may be explained by activation of different nicotine receptor subunits and various combinations of these subunits.

Nicotine receptors are found on dopaminergic ($\alpha 4\beta 2$, $\alpha 6\beta 2$, and $\alpha 6\beta 3$), glutamatergic ($\alpha 4\beta 2$ and $\alpha 7$), γ -aminobutyric acid (GABA)ergic ($\alpha 4\beta 2$), adrenergic ($\alpha 3\beta 2$ and $\alpha 7$), and cholinergic ($\alpha 3\beta 4$) nerve terminals. The receptors are located in several areas of the brain relevant to reward, addiction, and psychoactive effects, including the substantia nigra pars compacta (SNc), ventral tegmental area (VTA), nucleus accumbens (NAcc), midbrain tegmentum, striatum, and various regions of the cerebral cortex. The receptors are located presynaptically in the brain. Nicotine binding increases depolarization of the nerve terminal, leads to an influx of Ca^{2+} , and enhances neurotransmission at that terminal. Stimulation of nAChRs in the VTA, for example, releases dopamine in the NAcc, an area responsible for the reinforcing effects of many drugs. Mice genetically bred with the $\alpha 4$ - or the $\beta 2$ -subunit knocked out do not exhibit increased dopamine release in response to nicotine, and do not maintain nicotine self-administration. Further, $\alpha 4$ knock-in mice (which express a defective $\alpha 4$ -subunit) show reduced sensitization, reinforcement, and tolerance to nicotine. These data suggest that the $\alpha 4\beta 2$ receptor is necessary for dopamine release in the NAcc and is a key receptor underlying nicotine self-administration. The $\alpha 7$ -subunit seems to be involved in effects of nicotine on attention and memory and also may be involved in axogenesis and neuroprotection. Ongoing studies of nicotine subunits are focusing on the development of new medications to treat nicotine dependence and to treat other conditions that may be helped by nicotine agonists, including cognitive dementias; anxiety, mood, and thought disorders; and skeletomuscular problems.

Nervous System and Neurotransmitters

Nicotine acts at many sites in the brain, including the medial habenula, interpeduncular nucleus, SNc, and VTA. These sites are relevant to nicotine's physical (movement), cognitive (attention), motivational (reinforcement and reward), and therapeutic effects (e.g., to treat schizophrenia, dementia, or Parkinson's disease). Nicotine acts in the central nervous system (CNS) and peripheral nervous system (PNS). It is classified as a sympathomimetic pharmacological agent but it actually stimulates both the sympathetic and parasympathetic branches of the autonomic nervous system (ANS). Nicotine induces the release of norepinephrine in the sympathetic branch and acetylcholine in the parasympathetic branch of the ANS. Because the two branches have

opposing actions, nicotine can exert differential effects depending on which branch has greater activation. These opposing effects may help explain why nicotine seems to be unique in that it can stimulate or relax, arouse, or calm. Colloquially stated, nicotine can bring people up when they are down and down when they are up. Although these opposite physiological effects have been well known to scientists and smokers for a century, psychologist Stanley Schachter (in the late 1970s) referred to this phenomenon as Nesbitt's paradox, based on research in his laboratory being conducted by Paul Nesbitt, and the nickname stuck.

Nicotine acts on mesolimbic and mesocortical dopaminergic pathways that are involved in reward and addiction. The major dopaminergic neurons of these pathways originate in the VTA and project to the NAcc, pallidum, hippocampus, amygdala, and medial prefrontal cortex (PFC) in the mesolimbic circuit, or to other areas of the frontal cortex in the mesocortical pathway. The mesocorticolimbic dopamine pathway is involved in reinforcing or rewarding effects of pleasurable experiences or activities including drug use. After smoking a cigarette, dopamine levels in the NAcc increase, which increases the likelihood that the person will smoke (self-administer nicotine) again in the future. Nicotine also increases release of serotonin, which may underlie nicotine's effects to help modulate mood. The insula, sometimes called the fifth lobe of the brain, is involved in conscious urges, and also may be involved in maintenance of nicotine self-administration and smoking. Nicotine increases the respiration rate through receptors in the carotid body and aortic arch, induces nausea and vomiting through receptors in the emetic trigger zone of the midbrain's area postrema (which is why first-time smokers often feel sick), and induces vasopressin secretion by acting in the supraoptic nucleus of the hypothalamus.

Physiology

Nicotine is considered a CNS stimulant or sympathomimetic because it increases heart rate, respiratory rate, blood pressure, and causes peripheral vasoconstriction. Increased arousal is evident in the electroencephalogram (EEG). Nicotine decreases slow-wave electrical activity in the brain; increases faster, high-voltage waves that are involved in conscious, active thought; and enhances responses to auditory and evoked potential responses reflecting increased attention and information processing. Nicotine decreases skeletal muscle tone as reflected by electromyogram (EMG) recordings, which may contribute to feelings of relaxation when smoking. Nicotine also decreases body weight by decreasing appetite and by increasing metabolism.

Behavior

Nicotine's ready passage into the CNS, especially when self-administered in tobacco smoke, produces marked central effects that increase subsequent self-administration of nicotine-containing products. The close temporal association between nicotine self-administration and central actions and the rewarding effects of nicotine (including increased arousal, attention and mood, and reduced anxiety, appetite, and body weight) increase the likelihood of nicotine self-administration.

Cognition

Nicotine increases selective attention, sustained attention, alertness, and vigilance. It also decreases distraction. Clinical studies suggest that nicotine can improve cognitive function in cases of senile dementia and Alzheimer's disease.

Motivation

Nicotine acts in several ways to alter motivation for nicotine self-administration. Nicotine decreases general and specific hunger (to sweet tastes) and increases desire for nicotine itself. It is likely that these motivational effects are related and that both involve mechanisms of the mesocorticolimbic dopamine pathway. These effects include alterations in hedonic tone, so it is likely that the limbic system also is involved in the pleasant experience associated with nicotine administration with repeated exposure. Further, it is likely that endogenous opioid systems and serotonergic mechanisms act in concert with the dopaminergic pathways to underlie reinforcement of nicotine self-administration. Both positive and negative reinforcement also contribute to motivation to self-administer nicotine. Nicotine's neurochemical actions (especially on dopamine, serotonin, and endogenous opioid peptides), appetite-controlling effects, and attention-enhancing effects, all act as positive reinforcers to increase the likelihood of nicotine self-administration. The unpleasant withdrawal effects following nicotine abstinence act through negative reinforcement to motivate nicotine self-administration to offset the abstinence effects (see the section titled 'Abstinence effects'). The fact that nicotine self-administration accompanies stress also may reflect a motivational effect and seems to involve the corticotropin-releasing factor (CRF) system.

Toxicity

Nicotine is a poisonous chemical and is used as a powerful pesticide. It is toxic at 60 mg for the average human adult and roughly 10 mg for a child. Exposures to toxic levels of nicotine are most common in tobacco farmers and in

people exposed to high amounts of nicotine-containing pesticides. Symptoms of acute nicotine poisoning include nausea, vomiting, salivation, cold sweat, pallor, abdominal pain, diarrhea, and respiratory distress as a result of over-stimulation of nAChRs in the ANS. Prolonged exposure to high dosages of nicotine results in severe CNS depression, muscle paralysis, and respiratory failure. The leading cause of death from nicotine poisoning is respiratory failure.

Metabolism

The liver is the major site of nicotine metabolism in the body, accounting for 80–90% of its metabolism. Approximately 70–80% of nicotine metabolized by the liver is converted to the nicotine iminium ion and 5'-hydroxynicotine by the cytochrome P450 (CYP) enzymes 2A6 and 2B6, and then to cotinine by aldehyde oxidase. Sixty percent of cotinine is further metabolized. Whereas it is clear that nicotine is an active drug, there is some evidence that cotinine also may have physiological and psychopharmacological actions. A small percentage of nicotine is converted to nicotine-1'-N-oxide (4%) by flavin-containing monooxygenase, nicotine glucuronide (4%) by *N*-glucuronidation, and nornicotine (<1%) by *N*-demethylation. Some nicotine is excreted unchanged. Minor sites of nicotine metabolism include the brain, lungs, and kidneys.

Elimination

Nicotine has an elimination half-life ($t_{1/2}$) of approximately 2 h in humans, but this value varies from 1 to 4 h among people. This relatively short $t_{1/2}$, and the relative pharmacological inactivity of nicotine's metabolites contribute to frequent smoking by people who are addicted to nicotine. The $t_{1/2}$ for cotinine is 17 h, and cotinine clearance is highly correlated with nicotine clearance. Concentrations of cotinine in the saliva, plasma, and urine are correlated, so salivary cotinine serves as a good biomarker for tobacco or nicotine exposure.

The major site of elimination for nicotine and its metabolites is in the urine, through the kidneys. Approximately 10% of nicotine and 10% of cotinine are excreted unmetabolized in the urine, although the process is pH dependent. When the pH of urine is acidic, then nicotine reabsorption from the kidney decreases which results in increased renal clearance of nicotine. Certain foodstuffs as well as physical and psychological stress can acidify the urine and may thereby contribute pharmacokinetically to increased nicotine intake through cigarette smoking.

Trace amounts of nicotine and its metabolites remain in other body fluids, such as the saliva. Nursing mothers also secrete nicotine in breast milk which can expose nursing children to nicotine.

Abstinence Effects

Abstinence from nicotine self-administration in a drug-dependent or addicted individual results in withdrawal effects. Symptoms of nicotine abstinence include craving for nicotine, irritability, difficulty concentrating and paying attention, sleep difficulties, dysphoria, impatience, increased appetite, and weight gain. Most of these symptoms begin within 24 h after nicotine abstinence, peak between 36 and 72 h, and gradually subside after several days. However, urges or craving for nicotine and increased appetite and weight gain can persist for 6 months to a year. The withdrawal symptoms, severity, and length of time symptoms last vary widely among people, and may be influenced by gender, age, ethnicity, duration of nicotine self-administration, and amount of nicotine self-administration.

Administration of nicotine will attenuate or offset the unpleasant withdrawal symptoms and will enhance dependence on nicotine via negative reinforcement. NRTs are used to offset withdrawal symptoms and to complement behavioral, cognitive, and motivational strategies and techniques to help people successfully give up tobacco use.

Glossary

Aberrant drug-related behaviors – Behaviors such as unauthorized dose escalations or obtaining controlled prescriptions from multiple physicians may signal the presence of abuse or addiction. However, such behaviors sometimes reflect inadequate analgesia (pseudoaddiction) or the misuse of opioid analgesics to treat mood or other psychiatric symptoms.

Buprenorphine – Partial μ -opioid agonist and kappa antagonist, listed on Schedule II and approved by the Food and Drug Administration (FDA) for the treatment of opioid dependence since 2002. The combination tablet Suboxone (buprenorphine/naloxone) is the abuse-deterrent formulation recommended for the treatment of opioid abuse. Suboxone can be used for the concurrent treatment of opioid dependence and chronic pain.

Medication agreement – Written agreements delineating rules for patients receiving opioid analgesic therapy. Intended to be a communication tool, such agreements specify parameters for adherence, methods for monitoring compliance (e.g., random urine testing, pill counts), and general goals of treatment. Medication agreements typically call for periodic reassessment and a clear exit strategy for opioid tapering and termination, in the event of either lack of therapeutic response or nonadherence.

Methadone – Full μ -opioid agonist with a long half-life (17–128 h). When used to prevent opioid withdrawal, once-daily dosing is sufficient. Analgesic effects only last for 6–10 h, however. Methadone must be prescribed at a low dose initially and then titrated slowly to avoid toxicity.

Prescription-opioid addiction – Distinguished from simple physiological dependence, opioid addiction consists of one or more of the following behaviors: impaired control over drug use, continued use despite harm, and craving. Rates of the nonmedical use and abuse of prescription opioids have risen dramatically in the United States of America (USA) in the past two decades.

Pseudoaddiction – Reversible opioid-seeking behavior occurring in a patient with under-treated pain whose behavior normalizes once the pain is under control. This behavior is not maladaptive and, thus, does not represent drug addiction but may be misinterpreted as opioid abuse.

Epidemiology of Pain in the United States of America

Pain that persists or recurs for more than 6 months is defined as chronic and is one of the largest medical problems in the developed world. Chronic pain is a major health issue in the United States of America (USA), affecting approximately 76 million Americans. There is, thus, an enormous population at risk for becoming involved in prescription-opioid misuse. Its economic toll, including healthcare costs and lost work productivity, is about \$100 billion per year. These individuals experience decreased quality of life and frequently suffer from sleep disturbance, depression, and anxiety. A recent cross-sectional survey found that 13% of the total US workforce experienced a loss in productive time in a 2-week period due to a common pain condition. Headache is the most common (5.4%) pain condition resulting in lost productive time, followed by back pain (3.2%), arthritis pain (2.0%), and other musculoskeletal pain (2.0%). A large study in the Southwest found that 30% of hospitalized patients reported being under-treated for pain. In addition, in the ambulatory population, it is estimated that 50–70 million people in the USA suffer from pain that is under-treated or not treated at all.

Despite the prevalence and importance of chronic pain, many healthcare providers wish to avoid becoming involved in its treatment for several reasons. Persons with chronic pain who have seen many physicians without relief

may be perceived as less than honest concerning their symptoms. The treatment of pain is complicated and requires a multidisciplinary approach, which often receives poor reimbursement. In addition, chronic pain does not produce sympathetic arousal, and the absence of objective signs of physiological stress often leads to potential skepticism about the reported symptoms. Finally, in the face of increased regulatory scrutiny and an epidemic of prescription drug abuse, many clinicians have shied away from using opioids. This position of real or perceived vulnerability in which healthcare professionals find themselves places patients at risk for suboptimal management of an often treatable medical condition.

Epidemiology of Prescription-Opioid Abuse in the USA

In the past two decades, the nonmedical use and abuse of prescription opioids has risen dramatically in the USA. Between 1990 and 2003, the rate at which young adults (age range: 18–25) initiated prescription-opioid abuse tripled from 10.2 per thousand-person-years in 1990 to 31.6 per thousand person-years in 2003. From 1992 to 2005, the US population increased by 15%, whereas during this period the number of adults abusing controlled substances increased by 98%. A 2006 survey by the Partnership for a Drug-Free America showed that 19% of US teens (4.5 million) reported using prescription opioids that were not prescribed to them. In 2005, 2.4% of the US population in the age range 18–25 initiated the use of a pain reliever for a nonmedical purpose. The abuse of prescription opiates starts later (21.9 years) on average than that of marijuana (17.4 years) and alcohol (16.6 years). ‘Generation Rx’ is the popular name given by the Partnership for a Drug-Free America for these young, adult, prescription-opioid abusers.

Young adults are much more likely to start abusing prescription opioids than illegal opioids such as heroin. Dependence on or abuse of prescription opioids is now as common as dependence/abuse of cocaine, and more common than dependence/abuse of any other drug except marijuana. Compared to heroin abusers, prescription-opioid abusers are more likely to be white, be younger, have higher incomes, and use less opioid per day. Prescription-opioid users also seek treatment earlier, are more likely to complete treatment, and have better outcomes than patients using heroin. In addition, prescription-opioid users are less likely to have hepatitis C infection.

The Drug Abuse Warning Network – another indicator of problem drug use – revealed that overall narcotic analgesic emergency department (ED) visits rose from 42 857 in 1995 to 160 363 in 2005. Methadone, oxycodone, and hydrocodone were the most frequent opioids. During the period 1992–2002, ED visits involving narcotic analgesics increased for all age groups, except those in

the age range 12–17, and the 45–54 age group experienced the largest increase (298%). From 1995 to 2002, increases in drug abuse-related ED visits were observed for several individual opioid analgesics: oxycodone (512%), methadone (176%), hydrocodone (159%), and morphine (116%). The most frequently mentioned motive underlying drug abuse-related ED visits involving narcotic analgesics was dependence (47%; 50 623 visits), followed by suicide (22%; 24 308 visits), and psychic effects (15%; 16 153 visits). Further, among reported drug-induced and drug-related deaths, a narcotic analgesic ranked in the top three most frequently reported drugs in New York and in seven other US cities. Taken together, these data reveal that the continuing trend toward increasing nonmedical use and abuse of prescription opioids in the USA has resulted in sharp recent rises in morbidity and mortality at the local and national levels.

While prescription opioid abuse is increasingly common among young adults, its initiation is also closely tied to the relief of pain. A 2004 survey of patients presenting for methadone therapy found that 83% had been using prescription opioids (with or without heroin), and 24% had been using prescription opioids exclusively. The majority of patients using opioids only (or initially) reported that their primary reason for starting to use opioids was to treat pain: 86% (and 62%, respectively). Most (61%) of those using prescription opioids obtained at least some of their supply from physicians. However, most prescription-opioid abusers obtain their drugs from family members or friends, and not directly from physicians. The most common source for nonmedical users to obtain pain-relievers is from a friend or relative for free; 53% of past-year prescription-drug users said they received the prescription drug in this way, while 13% obtained prescriptions from one physician, and 11% bought the pills from a friend or relative. In a sample population of nearly 28 000 patients presenting for addiction-treatment programs in 2001–04, 78% of those who reported OxyContin use had not received a prescription for any medical reason.

Neurobiology of Opioid Addiction

Like other types of substance dependence, opioid addiction is a chronic neurobiological disease arising from repeated exposure to an addictive drug and characterized by loss of control over drug use. Neuroadaptive dysregulations within the brain reward systems and emotional/stress systems occur with chronic abuse to produce the profound dependence that characterizes opioid addiction. The ‘reward circuits’ that play a pivotal role in maintaining a pattern of compulsive drug taking are comprised of neuronal pathways that originate within the ventral tegmental area (VTA) and project to the nucleus accumbens

(NAcc), amygdala, and prefrontal cortex. Opioids act to release dopamine (DA) directly via the opioid receptors in the NAcc, as well as indirectly by decreasing γ -aminobutyric acid (GABA) inhibition in the VTA.

Certain neuropathological changes have been found in individuals with a history of opioid abuse. These include reductions in gray matter in the prefrontal, insular, and temporal cortices in patients on methadone maintenance compared with age- and sex-matched controls. Lower-than-normal levels of *N*-acetylaspartate, a marker of neuronal viability, have also been detected by magnetic resonance spectroscopy in frontal gray matter of patients maintained on methadone, buprenorphine, or heroin. To date, these studies do not allow the differentiation of pre-existing conditions from possible effects of opioid abuse.

Several recent studies have provided some insight into the poor behavioral regulation that is a core feature of substance abuse. Chronic pain patients demonstrate cognitive deficits including decision-making abnormalities and impaired prospective short-term memory. Functional magnetic resonance imaging (fMRI) studies have shown that chronic pain patients display reduced deactivation in several key regions of the 'default mode network' (DMN), representing areas of the cortex known to be active at rest. Absent or diminished error-related activation has been found in the anterior cingulated cortex in opiate users, with compensatory recruitment in the parietal and temporal areas in order to perform the task. Heroin addicts also display disadvantageous decision making and prolonged deliberation times while making risky decisions. Evidence from neuropsychological and neuroimaging studies suggests that impairments in prefrontally mediated cognitive functions, namely decision making and inhibitory control, are associated with addiction. These deficits increase the risk for impulsive decisions and may underlie the 'loss of control' pattern characteristic of opioid addicts, who display poor inhibitory control of drug-related behavior despite adverse consequences.

Recent US Trends in Opioid Prescribing

Opioid prescribing practices play an important role in the supply of abusable opioids and hence the rise in prescription-opioid dependence. Opioid prescriptions have increased substantially from 1997 to 2005, with increases of 933% in methadone prescriptions, of 588% in oxycodone prescriptions, and of 198% in hydrocodone prescriptions. Much of the increase in methadone prescriptions occurred because of escalating abuse and diversion of OxyContin. Physicians looked for a suitable long-acting analgesic and erroneously chose methadone, which has a duration of analgesic action only slightly longer than morphine. In EDs, opioid prescribing for pain-related visits increased from 23% in 1993 to 37% (95% CI: 34–39%)

in 2003 ($p < 0.001$ for trend). This trend was more pronounced in 2001–05 ($p = 0.02$), following national quality-improvement initiatives in the late 1990s which emphasized the need for adequate treatment of pain. Similarly, a nationally representative stratified cluster sample of 30 000 physician office visits in the decade 1993–2003 revealed a significant increase in the visit rate over the decade from 0.126 opioid visits per person in 1993 to 0.1666 – a 32% increase ($p < 0.001$ for trend). During this same period, there was a large shift in the types of opioids prescribed; while codeine and propoxyphene visit rates declined by 40% and 28% respectively, substantial increases occurred in visit rates for higher-potency opioids such as hydrocodone and oxycodone (115% and 156%). The co-occurring increases in opioid abuse and prescribing in the last decade suggest that both EDs and office visits are channels for the supply of abused opioids. Regulatory actions by the Drug Enforcement Administration (DEA) in 2006–07 have substantially curtailed the availability of prescription-opioid analgesics via Internet pharmacies.

In pain-management settings, at present up to 90% of patients receive opioids for chronic pain management. While chronic opioid analgesic therapy will lead to opioid abuse or addiction in a small percentage of chronic pain patients (3.3%), a larger percentage will demonstrate aberrant drug-related behaviors or illicit drug use (11.5%). While these percentages are considerably lower (0.2% and 0.6%, respectively) if chronic pain patients are preselected for the absence of a current or past history of alcohol or illicit substance use or abuse/addiction, the presence of an addictive disorder does not adequately predict prescription-opioid abuse.

Education with regard to the risks attendant in prescribing controlled substances is currently lacking in schools of medicine and pharmacy. Surveys have shown that less than 40% of physicians have received any training in medical school in identifying prescription-drug abuse or diversion. In addition, only 50% of pharmacists receive any training in recognizing prescription drug abuse, addiction, or diversion. Moreover, at present it is not known whether the risk of iatrogenic addiction in patients treated with opioid analgesics is relatively high (>10%) or low (<0.1%). Randomized trials and comparative longitudinal studies have been lacking, and methodologically weak studies have yielded conflicting results.

Psychiatric Comorbidities in Chronic Pain Patients

Chronic pain patients frequently present with psychiatric comorbidities including depression, anxiety, substance-use disorders, somatization, and personality disorders. Among chronic pain patients, the prevalence of drug or alcohol

abuse has been noted to be 3–19%. Some recent studies have suggested even higher rates. A prospective cohort study among opioid-treated chronic pain patients reported a 1-year incidence of 32%. Although the direction of causality remains controversial, there is some recent evidence to suggest that psychiatric disorders lead to substance abuse among prescription-opioid users, rather than prescription opioids posing an iatrogenic risk for substance abuse.

By contrast, the rates of new-onset opioid abuse in patients introduced to opiates medically appear to be quite low. Of the total of 15 000 veterans who were initiated and maintained on opiates for at least 3 months, only 2% developed an opioid abuse diagnosis. Another recent prospective study found a new opioid abuse incidence of about 6% in individuals previously treated for pain. Of note, this study found prior amphetamine use to be the single best predictor of future nonmedical opioid use. This association is striking in light of the recent finding that in patients treated for the first time with opioids for chronic pain, a subjective feeling of stimulation was predictive of eventual addiction.

Assessment of Substance Abuse in Long-term Opioid Therapy

Given that many patients taking opioids may not exhibit psychological dependence such as craving or other overt addictive behaviors, special attention is needed to assess potential opioid abuse in pain patients. In a study of opioid-abuse criteria among 404 chronic pain patients enrolled in a pain clinic, neither past opioid or alcohol abuse, nor psychosocial testing on admission reliably predicted who would become an opioid abuser. Aberrant drug-related behaviors that suggest an addiction disorder in pain patients include: (1) selling prescription drugs; (2) forging prescriptions; (3) stealing drugs; (4) injecting oral formulations; (5) obtaining prescription drugs from non-medical sources; (6) concurrent abuse of alcohol or illicit drugs; (7) repeated dose escalations or otherwise failing to comply with the prescribed regimen despite warnings; (8) losing prescribed medication on multiple occasions; (9) repeatedly seeking prescriptions from other clinicians or from emergency rooms without informing the prescriber or after warnings to desist; (10) showing evidence of deterioration in the ability to function (at work, in the family, or socially) that appears related to drug use; and (11) repeatedly resisting changes in opioid therapy despite evidence of adverse effects from the drug.

Another screening tool for the assessment of addiction in patients with chronic pain – the Prescription Drug Use Questionnaire (PDUQ) – evaluates patterns of opioid use, social and family factors, and substance-abuse and psychiatric history. Screening indicators identified as strong predictors of the presence of addictive disease in patients

with chronic pain were: a tendency to hoard unused medications, using analgesics to relieve symptoms other than pain, supplementing analgesics with alcohol or other psychoactive drugs, and a history of being terminated from care by a healthcare professional because of concerns about analgesic use. Further, responses to three questions were identified as key predictors of addictive disease: (1) patient believes he/she is addicted; (2) increases analgesic dose/frequency; and (3) route of administration preference. These preliminary findings, while promising, have not been validated in larger samples of chronic pain patients. At present, there are no clear clinical guidelines for identifying chronic opioid users in pain treatment who are abusing their prescription opioids. The most objective methodology developed to date for identifying such patients has been the Pain Assessment and Documentation Tool (PADT) which assesses four domains of patient response during long-term opioid therapy: pain relief, patient functioning, adverse events, and drug-related behaviors.

The term ‘pseudoaddiction’ refers to reversible opioid-seeking behavior occurring in a patient with under-treated pain whose behavior normalizes once the pain is under control. Because the behavior is not maladaptive, it does not meet the criteria for drug addiction. Drug-seeking behavior may be seen with either active addiction or pseudoaddiction, or as part of deviant behavior such as drug diversion. A way to distinguish between these conditions is by giving the patient appropriate pain medication and subsequently observing the pattern of behavior to determine the cause of the drug-seeking behaviors.

There are difficulties associated with applying the definitions and criteria developed for addiction in illicit drug users to pain patients. Depending on the measure of abuse cited in various studies (i.e., opioid abuse vs. any substance use), reported rates of drug abuse among chronic pain patients maintained on opioid therapy may be relatively low or quite high. Further, opioid-maintained pain patients often develop physical dependence and analgesic tolerance without apparent behavioral change. In pain patients, the clinical picture of progression from simple dependence through problematic use to addiction is more subtle and insidious than that observed in illicit users. Addiction is thus far more difficult to identify in this population.

Treatment Strategies for Prescribing Narcotics to Pain Patients

The use of prescription opioids for the treatment of pain is associated with the need to monitor patients carefully for signs of the misuse or abuse of medications. A common strategy employed in the clinical setting is the use of a narcotic protocol, consisting of a narcotic contract,

consent, psychological evaluation, and random urine-toxicology testing to ensure that controlled substances are being used safely and appropriately. Opioid abuse or other substance abuse appears to be relatively common in patients maintained on chronic opioid therapy. A retrospective 3-year study of such patients found that 43% had either positive urine toxicology or one or more aberrant drug-taking behaviors. Of patients with no behavioral issues, 21% had a positive urine screen for either an illicit drug or a nonprescribed controlled medication. In addition, in patients with no evidence of drug abuse on urine toxicology, 14% displayed one or more problematic behaviors. Thus, monitoring both urine toxicology and aberrant behaviors in chronic pain patients treated with opioids will detect more patients with inappropriate drug taking than either strategy alone.

Since there is no definitive test to predict which patients will do well with a therapeutic trial of opioids for chronic pain, it is advisable to take a universal precautions approach to all patients. This uniform approach reduces stigma, improves patient care, and reduces risks. Universal precautions include asking patients about personal and family history of substance abuse (often using screening tools), obtaining informed consent for treatment (usually with a formal, written treatment agreement), ongoing reassessment of benefits from a trial of opioid therapy, and complete documentation of the evaluation and reassessments.

By using universal precautions, clinicians can triage individuals to different categories (low-, medium-, and high-risk) in terms of addiction liability. Low-risk patients with chronic noncancer pain have no history of substance abuse and lack any major psychiatric comorbidity. There are no indications of aberrant behaviors in such individuals, and they can be managed in a primary care setting. Medium-risk patients may have a prior history of substance abuse or dependence, family history of substance abuse, or may have psychiatric comorbidity. These individuals can be managed in a primary care setting, particularly with consultation from a specialist (e.g., an addiction specialist or psychiatrist). High-risk patients are those with active addictive disorders. These individuals are at an increased risk for aberrant behaviors and should be referred to a tertiary clinic that specializes in pain management. In this setting, it is recommended that clinicians, together with the patient, prepare treatment agreements that delineate rules such as having no early refills and requirements for urine toxicology.

Sometimes referred to as a contract, a medication agreement is intended to be a communication tool rather than a legally binding contract. Medication agreements usually specify parameters for adherence, means by which compliance will be monitored, and general goals of treatment. In a recent study, monitoring adherence was associated with a 50% reduction in opioid abuse among patients in

chronic pain management. Adherence monitoring is carried out by obtaining an appropriate history and using an initial medication agreement to communicate the parameters for periodic evaluation of appropriate medication use, random drug testing, and pill counts.

The appropriateness of ongoing opioid use should be periodically evaluated, especially if there is little or no objective evidence of improvement in terms of pain relief or function. In any trial of opioid pain-management therapy, there must be a clear exit strategy which may include opioid tapering and termination, in the event of either a lack of therapeutic response or nonadherence to the treatment contract.

Treatment of Chronic Pain in Substance Abusers

Both methadone and buprenorphine are medications available for the treatment of opioid dependence, and can also be used for the treatment of chronic pain. They are recommended for patients with a history of substance abuse, especially opioid abuse or dependence. Methadone is a full opioid-agonist with a long half-life (17–128 h). While once-daily dosing is sufficient to prevent opioid withdrawal, analgesic effects last only for 6–10 h. Caution should be used with titrating the dose of methadone. It should be prescribed at a low dose initially, and then increased slowly to avoid toxicity.

Buprenorphine is a semisynthetic thebaine derivative. It is classified as a partial μ -opioid agonist and κ -opioid antagonist. Its analgesic potency is 25–40 times that of morphine and it slowly dissociates from opioid receptors, which is in part responsible for its long duration of action. Buprenorphine is well absorbed sublingually, with 60–70% of the bioavailability of intravenous doses. At higher doses, its agonist effect plateaus and it begins to behave more like an antagonist, thus limiting the maximal analgesic effect and respiratory depression. Analgesic doses of buprenorphine are usually given in divided daily doses because the analgesic duration is 6–9 h.

Buprenorphine, listed on Schedule III, was approved by the FDA for the treatment of opioid dependence in 2002. It is the first agent available in the USA for office-based treatment of opioid dependence under the Drug Abuse Treatment Act of 2000. The main objective of this law was to expand access to treatment for opioid dependence by incorporating its management into primary care medicine. The ‘ceiling effect’ of buprenorphine as a partial agonist confers a high safety profile clinically and results in a low level of physical dependence and only mild-to-moderate withdrawal symptoms upon cessation after prolonged administration. The lower total daily doses of sublingual buprenorphine used for opioid dependence overlap with the upper end of the dosing range

evaluated for chronic pain (2–16 mg per day vs. 0.4–3.2 mg sublingually per day, respectively). Several studies have shown that buprenorphine treatment for opioid dependence reduces illicit opioid use, retains patients in treatment, has few side effects, and is acceptable to most patients. The combination tablet Suboxone (buprenorphine/naloxone) is the formulation recommended for use in opioid abusers. The inclusion of naloxone in this preparation discourages street diversion for parenteral administration. When taken as directed, the pharmacological effects of the mono- and combination formulations do not differ, so the use of the combination product in opioid abusers with chronic pain is appropriate.

Conclusions

Prescription opioids remain safe and effective pharmacotherapies for chronic nonmalignant pain. Over the last decade, however, a marked increase in abuse of prescription opioids has occurred in the USA. This continuation in nonmedical use of opioid analgesics has resulted in sharp recent rises in morbidity and mortality at the local and national levels. To date, predictive factors for opioid abuse or addiction among opioid-maintained chronic pain patients have not been clearly identified. Moreover, the risk of iatrogenic addiction in patients treated with long-term opioid analgesics has not yet been adequately characterized.

The vast majority of pain patients taking opioids are physically dependent but not addicted; that is, they have developed an expected physiological response to the regular use of opioids and will experience a characteristic withdrawal syndrome, including myalgias and gastrointestinal distress, upon abrupt cessation of the drug. Some opioid-maintained pain patients will also develop addiction, which is a treatable neurobiological disease influenced by genetic, psychosocial, and environmental factors. Addiction is characterized by one or more of the following behaviors: impaired control over drug use, compulsive use, continued use despite harm, and craving.

Aberrant medication-taking behaviors (e.g., unauthorized dose escalation, ‘doctor shopping’ – i.e., visiting multiple physicians concurrently to obtain controlled substance prescriptions) may signal the presence of abuse or addiction. On the other hand, such behaviors sometimes reflect inadequate analgesia (pseudoaddiction) or the misuse of opioid analgesics to treat symptoms of depression, anxiety, or personality disorders. For patients who do develop opioid addiction, opioid substitution with buprenorphine and medical management of addiction through the use of medication agreements and adherence monitoring can be safely and effectively carried out in an office setting. There is a clear imperative to develop analgesics with lower abuse liability, and current research

efforts are also targeting the development of better methods to detect patients at risk for developing addiction.

Psychiatric and Substance Use Disorder Comorbidity

Glossary

Comorbidity – The occurrence of two diagnostic syndromes in one individual. While clinicians typically use this term to refer to disorders that occur simultaneously, epidemiologists often calculate lifetime comorbidity rates for which both disorders may be separated by substantial periods of time. The term ‘co-occurrence’ is more appropriate than ‘comorbidity’ when referring to the simultaneous occurrence of the specific symptoms associated with distinct syndromes.

Genetic epidemiology – A research domain dedicated to the study of genetic factors in determining health and disease in families and in populations, as well as to the investigation of gene–environment interactions. The common paradigms of genetic epidemiology include family studies, twin studies, adoption studies, and linkage or association studies.

Nosology – The branch of medicine that deals with classification of diseases. In psychiatry, the most widely applied systems of nosology include those described in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM; American Psychiatric Association) and the International Classification of Diseases (ICD; World Health Organization). Both systems are based on a categorical approach to diagnosis. The application of diagnostic hierarchies is frequent in psychiatric nosology and may influence the estimations of the magnitude of comorbidity as well as the investigation of the underlying mechanisms.

Prevalence – An estimate of how common a disorder or disease is within a population over a defined period of time. It is calculated based on the total number of cases of the condition divided by the number of individuals in the population. In psychiatric epidemiology, prevalence is most often calculated for disorders occurring over the entire lifetime, over the past 12 months, or at the moment of the diagnostic interview.

that the term comorbidity should only be used to describe the co-occurrence of diseases or disorders, it has also been increasingly applied to describe the co-occurrence of symptoms associated with distinct syndromes. Application of such loose definitions is common and has been an ongoing source of confusion. In this article, the term comorbidity is reserved to describe the occurrence of two diagnostic syndromes in one individual, while the term co-occurrence refers to the simultaneous appearance of specific symptoms associated with distinct syndromes.

A large number of clinical and epidemiologic investigations have demonstrated consistent patterns of association between many mental disorders at the diagnostic level. The most commonly examined forms of comorbidity include associations among anxiety, mood, behavioral, and substance use disorders. Strong correlations between symptom measures of these syndromes also verify this relationship at subclinical levels. However, the assignment of dual diagnoses has often been counter to the prevailing clinical practice, and similarly, the intent of many experimental studies has been to attain symptom measures with the greatest discriminative power. This lack of acknowledgment that mental illnesses naturally co-occur with high frequency has hindered research on this topic, and much remains to be known about the underlying mechanisms of comorbidity for a large number of mental disorders. Nonetheless, it is increasingly clear that psychiatric comorbidity is associated with a worsened course and poorer outcome among affected individuals and that the implications of psychiatric comorbidity for treatment and prevention strategies place it among major public health priorities.

The Comorbidity of Mental Disorders

Logically, two disorders having high prevalence rates are more likely to be found in the same individual than two disorders with low prevalence rates. For this reason, any study of comorbidity must first start with an understanding of the base rates of these disorders in the general population. The random probability of the two disorders occurring together can then be identified, thereby allowing an assessment for the probability of a second disorder occurring if the first is already present.

Several large-scale epidemiologic studies have underscored the frequent overall occurrence of mental

Introduction

The term ‘comorbidity’ was first used to describe any distinct additional clinical entity that has existed during the course of an index disease in any one patient. Although psychopathology researchers have cautioned

disorders in the general population, but with surprising variance in lifetime prevalence rates. These discrepancies are partly attributable to changes in diagnostic criteria, societal or cultural characteristics of the populations studied, and other differences across surveys. However, among the most substantial reasons for the wide range of prevalence rates concerns the application of methodological techniques in the more recent investigations that reduce response biases that may have underestimated lifetime prevalence rates among participants. **Table 1** presents an illustration of this effect across four large-scale psychiatric surveys conducted in the 1980s and 1990s. While some differences are observed among the first three investigations concerning the prevalence of common conditions such as anxiety, mood, or substance use disorders, the overall prevalence rates are generally comparable. By contrast, the National Comorbidity Survey (NCS) reported markedly higher rates not only for most categories of disorder but also for the overall lifetime prevalence of any mental disorder. The prevalence rates in this landmark investigation are higher because they reflect strategies to reduce errors in disorder estimates or data collection, such as adjustments for non-response bias (i.e., depressed individuals are more likely to decline participation in such surveys) and for the tendency of long diagnostic interviews to encourage respondents to progressively deny having particular symptoms in order to finish the interview more quickly. Importantly, this same investigation reported that among all individuals who experience at least one mental disorder over their lifetime, the majority would meet diagnostic criteria for at least one more mental disorders (and nearly one-third would meet the criteria for three or more disorders). Comorbidity rates for mental disorders over a 12-month period were also particularly high, indicating that most affected individuals experience two or more disorders simultaneously or in very close temporal proximity. Investigations such as the NCS thereby confirmed in community samples what clinicians have long observed among patients seeking treatment: psychiatric comorbidity is the norm rather than the exception, and

that a specific and singular diagnosis of individual conditions is often an oversimplification of the true clinical state of these patients.

Two unassociated disorders that each have a prevalence rate of 10% should be expected to be comorbid in approximately 1% of individuals. However, if the true rate of comorbidity is 5%, for example, then their association far exceeds chance expectations. The magnitude of comorbidity between two disorders is generally represented by an odds ratio (OR), a statistic that indicates the degree to which two disorders occur together relative to what would be expected by their base prevalence rates. In general, ORs tend to be greater within than between broad classes of disorders, such as for internalizing (e.g., anxiety or mood) disorders or externalizing (e.g., conduct or oppositional defiant) disorders. The magnitude of comorbidity may frequently appear to be inversely related to the base prevalence of disorders, where more rare or severe disorders seem to be more strongly associated with other forms of psychopathology. For example, commonly reported ORs for the comorbidity of alcohol dependence and prevalent mood disorders such as major depression generally range from 1.5 to 4.0, but are much higher when considering severe but less prevalent mood syndromes such as bipolar I disorder. It is important to note, however, that even a modest OR of 1.5 among highly prevalent disorders translates into substantial portions of the general population being affected by both conditions.

In addition to the basic information concerning the magnitude of comorbidity among mental disorders, their patterns of association provide clues as to the nature and mechanisms of comorbidity. Aside from methodological issues or biases, the most commonly cited explanations for comorbidity involve causal and shared etiologic models (see **Figure 1**). Causal models assume that the presence of an initial disorder increases the risk of a secondary disorder. Basic examples of such mechanisms can be found among individuals who develop alcohol or drug abuse as a means of alleviating anxiety or, conversely, among individuals who become depressed due to the physical, psychological, or social consequences induced by alcohol or drug use. Therefore, causal associations may, at times,

Table 1 Prevalence of mental disorders

	ECA 1984	Edmonton 1988	CPES 1989	NCS 1994

be bidirectional, although most theoretical and treatment models emphasize unidirectional associations due to their frequent focus on the prevention or remission of a specific disorder.

Shared etiologic models point to a specific factor or mechanism that increases the risk of more than one condition, such as the possibility that a common genetic vulnerability might increase the risk of both depression and panic disorder, or that traumatic life events may increase the risk of both depression and alcohol dependence. The two disorders are not causally linked to each other, but both occur together at a rate greater than chance because both are linked to a common underlying risk factor. These pathways of association may be direct or indirect, and multiple mechanisms of association may be simultaneously active for a single form of comorbidity (both at the population level as well as within any given individual).

This heterogeneity may be illustrated by the case of an individual with panic disorder and alcohol dependence. The self-medication for persistent anxiety using this substance over several years may have led to increased tolerance for alcohol as well as increased time and energy spent to obtain it. The cessation of alcohol use once dependence has occurred, in turn, increases the risk that this individual would experience severe agitation, nervousness, or panic attacks. These symptoms may not be limited only to a period of immediate alcohol withdrawal, but may persist over time due to fear of the consequences of these anxious states and conditioned anxiety upon the experience of such symptoms (leading to panic disorder). Based on their family history, which may reflect social modeling and genetic factors, this same individual may have already been at greater risk for alcohol dependence and panic disorder as independent syndromes. The capacity of these disorders to interact through causal mechanisms simply adds to this shared underlying vulnerability in increasing the overall risk of comorbidity. Causal models of association are often raised to explain comorbidity when at least one of the associated disorders has a strong behavioral component (such as for substance dependence or agoraphobia), while shared etiology is often raised in the context of comorbidity among internalizing disorders. However, the models presented in **Figure 1** are potentially applicable to explain comorbidity both within and between all psychiatric and substance use disorder categories.

In light of their complexity, specific mechanisms of comorbidity can only be fully tested using a diversity of research paradigms. The case of anxiety and depression will serve to illustrate this point, as it is among the most commonly examined forms of psychiatric comorbidity and has been investigated within a number of scientific disciplines. Cross-sectional investigations over the past two decades have repeatedly found that the lifetime

comorbidity of major depression and any anxiety disorder is elevated, but without equal associations between these disorders. That is, anxiety disorders are more often found among individuals with depression than is depression found among individuals with anxiety disorders. The cross-sectional examination of anxiety and depression reveals the additional pattern that most episodes diagnosed as depression also involved significant anxiety symptoms, but that the reverse is less frequent. It is relatively rare to find a person with an isolated (or pure) depressive disorder, but relatively common to find a person with a pure anxiety disorder. Longitudinal data from community cohorts have also demonstrated that patients with anxiety disorders tended to develop depression in conjunction with anxiety at follow-up more often than did subjects with depression. By contrast, diagnoses of depression were found to be relatively stable over time and did not evolve as often into anxiety disorders. Among those subjects who developed both disorders longitudinally, the majority of subjects with a first diagnosis of anxiety later developed depression, compared with a minority of those with depression who later developed anxiety.

Taken together, these findings may be consistent with the possibility that anxiety is a causal risk factor for later depression, or that pure anxiety and mixed anxiety-depression represent distinct syndromes. This latter possibility has been subsequently examined through several paradigms of genetic epidemiology. Family studies of depression and specific anxiety disorders such as panic, for example, are in agreement in indicating that both conditions are familial, as demonstrated by the increased risk of each disorder in families of probands with that disorder. However, while some of these studies indicate that depression and anxiety disorders do not breed true, others provide evidence of specificity of transmission for panic and major depression. Family studies are limited, however, in that they only describe the relationship between anxiety and depression within a given family lineage, and therefore cannot specifically examine the question of genetic transmission separately from shared environmental factors. The analysis of the questions among twins has demonstrated that mixed anxiety-depression is relatively frequent among the monozygotic twin of probands with pure anxiety, pure depression, or mixed states. Such findings seemingly support the hypothesis that mixed anxiety and depressive syndromes (comorbid states) are partly variants of both anxiety and depressive disorders. However, when such data are reanalyzed without using diagnostic exclusion hierarchies for these disorders, the concordance rate of pure depression and mixed anxiety-depression is three times higher in monozygotic twins than in dizygotic twins. Similarly, for monozygotic twins, major depression without anxiety in probands predicts major depression with anxiety in the

co-twins, and the reverse. In contrast, the occurrence of pure anxiety disorders in monozygotic probands predicts only the same disorder in co-twins. Taken together, such results argue for a similar genetic basis of pure major depression and mixed anxiety–depression, and also indicate a different genetic etiology for pure anxiety disorders without major depression. These conclusions are also in accordance with the observations from family studies that when depression is present with an anxiety disorder in probands, families tend to have aggregations similar to families of probands with pure major depression rather than pure anxiety. The identification of transmission patterns, in turn, may provide guidance for additional research paradigms, such as by improving the validity of phenotypic description for linkage and association studies. This illustration for the comorbidity of depression and anxiety disorders demonstrates the manner in which findings from diverse research disciplines are necessary for understanding the underlying mechanisms of association, each providing a complementary source of information.

Barriers to Investigating Comorbidity

Limitations of the Categorical Approach

Studies of comorbidity rely on the benefits and limitations of the nosologies used in categorizing and separating these disorders, and comorbidity rates are inevitably a function of the structure of diagnostic categories and hierarchies. For example, much of the confusion in family studies (such as for the example of anxiety and depression) is due to the fact that most family studies have applied nosological hierarchies in diagnosing comorbid episodes, and, therefore, certain diagnoses have often been excluded. When this is done, studies are unable to test the degree of specificity or cross-transmission of these disorders, and, therefore, it becomes impossible to draw conclusions regarding the etiologic origins. An important outcome of such criticisms has been a critical examination of the current nosological systems used in psychiatry, which many researchers claim has often forced diagnostic labels and boundaries between disorders when no distinction may be warranted.

The majority of critics of the categorical system propose that a dimensional approach be used to prevent inaccurate descriptions of clinical states. The dimensional approach to classification (based on a continuum of features and symptoms) does not systematically ignore certain symptom presentations and does not force a categorical solution. In the most general sense, the description of symptom co-occurrence is the starting point for understanding the more complex associations at the diagnostic level. Diagnostic syndromes are in themselves collections of more basic symptoms, and patients with coexisting

disorders, by definition, show a greater overlap at the symptom level than at the diagnostic level. It has therefore been argued that researchers should first describe the mechanisms of this association at more fundamental levels before increasingly complex (diagnostic) associations can be fully understood.

Barriers of Time and Context

A second major impediment confronting comorbidity researchers concerns the important differences between the natural phenomena under study and the methods used in their investigation. In particular, this discrepancy is most visible with regard to the assessment of temporal relationships among symptoms. In contrast to diagnostic criteria that are based, in part, on the importance of duration over time as a defining feature of mental disorder, the actual pathological mechanisms at the origin of a given syndrome—and of comorbidity—are often highly dynamic. That is, the expression of many forms of psychopathology is characterized by a relatively short life cycle concerning the period of time in which a given vulnerability or risk factor may influence the severity of symptoms or the expression of abnormal behavior. Such phenomena are observable over periods that are typically limited to a matter of minutes or hours, while most standard methodologies apply retrospective, cross-sectional, or longitudinal assessments spanning weeks, months, or years.

An illustration of the importance of the timing of symptom expression can be easily seen in the comorbidity of alcohol dependence with both anxiety and depression. A large body of clinical and epidemiologic research has demonstrated the strong association between these syndromes, with approximately equal ORs for the association of alcoholism with each disorder. Despite our ability to conclude with confidence that there is a general association among these syndromes, however, the actual mechanisms of comorbidity remain a source of debate. One of the most commonly cited potential explanations is that of self-medication, whereby the individual would use or abuse alcohol to assuage pre-existing anxiety or depressive states. The self-medication model would indeed have important treatment implications if it were able to accurately characterize the majority of cases of these forms of comorbidity, as it would clearly indicate that comorbid disorders should be addressed before the treatment of alcohol dependence could be effective. The association between these conditions is illustrated by the results of an example investigation in **Figure 2**, where the severity of anxiety or depressive syndromes is correlated with the quantity of alcohol use. However, the ability for clinicians to exploit the knowledge of these associations depends heavily on the nature of data collected in the

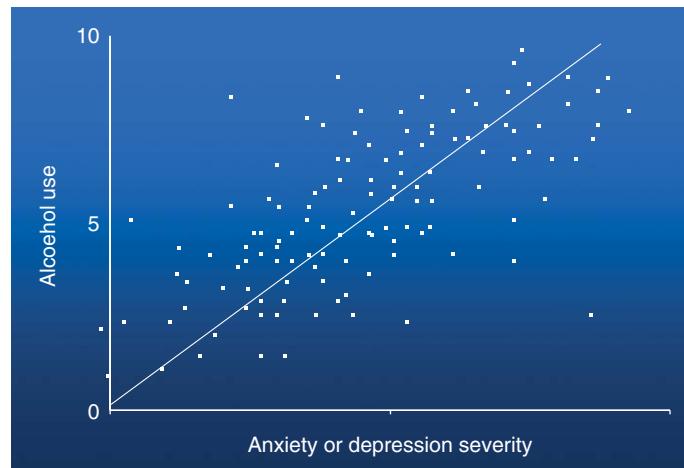

Figure 2 Example of common research demonstrating a correlation between alcohol use and anxiety or depression.

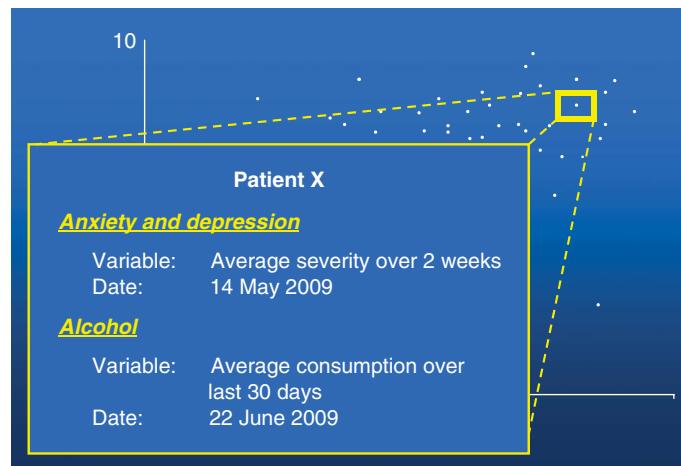

Figure 3 Illustration of why correlations cannot examine causes of comorbidity.

samples studied. Using an example patient, **Figure 3** illustrates to what extent this same study is based on assessments of anxiety or depression averages that show little or no within-subject variation. As a result, at no point did this example investigation demonstrate that Patient X, or anyone else in the sample, was more likely to consume alcohol when anxious or depressed. The phenomenon of interest was therefore never studied directly, rendering it difficult to exploit such investigations on a clinical level. Logically, a person consuming alcohol to alleviate anxiety or depression would be motivated to do so only if they were anxious or depressed at that particular moment, and not because they are an anxious person on average nor because they were anxious the week or month before. Self-medication is therefore an example of phenomena that can only be directly studied over considerably shorter time frames.

A third major impediment to understanding comorbidity expression concerns the ecological validity of the

existing literature. Although it remains possible for laboratory- or clinic-based investigations to overcome some of the temporal constraints described previously, they remain limited to the study of artificially induced states or to assessments conducted within the same context (clinic or hospital). It is therefore difficult or impossible to determine how these variables will express themselves in naturalistic contexts. To again take the example of self-medication, alcohol consumption has been shown to immediately reduce the negative emotional states induced through certain laboratory-based experimental procedures. However, this paradigm cannot determine if subjects would actually choose to use alcohol as a means of assuaging negative affect outside of the laboratory. It is also impossible to determine the contexts in which the phenomenon of self-medication is most likely to express itself (e.g., when the individual is alone vs. accompanied, or when under specific forms of stress). A clearer description of the contexts in which symptoms

express themselves *in vivo* would permit a better understanding of the comorbidity mechanisms that may vary by environmental context.

New Methods for Comorbidity Research

As previously underscored, a dimensional approach to the study of comorbidity would palliate many of the limitations imposed by categorical diagnostic systems. However, overcoming barriers associated with the brief temporal period of symptom expression or with environmental context specificity requires entirely new research strategies. Ambulatory data collection methods, such as the experience sampling method (ESM) or ecological momentary assessment (EMA), hold particular promise in this regard as they permit the examination of a representative sample of mental states in daily life through the use of electronic devices (e.g., personal digital assistants (PDAs) and cellular telephones). Such devices are used to indicate to subjects the moments to provide specific information concerning their behaviors, environment, specific symptoms, and other data at different moments throughout the day. In this way, ESM and EMA provide brief, prospective, and comprehensive assessments of daily life experiences of the individual. Subject compliance in such studies is particularly high (even for severe disorders such as schizophrenia or drug dependence), and the minor fatigue effects observed are controlled for by assuring that the start day is counterbalanced across subjects, therefore allowing for the number of days of participation to be used as a covariate in analyses. These novel methods are increasingly used in psychiatry, and their capacity to overcome barriers of time and context render them particularly interesting for the study of comorbidity. For example, their application to testing the self-medication hypothesis in recent years has offered new insights into the validity of this hypothesis for different clinical populations. Concerning alcohol use disorders, ambulatory monitoring has shown important differences in the association of drinking with anxiety and depressive symptoms. Strong support was found for the self-medication of anxious states in that anxiety led to increases in alcohol use over subsequent hours, and the eventual use of alcohol was indeed associated with reductions in anxiety. In contrast, no self-medication effect was found relative to depressed moods. In addition, alcohol consumption following anxiety was primarily a male phenomenon, and those with a family history of alcoholism required greater quantities of alcohol to achieve the same anxiolytic effects of alcohol than did participants without a family history of alcoholism. These findings provide potentially important insight into commonly cited sex differences in alcohol use, as well as concerning the strongly heritable nature of alcohol use disorders by explaining why certain individuals might be more

susceptible to use alcohol in greater quantities as a means of alleviating anxiety symptoms. Self-medication was also directly tested using ambulatory monitoring techniques relative to cannabis use in psychosis-prone individuals. Contrary to expectations, increases in psychotic-like symptoms did not lead to increases in cannabis use. Rather, cannabis use in vulnerable individuals exacerbated these symptoms, a finding suggestive of a causal relationship in the reverse direction than self-medication. Such findings therefore have important implications for understanding the mechanisms underlying associations observed at the diagnostic level and that are necessary for ameliorating treatment and prevention programs.

General Conclusions

Faced with the high rates of comorbidity between mental disorders, diverse research paradigms are necessary to investigate and ultimately control underlying mechanisms of association. At first glance, the capacity of such research to lead to more efforts in effective treatment and prevention may appear most obvious in the case of causal associations between conditions. However, evidence for common etiologic factors not only provides information concerning specific risk factors or vulnerabilities that can potentially be controlled, but also offers insight into the most valid boundaries or definitions of specific disorders that may alter treatment approaches. The contributions of epidemiology, clinical psychiatry and psychology, and genetic epidemiology to the study of comorbidity will continue to progress as a function of new questions and findings within each discipline. Future research should also benefit from a dimensional approach to the study of symptom co-occurrence as well as from the application of new research strategies designed to overcome longstanding methodological barriers in this domain.

Psychostimulants

S B Caine, McLean Hospital – Harvard Medical School, Belmont, MA, USA

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Dopamine – One of the monoamine neurotransmitters important in processing reinforcing stimuli including natural rewards and drugs of abuse.

Nucleus accumbens – The terminal region where dopamine is released in the ventral striatum from the brain pathway arising from the ventral tegmental area in the midbrain.

Positive reinforcer – Something that engenders repetition of a behavior that precedes it, such as presentation of an appetitive food or administration of an addictive drug.

primarily an agonist at nicotinic acetylcholine receptors. This is hardly a controversy, because caffeine and nicotine can be termed weak, indirect dopamine agonists inasmuch as they increase dopaminergic activity, though not directly via actions at dopamine transporters (reuptake sites) on dopaminergic nerve terminals. Although it remains to be entirely clarified, the stimulant effects of caffeine may be due to the blockade of adenosine at adenosine A_{2A} receptors that normally function in an opposing fashion to dopamine D₂ receptors. Indirect activation of dopaminergic systems via increased activity of dopamine neurons and/or inhibition of the dopamine metabolic enzyme monoamine oxidase probably contributes to the stimulant effects of nicotine.

In contrast to all of those agents, there are many drugs that have some overlapping pharmacology but whose primary mechanisms of action differ sufficiently from the indirect dopamine agonists that their classifications – both pharmacodynamic and behavioral/clinical – fall outside the realm of psychostimulants. Examples include some antidepressants such as bupropion (Wellbutrin) that has a primary noradrenergic component; monoamine oxidase inhibitors used as antidepressants and/or anti-parkinsonian agents including selegiline (l-deprenyl, Eldepryl); substituted phenethylamines with prominent serotonergic activity at 5-HT_{2A} receptors that are sometimes referred to as entactogens – including methylenedioxymethamphetamine (MDMA or ecstasy) and a group of similar drugs beginning with 2C based on chemical structure; and muscarinic cholinergic antagonists, including scopolamine that, in small doses, has been used in the treatment of motion sickness, and benztrapine that has been used for its anti-parkinsonian effects.

Chemical Classes and Pharmacology of Psychostimulants

Many psychostimulant drugs, including, for example, cocaine and ephedrine, exist in nature as alkaloids and are derived from plants. Synthetic drugs that can be chemically classified as substituted phenethylamines include amphetamine, methamphetamine, and methylphenidate. Despite natural versus synthetic sources and differences based on chemical structures, all of these drugs function primarily as indirect dopamine agonists in central nervous system (CNS) synapses, which leads to their stimulant effects in the human and laboratory animals (**Table 1**). Some pharmacologists may define the term ‘psychomotor stimulants’ by a primary biological activity as an indirect dopamine agonist (i.e., causing dopamine-reuptake inhibition or release at dopamine nerve terminals). A historical term for psychostimulants is sympathomimetics, meaning drugs that mimic endogenous chemicals of the sympathetic nervous system, including all three ‘catecholamine’ neurotransmitters dopamine, norepinephrine (noradrenaline), and epinephrine (adrenaline). For example, ephedrine most prominently activates peripheral adrenergic systems, at least in part due to poor CNS penetration. Many psychostimulants have additional pharmacological activities, such as the local anesthetic effects of cocaine, and many have indirect agonist activity in serotonin synapses.

Some pharmacologists would include among the psychostimulants the xanthines such as caffeine that are primarily adenosine antagonists, and nicotine, which is

Historical Perspective on Psychostimulants

The coca plant was named by Lamarck in 1786 after the plant family was coined as *Erythroxylaceae* by Linnaeus. The plant thrives at high elevations such as the Andes and can be found both in the wild and cultivated forms from northwestern Argentina to Ecuador. Ancient Colombian legends describe the people’s emergence from the Milky Way Galaxy in a canoe that included a man, a woman, and various plants including coca. Leaves of the plant have been found in burial mounds in Peru estimated to

Table 1 Summary of psychostimulants

<i>Pharmacodynamic classification</i>	<i>Generic name</i>	<i>Therapeutics</i>	<i>Side effects</i>	<i>Animal measures</i>
<i>Indirect dopamine agonists</i>	Amphetamine	Attention-deficit disorders (ADD/ADHD), narcolepsy,	Abuse liability	Motor hyperactivity
	Cocaine*	topical (local) anesthetic*, cold medicines, diet pills, shift-work sleep disorder, wakefulness/alertness	Insomnia	Fully generalizes to stimulant cue in drug discrimination
	Ephedrine		Increased heart rate	Strong positive reinforcer in self-administration
	Methamphetamine			Decreases prepulse inhibition of startle
	Methylphenidate			
	Modafinil			
<i>Adenosine antagonists</i>	Caffeine		Dependence	Motor hyperactivity
	Theobromine		Insomnia	Generalizes to stimulant cue in drug discrimination
	Theophylline			Positive reinforcer in self-administration under some conditions, particularly dependence
<i>Nicotinic acetylcholine agonist</i>	Nicotine	Nicotine replacement therapy for smoking cessation	Dependence	Weak motor hyperactivity Generalizes to stimulant cue in drug discrimination under some conditions Positive reinforcer in self-administration under some conditions

* Characteristics apply to all drugs in that pharmacodynamic category, with the exception of cocaine that is the only local anesthetic listed and that is its only accepted therapeutic application.

be nearly 5000 years old. When the Inca conquerors arrived in the tenth century, the leaf was consumed primarily by priests and nobility and was considered a gift of the sun god. The plant was accorded such virtues as satisfying the hungry, providing the weak with new vigor, and causing the unhappy to forget their misery.

Shortly after cocaine's purification by Albert Niemann in the mid-nineteenth century, Sigmund Freud investigated the drug's powerful psychoactive effects. Freud came to many of the same conclusions as the Incas, in self-reports that the drug warded off hunger, sleep, and fatigue, enhanced intellectual efforts, and induced cocaine euphoria. Having known about the chewing of coca leaves by Peruvian Indians in order to prolong physical exertion, Freud was interested in the potential of cocaine hydrochloride as a treatment for nervous exhaustion. An additional clinical error was his prescription of the drug for morphine dependence. However, Freud accurately recognized certain properties of cocaine that "suggests its occasional use as a local anesthetic." Freud's associate, Karl Koller, is credited with introducing cocaine's only current medical use, as a local anesthetic for ophthalmic surgery and other specialized applications. However, more commonly used local anesthetics are analogs, such as procaine and lidocaine, that have limited abuse liability relative to cocaine.

The abuse of coca throughout Europe and then the United States of America (USA) came about via an oral preparation patented by a Corsican chemist named Angelo Mariani. Vin Mariani – a wine-containing coca extract – is rumored to have been Europe's most popular beverage in the mid-nineteenth century. For developing coca-containing wine, lozenges, and tea, Mariani was presented with a special medal of appreciation by the Pope. Shortly thereafter, an American chemist from Georgia, John Pemberton, registered a trademark in the USA for Coca-Cola, a refreshment that also included wine and coca extracts. Pemberton later substituted the wine component of the drink with a kola nut extract that contained caffeine, and also incorporated soda water into the beverage. Another pharmacist, Asa Candler, founded the Coca-Cola Company in 1892. As a result of the Pure Food and Drug Act of 1906, coca was removed from the recipe for Coca-Cola. Shortly thereafter, cocaine was included with morphine and opium in the Harrison Narcotic act of 1914, which banned the use of these drugs in the USA and drove cocaine use to the underground.

Although historically the predominant recreational use of cocaine was via oral administration (e.g., chewing coca leaves, drinking beverages containing coca extracts), common routes in modern society include insufflation (snorting) and intravenous administration (injecting) of cocaine hydrochloride, and inhalation of cocaine base (smoking crack). Compared with oral

administration, effective concentrations of cocaine in the blood and brain can be achieved more rapidly by these routes, particularly for intravenous injection and vapor inhalation. After insufflation, peak blood levels of cocaine are achieved in about 10 min, and after injection or inhalation, peak blood levels are achieved within the first several minutes. Cocaine abusers may report experiencing a rush during the rapid onset of the drug's effects, and animal studies confirm that the reinforcing effects of the drug are more easily established when blood and brain levels are achieved rapidly. The more rapid consumption of quantities of drug and the shorter duration of action associated with inhalation and injection probably contribute to the cycle of increasing frequency of administration and resultant addiction.

The devastating public health consequences of cocaine abuse are related not only to the myriad sociopathic aspects of drug addiction, but also to various physiological conditions and comorbid diseases. For example, cocaine self-administration can lead to cardiovascular, cerebrovascular, and respiratory problems, including disturbances in heart rhythm, heart attacks, chest pain, and respiratory failure. Endocrine and liver dysfunctions, gastrointestinal problems, and various neurological disorders including strokes, seizures, and headaches have also been linked to cocaine use. Cocaine abuse and dependence can lead to cycles of anxiety, depression, and even delirium. Perhaps the most recent, insidious, and serious public health consequence of cocaine abuse has been referred to as a twin epidemic comprising of intravenous drug use and infection with human immunodeficiency virus (HIV).

The advent of the amphetamines is much more recent. Ephedrine from *Ephedra vulgaris* has been used as an herbal remedy for congestion in preparations such as *ma huang* tea for at least 5000 years. However, that phenethylamine is more potent in its activation of peripheral adrenergic systems than central dopaminergic synapses. Shortly after ephedrine's isolation and use for the treatment of asthma in the late nineteenth and early twentieth century, the substituted phenethylamine amphetamine was developed as an alternative. By the 1930s, the American Medical Association (AMA) sanctioned the use of amphetamine (Benzedrine) for mild depression and to promote wakefulness as in the treatment of narcolepsy. The latter remains a clinical use of the substituted phenethylamines to this day (e.g., d-amphetamine, methylphenidate). The amphetamines have also been used as appetite suppressants and for general alertness, but the most important clinical utility in modern society is in the management of attention-deficit disorders (e.g., attention-deficit disorder (ADD) and attention-deficit hyperactivity disorder (ADHD)).

Unfortunately, the amphetamines – like cocaine – have significant abuse potential. They also are snorted,

injected intravenously, or smoked (e.g., crystal meth) recreationally. However, they are much more orally active and long-acting, with a half-life, in human blood, of 14 h for d-amphetamine compared with 40 min for cocaine. The longer half-life may contribute to more frequent reports of psychoses with high doses of amphetamines relative to cocaine. Finally, the drug methamphetamine has produced neurotoxicity in laboratory studies, and that may be relevant in the high-dose range and/or chronic recreational use in some of the humans that abuse the drug.

Use of Animal Behavioral Procedures to Study Psychostimulants

There are many unconditioned, overt behaviors that can be used to study the behavioral effects of psychomotor stimulants in laboratory animals. The most common by far is the locomotor activity test. Psychostimulants dose-dependently increase motor activities, and ambulations or distance traveled can be efficiently measured using a photobeam apparatus or other tracking system. There are several important considerations in optimizing such measures for the evaluation of the potency, efficacy, and time course with which a drug produces a change in this behavior, as described below.

First, because psychostimulants can be relatively potent and effective in increasing this behavior, the most sensitive measures occur when ongoing rates of behavior in the absence of the drug are low. For this reason, the drug should be administered after the animals have had a behavioral history of ample habituations to the test chamber, so that spontaneous exploratory activity has been largely extinguished. More generally, drug effects on most rates of behavior are, in part, determined by the ongoing rate of activity. For many behaviors including locomotor activity, psychostimulants often increase low rates of behavior and decrease high rates of ongoing behavior.

Second, the dose or doses of the drug that are studied are a critical determinant of the behavioral effect observed. Specifically, low-to-intermediate doses of psychostimulants dose-dependently increase locomotor activity. But higher doses can produce repetitive, more restricted motor behaviors (such as sniffing, grooming, licking, and biting), that are often collectively termed motor stereotypies, that compete with ambulatory activity, and reduce overall distance traveled. Thus, locomotor hyperactivity decreases as motor stereotypies increase with higher doses of psychostimulants. By studying a full range of doses of a drug, relative potencies for locomotor hyperactivity and stereotypies can be obtained.

Third, the time course of the psychostimulant drug is a critical factor in making assessments. For example,

studying total ambulations over a 12-h period for equivalent doses of cocaine and amphetamine in terms of their peak effects at any given moment would yield much larger values for amphetamine due to its longer duration of action. But measuring the behavior for 1 h during the peak effects of each drug's time course at equivalent doses would yield more comparable effectiveness.

Finally, the subjects, in terms of drug history, behavioral history (see above), species, and strain are all critical determinants. For example, locomotor activity has been widely used to evaluate a phenomenon termed behavioral sensitization. In that case, prior exposure of outbred rats or mice to several daily injections of a psychomotor stimulant sensitizes the animals to locomotor hyperactivity, particularly in a novel test environment in which they received a psychostimulant on prior occasions. The species and strain of the animal can also markedly influence drug effects. For example, most rats that have been studied exhibit locomotor hyperactivity in response to drugs that produce either dopamine D₁ or D₂ receptor stimulation. In contrast, most strains of mice exhibit locomotor hyperactivity only in response to dopamine D₁ receptor stimulation.

In summary, the locomotor activity test in rodents can be a sensitive assay for evaluating the potency, efficacy, and time course of psychostimulants, when behavioral and drug history, dose and time course, and species and strain are all taken into account. This test has been used to screen drugs for psychostimulant activity that may have clinical implications (see above).

Another test of unconditioned behavior used widely in behavioral neuroscience that is useful for evaluating psychostimulants is the 'prepulse inhibition of startle' (PPI). In this test, when a startling stimulus, such as a brief, 120-dB acoustic noise burst, called a pulse is presented to a subject, a motoric startle response can be measured, such as the jump of a rodent positioned atop a pressure-sensitive platform. Presentation of a weaker brief stimulus called a prepulse (e.g., 75 dB, just 10 dB above a constant 65 dB background noise), that by itself does not alter the behavior, approximately 100 ms prior to the pulse reduces the startle response to the pulse. This behavioral inhibition produced by the prepulse is thought to be an operational measure of sensory gating. Psychostimulants that are indirect dopamine agonists (see Table 1) dose-dependently decrease PPI. This test has been very useful for measuring dose- and time-dependent activation of dopaminergic pathways by psychostimulants. Perhaps more importantly, reversal of psychostimulant effects on PPI has been broadly used as a preclinical screen for drugs that may have therapeutic activity as antipsychotics. For example, most drugs that are effective in treating schizophrenia are also effective in reversing psychostimulant-induced decreases in PPI. As with the locomotor test described above, PPI is also dependent upon critical

variables, such as dose and time course of the psychostimulants tested, and species and strain of the subjects. Of course, this test is extremely sensitive to manipulations of the intensity and duration of the startling stimulus and the prepulse, as well as factors such as background noise and interstimulus intervals.

Conditioned behaviors including operant conditioning can also be used to evaluate the behavioral effects of psychostimulants. Drug-discrimination procedures are used to evaluate the interoceptive effects of drugs in laboratory animals, sometimes termed ‘subjective’ effects in the human. In this procedure, animals are trained to press one of two levers in order to obtain a food reward if they detect a training drug in their body, and to press the other of the two levers to obtain food reward if they do not detect the training drug in their body. Typically, training is required for at least 30 or 40 daily sessions in which conditions are randomized on different days for one lever to be reinforced with food after cocaine was administered to the animal, and the other lever to be reinforced with food after saline was administered to the animal. Then tests can be conducted in which the animal’s lever selection essentially reports whether the drug discriminative stimulus or cue was detected by the animal. The indirect dopamine agonists all strongly generalize to each other, and not nearly as much to drugs in other pharmacological classes. In other words, if an animal is trained to a cocaine cue, substitution with d-amphetamine produces identical responding to cocaine, and vice versa. Xanthines generalize to indirect dopamine-agonist cues under most conditions, and nicotine under some conditions. Psychoactive drugs that are not psychostimulants, such as sedative hypnotics or κ -opioid agonists, may engender very little or no generalization to psychostimulants. This procedure has been very useful for classifying the interoceptive effects of novel drugs as stimulant-like or not. It also has been extensively used to study the pharmacological mechanisms of stimulant drugs. For example, various types of dopamine agonists often generalize to stimulant drugs, and conversely, dopamine antagonists (e.g., haloperidol) when given in combination with psychostimulants can block their discriminative stimulus effects. By contrast, noradrenergic and serotonergic agonists and antagonists are less effective than dopamine agents in this regard.

Drug self-administration procedures are a type of operant conditioning in which the positive reinforcing effects of psychostimulants can be measured, and they can be predictive of abuse liability in the human. Animals are trained to associate a behavioral response, typically a lever press or nose-poke, with rapid administration of a drug, often by automated intravenous infusions immediately following each appropriate behavioral response. Drugs that maintain lever-pressing behavior above levels maintained by saline infusions are

termed positive reinforcers. Over 20 drugs that are abused by the human function as positive reinforcers in the rat self-administration test. Psychostimulants such as cocaine and amphetamine are probably the most effective drugs ever observed to produce reinforcing effects in this procedure. This procedure has been used for evaluating the abuse liability of new chemical entities, including psychostimulants, that may have therapeutic applications. It has also been used for studying the pharmacological and neurobiological mechanisms underlying drug abuse and addiction.

Neuropharmacology and Brain Pathways Underlying Psychostimulant Effects

The use of psychostimulants to study the synaptic mechanisms of action and brain pathways underlying the behavioral effects of stimulant drugs, and, in particular, their abuse-related effects, represents an enormous body of literature and will only be summarized briefly.

Most of the psychostimulants that are indirect dopamine agonists (**Table 1**) are either inhibitors of dopamine reuptake into dopamine nerve terminals such as cocaine, or else are releasers of dopamine from dopamine nerve terminals such as amphetamine. All of those drugs act, at least partly, by binding to the dopamine transporter (reuptake site). In contrast to the indirect dopamine agonists, indirect agonists for other neurotransmitters – and even for other monoamine neurotransmitters, such as norepinephrine and serotonin – fail to produce psychostimulant effects in assays of locomotor activity, prepulse inhibition of startle, drug discrimination, and drug self-administration. Generally, dopamine receptor antagonists (e.g., haloperidol) produce rightward shifts in dose–effect functions for psychostimulants in all of those assays, indicating competitive antagonism of the dopamine receptor antagonists with the indirect dopamine agonist effects of the psychostimulants. Finally, removal of dopamine in the brain pathway arising from the ventral tegmental area (VTA, located in the midbrain) and terminating in the nucleus accumbens (ventral striatum located in the basal ganglia) attenuates behavioral effects of psychostimulants in all of those assays. Collectively, these experimental observations suggest that enhanced dopaminergic activity in the mesolimbic pathway (from the VTA to nucleus accumbens) is the principal mechanism underlying most of the important behavioral effects of psychostimulants that are indirect dopamine agonists. In contrast, enhanced dopaminergic activity in the brain pathway arising from the substantia nigra and terminating in the dorsal striatum has been associated with motor stereotypies produced by psychostimulants. It should be noted that psychomotor stimulant drugs that have a principal mechanism of action different from the indirect dopamine agonists appear to be

able to produce stimulant effects independently of dopamine. For example, the locomotor hyperactivity produced by the adenosine receptor antagonist caffeine, or by the muscarinic receptor antagonist scopolamine, are not blocked by depletions of dopamine in the mesolimbic pathway.

Psychostimulant Addiction: Abuse, Dependence, and Withdrawal

The abuse of psychostimulants arises from the drugs' powerful reinforcing effects that can be measured using the self-administration test in a variety of laboratory animals and in the human under controlled conditions. The development of psychostimulant addiction begins with abuse and probably includes the development of dependence on the drug as well as some form of withdrawal in the absence of the drug. However, evidence of marked tolerance to the drug (i.e., the need for higher doses to achieve a given effect), and a physical withdrawal syndrome, are nearly absent for this drug class compared with addiction to opioid drugs, for example.

Activation of the mesolimbic dopamine pathway occurs naturally, in the absence of psychostimulant drugs, under a variety of conditions, and particularly when unexpected rewarding stimuli are presented. Psychostimulant drugs hijack this pathway and drive it unnaturally. One prominent hypothesis is that dopamine systems are compromised during the addiction cycle and this contributes to withdrawal, which may lead to decreased motivation for nondrug-related stimuli and increased sensitivity to the abused drug.

Psychostimulant withdrawal in the human is associated with fatigue, depressive symptoms, anxiety, and psychomotor retardation. In animals, psychostimulant withdrawal is associated with decreased reinforcing effects of natural rewards and decreased exploratory activity, measured using operant conditioning and the locomotor activity test, respectively. Those behavioral effects probably involve decreased dopaminergic function. Decreases in the activity of the mesolimbic

dopamine system and decreases in serotonergic neurotransmission in the nucleus accumbens occur during drug withdrawal in animal studies. Decreases in the firing of dopamine neurons in the VTA have been observed during withdrawal from other drugs including opioids, nicotine, and ethanol. Imaging studies in the drug-addicted human have consistently shown long-lasting decreases in the numbers of dopamine D₂ receptors in drug abusers. In addition, cocaine abusers have reduced dopamine release in response to a pharmacological challenge with a stimulant drug. Decreases in the number of dopamine D₂ receptors, coupled with the decrease in dopamine neuron firing activity in cocaine, nicotine, and alcohol abusers, probably results in decreased sensitivity of reward circuits to stimulation by natural reinforcers. These findings suggest an overall reduction in the sensitivity of the dopamine synapses and dopamine brain pathways to natural reinforcers and other drugs in drug-addicted individuals.

Rewarding Brain Stimulation

J Yeomans, University of Toronto, Toronto, ON, Canada

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Deep brain stimulation – Electrical activation of neurons provided by passing current through an electrode that is insulated along its length, but has an uninsulated tip, so that neurons near the tip are excited.

Myelinated axon – The part of the neuron that carries action potentials from the soma to the terminals (i.e., the axon) will conduct these action potentials faster and more efficiently when the axon is insulated by a fatty surrounding sheath (i.e., myelin) provided by surrounding cells.

Neurotransmitter – A chemical released from neurons at synapses that acts on other neurons to increase or decrease their activity or excitability.

Priming stimulus – A stimulus given before testing to facilitate performance, such as brain stimulation given by the experimenter to facilitate bar pressing for that stimulation by the animal.

Receptor – A protein that chemicals combine with to change cell functions.

Reinforcer – A stimulus, such as food or brain stimulation, whose presentation leads to increased responding to obtain that stimulus, for example, by bar pressing.

Theory of drive reduction – The proposal by Hull that all primary reinforcers, such as food and water, have their reinforcing effects on behavior by reducing specific motivated states, such as hunger and thirst, respectively.

these discoveries showed the value of behavioral methods and analysis (especially operant methods) to the understanding of brain functions.

Predecessors

In 1949, the Swiss physiologist Walter Rudolf Hess was awarded the Nobel prize for developing methods for chronic stimulation of the brain in freely behaving cats. These methods led Hess to discover several autonomic and motor functions of the midbrain and forebrain. Hess found that stimulation of the hypothalamus led to visceral changes (including salivation, feeding, and pupillary responses) and behavioral changes (including aggressive responses). Stimulation of the dorsal midbrain led to head and eye turns, which he called ‘visual grasp reflexes.’ Although electrical brain stimulation had been used since the 1860s, especially in mapping cortical areas for movement, Hess’s method of implanting deep brain electrodes permanently was essential for long-term studies of deep brain functions.

In the early 1950s, Jose Delgado at Yale University used Hess’ methods to study motivational changes in cats. He found that food intake increased with sustained electrical stimulation of the lateral hypothalamus, and that the cats will work to remove sustained electrical stimulation of some deep brain sites. He later moved to Spain where he studied electrical stimulation of the limbic system in monkeys, humans, bulls, and rats, using radio transmitters to control behavior and emotions.

Olds was trained at Harvard University, where he learned operant techniques developed by B.F. Skinner. Milner was an electrical engineer from England, conducting graduate studies in psychology at McGill University. Together, they implanted electrodes using the methods of Hess and Delgado in the deep brain of rats. Their rats were placed in a Skinner box, and were observed to respond to electrical brain stimulation by returning to the place in the box where the stimulation was delivered, a phenomenon now called ‘conditioned place preference’. Using Skinnerian shaping methods, Olds and Milner were able to train the rats to press a lever for deep brain stimulation at high rates (up to 70 presses per minute) for hours. Many rewarding sites were tested, from the septum in the limbic part of the forebrain, to the tegmentum of the midbrain.

Discovery

In 1954, James Olds and Peter Milner at McGill University reported that rats bar-press vigorously to electrically stimulate their own brains, in many deep brain sites. This phenomenon (which was soon called intracranial self-stimulation, and is now most commonly called brain-stimulation reward) quickly led to a re-evaluation of psychological theories of learning, reinforcement, motivation, and emotions. Over the next two decades, maps of brain regions and neural systems supporting brain-stimulation reward led to the discovery of several brain systems needed for natural rewards, drug rewards, and motivated behaviors of many sorts. Furthermore,

Psychological Theories

Olds and Milner showed that deep brain stimulation is positive reinforcement by definition, since it leads to increased probability of responding. They inferred that the stimulation was rewarding to the rats based on the vigorous approach behaviors of the rats toward the lever, and the lack of signs of pain after stimulation.

The finding that rats bar-press at stable rates for hours (i.e., the lack of satiation) challenged the leading theory of Clark Hull and his Yale University colleagues that reinforcement occurs due to drive reduction. Reinforcers, such as food and water reduce the motivation to eat and drink, so Hull proposed that all reinforcers work by the principle of drive reduction. Brain-stimulation reinforcement, however, was at least as powerful a reinforcer as food or water, yet seemed to increase motivation when delivered. Unlike food and water, this motivation was not decreased by repeated delivery of the reinforcer. So reinforcement does not require drive reduction.

Olds' assertion that brain-stimulation reward identifies 'Pleasure Centers in the Brain' (the title of his 1956 *Scientific American* review) was challenged by behaviorists who, like Skinner himself, were often philosophically opposed to subjective inferences about animal emotions. Studies of deep-brain stimulation in human patients by Robert Heath and Jose Delgado, however, showed that self-stimulation of amygdala and hypothalamic sites often leads to verbal reports of arousal, interest, as well as motivational or sexual feelings in some cases. Intracranial self-stimulation has since been described in dozens of different species, including goldfish, mice, rats, hamsters, monkeys, and humans.

In the following decades, studies of acquisition, extinction, and recovery of intracranial self-stimulation in many brain sites in rats led to competing psychological theories. First, continuous stimulation of lateral hypothalamic rewarding sites for seconds without interruption becomes aversive to the rats, who will then learn to turn the stimulation off by bar pressing. Second, rewarding hypothalamic stimulation in many sites has an arousing effect on the rat, leading to vigorous locomotor exploration, including sniffing, biting, and rearing. These exploration and approach responses facilitate learning of responses associated with the stimulation. One short stimulation provided by the experimenter quickly reinstates lever pressing in rats that have been previously trained, a powerful phenomenon called the priming effect. Different theorists have emphasized the arousing effects, the priming effects, or the aversive effects of sustained brain-stimulation reward.

Brain Maps

Many maps showed that hundreds of brain regions, including well over 20% of the volume of the brain, support brain-stimulation reward (Figure 1). These include the limbic frontal cortex, hippocampus, olfactory bulb, parts of the cerebellum, and regions as far back as the motor nuclei of the trigeminal and vagus nerve of the hindbrain. In many of these sites, rats bar-press at low rates (below 10 presses per minute), and required extensive training to press reliably. The most reliable sites were found in ventral brain regions stretching continuously from the basal forebrain to the tegmentum of the midbrain and rostral pons. These sites followed the anatomical

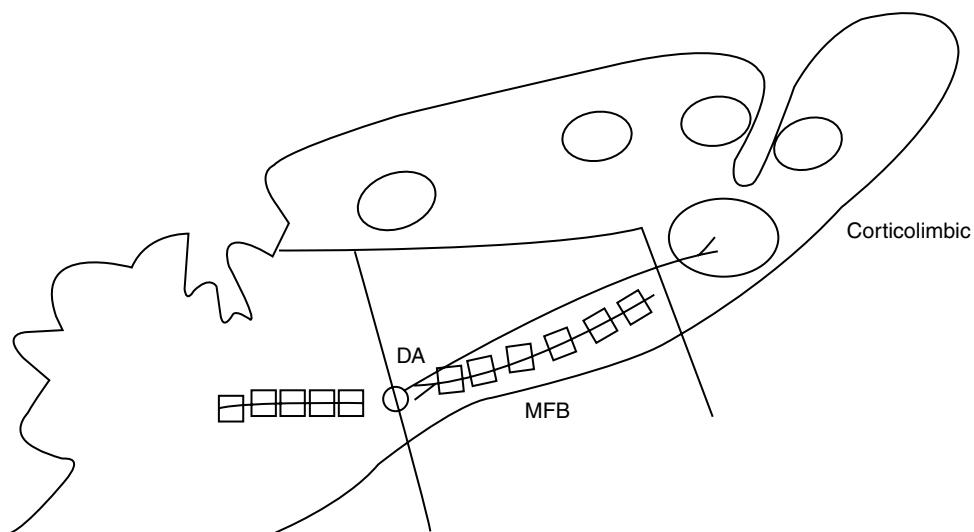

Figure 1 Brain-stimulation reward sites. Reproduced with permission from Yeomans JS (1990) *Principles of Brain Stimulation*. Oxford: Oxford University Press.

course of the medial forebrain bundle (MFB), the major pathway that connects forebrain limbic systems with the brain stem. The MFB sites with the lowest current thresholds and highest bar-pressing rates were located in the lateral and posterior hypothalamus, and ventral tegmental area (VTA), where MFB axons are most concentrated. This observation led to a search for the critical neurons and transmitters responsible for the rewarding effects of brain stimulation in these regions.

Catecholamine Theories

In the late 1960s, it was discovered that rats also bar-press at low, but steady, rates to inject drugs such as morphine, amphetamine, and cocaine into their veins by way of indwelling catheters (i.e., intravenous self-administration). The practical value of understanding brain mechanisms for drug abuse has remained a major motivation for understanding brain-stimulation reward.

About the same time, Swedish anatomists discovered several small clusters of neurons that use the catecholamine neurotransmitters, norepinephrine and dopamine. These catecholamine neurons are most concentrated in the pontine and midbrain tegmentum, respectively, and send their ascending axons to the forebrain via the MFB. The dopamine neurons in the VTA project to the nucleus accumbens and frontal limbic cortex by way of mesolimbic and mesocortical axons. The more lateral dopamine neurons of the substantia nigra project to the dorsal striatum by way of nigrostriatal axons.

Remarkably, the reinforcing drugs amphetamine and cocaine were found to act specifically on these neurons, increasing release of both norepinephrine and dopamine from their axon terminals in the forebrain. Arvid Carlsson won the Nobel prize in 2000 for showing the importance of catecholamine neurons and pharmacology to diseases. In particular, the motor disorder Parkinson's disease is caused by the death of dopamine neurons of the substantia nigra and is treated effectively by giving patients L-dopa, the chemical precursor of dopamine, to restore dopamine function. Schizophrenia is treated effectively by drugs that block dopamine receptors. Therefore, understanding how catecholamine neurons and drugs work in behaviors, such as brain-stimulation reward, provided a second major motivation for studies of brain-stimulation reward circuits.

In the late 1960s and early 1970s, both norepinephrine and dopamine neurons were proposed to be critical for brain-stimulation reward. Studies using amphetamine, or specific blockers of norepinephrine or dopamine functions, or their receptors, soon proved that dopamine neurons and receptors, and not norepinephrine neurons and receptors, were most critical for the activating and the rewarding effects of brain stimulation. Local brain

injections of dopamine-specific drugs and blockers, or of the specific catecholamine neurotoxin, 6-hydroxydopamine, showed that dopamine neurons are especially critical for brain-stimulation reward, or for cocaine, or amphetamine self-administration via dopamine axon terminals of the mesolimbic pathway in the nucleus accumbens.

NonDopamine Axons

The success of the dopamine hypothesis of reward, however, led to two problems in the 1980s. First, mesolimbic dopamine neurons that send their axons from the ventral tegmentum to the nucleus accumbens include less than half of the brain regions where brain-stimulation reward is obtained. Second, dopamine axons are tiny and lack a myelin sheath, and so are insensitive to brain stimulation at the lowest currents used to support brain-stimulation reward. Therefore, unlike cocaine or amphetamine, which acts directly on dopamine neurons, brain-stimulation reward stimulates dopamine neurons indirectly in most cases.

Detailed studies showed that thicker myelinated axons are the directly stimulated neurons in the MFB. To define these neurons, better stimulation methods, using trains of short pulses rather than 60-cycle sine waves, were needed. In particular, the refractory periods and conduction velocities of the MFB axons mediating brain-stimulation reward were measured by delivering trains of twin pulses, and then varying the interval between the twin pulses. If the interval between the two pulses is shorter than the refractory period of the axons, the second pulse will fail to produce any action potentials. The effectiveness of the second pulse in increasing reward was found to increase as the interval between the twin pulses increased from 0.4 to 2.0 ms. This indicates that the critical neurons for reward have refractory periods mainly from 0.4 to 1.2 ms, with smaller contributions from 1.2 to 2.0 ms. Dopamine axons in MFB have refractory periods from 1.2 to 2.5 ms, however.

When stimulating with two electrodes in MFB, say 3 mm apart, trains of pulses can be delivered via both electrodes at the same time. If the trains are slightly out of phase (say by 0–5 ms), the action potentials from the second train can be blocked by the action potentials from the first train, due to a well-studied phenomenon called 'collision' by which the action potentials collide and erase one another. Just as in the refractory period experiment, the effectiveness of the second train of pulses is blocked by the loss of action potentials. For MFB self-stimulation, the effectiveness of the second train was found to increase as the delay of the second train increased from 1 to 3 ms, indicating an added conduction time of 0.5–2.0 ms between the MFB electrodes. The conduction velocity

of the critical MFB axons was determined to be $1\text{--}8 \text{ m s}^{-1}$. Dopamine axons in MFB have conduction velocities of $0.3\text{--}1.0 \text{ ms}$, however.

These results indicate that small myelinated axons (diameters $0.5\text{--}2.0 \mu\text{m}$) mediate most of brain-stimulation reward, with smaller contributions from dopamine-like unmyelinated axons (diameters $0.1\text{--}0.5 \mu\text{m}$). Higher currents than are normally used are needed to stimulate these higher threshold dopamine-like axons. The more-sensitive myelinated axons pass down through the MFB to indirectly activate dopamine neurons in the ventral tegmentum (**Figure 1**). Similar myelinated axons also mediate feeding elicited by MFB stimulation, or the aversive effects of sustained MFB stimulation.

It is still uncertain exactly which neurons send their myelinated descending axons through the MFB to mediate brain-stimulation reward. Lesion studies using excitotoxins suggest that intrinsic neurons of the lateral hypothalamus provide a substantial contribution to brain-stimulation reward. For example, lateral hypothalamic neurons which use the peptide neurotransmitter orexin/hypocretin are known to excite dopamine neurons via descending MFB axons. Other clusters of neurons in the basal forebrain regions known as the substantia innomina-ta, bed nucleus of the stria terminalis, and ventral pallidum provide small contributions. Many neuropeptides found in the basal forebrain can activate or inhibit dopamine neurons, so these are of interest for brain-stimulation reward.

Acetylcholine and Nicotine

Acetylcholine is an important neurotransmitter at skeletal muscles where it excites muscles by way of nicotinic receptors. In the autonomic nervous system, acetylcholine can activate or inhibit visceral muscles via muscarinic receptors. Both nicotinic and muscarinic acetylcholine receptors are found widely in the brain.

Brain-stimulation reward is strongly inhibited by injecting cholinergic receptor blockers near dopamine neurons in the VTA. By contrast, brain-stimulation reward is facilitated by injections of cholinergic agonists, such as acetylcholine, nicotine, or carbachol applied to the same sites. Especially, carbachol in these VTA sites is highly rewarding, since carbachol works via both nicotinic and muscarinic acetylcholine receptors.

Nicotine is important as the addictive agent in tobacco that leads to smoking. Rats can be trained to self-administer nicotine, although it is much easier to train the rats using cocaine or amphetamine as the reinforcer. Nicotine is weakly rewarding in tests of conditioned place preference. Nicotine induces its rewarding effects mainly through activation of dopamine neurons in the VTA via nicotinic receptors.

VTA dopamine neurons are directly activated by way of cholinergic nerve terminals that release acetylcholine which then acts via nicotinic and muscarinic receptors near dopamine neurons. Nicotinic receptors excite dopamine neurons for seconds, while muscarinic receptors activate dopamine neurons more strongly, and over many minutes. Similarly, the rewarding effects of MFB stimulation or carbachol are due mainly to VTA muscarinic receptors, with smaller contributions from VTA nicotinic receptors.

The cholinergic activation of substantia nigra and VTA dopamine neurons comes from two cholinergic cell groups located in the pedunculopontine tegmental nucleus (PPT) and laterodorsal tegmental nucleus. The cholinergic neurons most important for brain-stimulation reward are in the PPT at the midbrain–hindbrain border. In particular, carbachol inhibits these PPT cholinergic neurons, and strongly inhibits brain-stimulation reward or locomotor arousal. PPT cholinergic neurons are themselves activated by water, food, or brain stimulation in rats, leading to release of the transmitter acetylcholine in VTA. This indicates an important role for these PPT neurons in natural rewards as well as brain-stimulation reward. It is not yet clear how PPT cholinergic neurons are activated by MFB or hindbrain stimulation, or by natural reward signals coming from the viscera or higher sensory systems. PPT receives strong, direct anatomical inputs from the lateral hypothalamus, and nucleus of the solitary tract (receiving visceral information from the mouth and gastrointestinal tract), however.

Opiate Reward and Brain-Stimulation Reward

Due to the widespread distribution of opiate receptors and endorphins in the brain, it is not yet clear how opiates induce rewarding effects in the brain. First, opiates can produce rewarding effects in the forebrain (such as the nucleus accumbens, or limbic frontal cortex) by acting independently of dopamine neurons. Lesions of dopamine neurons with 6-hydroxydopamine, therefore, have much weaker effects on opiate reward than on amphetamine, cocaine, or nicotine reward, or even on MFB brain-stimulation reward.

Second, opiates in the VTA are highly rewarding, which initially suggested that dopamine neurons may be sufficient for opiate rewards. High levels of opiate receptors (and endorphins) are found in the ventral tegmentum, but these opiate receptors are found on the nondopamine γ -aminobutyric acid (GABA) neurons, not on dopamine neurons. Several studies showed that the μ -type opiate receptors in the ventral tegmentum are important for a large part of the opiate reward.

PPT Lesions, Opiates and Brain-Stimulation Reward

PPT lesions have been made by infusing excitotoxins that kill cells in the nucleus. These lesions prevent rats from learning to bar-press for brain-stimulation reward or for heroin. Furthermore, van der Kooy and colleagues found that PPT lesions block the ability of morphine or food to induce conditioned place preference. This suggests that cholinergic or noncholinergic PPT neurons are important for opiate rewards, food rewards, and brain-stimulation reward.

PPT lesions, however, do not block the maintenance of brain-stimulation reward, or heroin self-administration in previously trained rats, and do not block the acquisition of conditioned place preference in rats previously exposed to multiple doses of morphine. Therefore, opiates can work by mechanisms independent of those for brain-stimulation reward.

Most theories now propose that opiates work by inhibiting tegmental GABA neurons that, in turn, inhibit PPT and dopamine neurons. Even when dopamine neurons are blocked, VTA opiates are rewarding via PPT.

Addiction and Glutamate

Dopamine neural changes are more important for opiate addiction (i.e., after repeated high doses of morphine or heroin) than for the initial rewarding effect of opiates. How repeated drug exposures and addictive behaviors increase the sensitivity of dopamine neurons is an active area for research. Descending excitatory inputs to dopamine neurons from limbic forebrain seem to be especially important for drug-induced plasticity and for the learned aspects of drug rewards. In particular, glutamate is the major excitatory input to dopamine neurons from the forebrain. The α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) and *N*-methyl-D-aspartate (NMDA) types of glutamate receptor in VTA are most important for morphine-induced plasticity in sensitization and drug self-administration.

However, brain-stimulation reward is not dependent on addiction-like changes in dopamine neurons. Brain-stimulation reward thresholds are stable over months of bar pressing, unlike self-administration of addictive drugs. This indicates that brain-stimulation reward does not work through highly plastic brain mechanisms (such as those for glutamate AMPA and NMDA receptors), but maintains its rewarding qualities more like those for food and water over the lifetime of the animal.

Natural Rewards and Brain-Stimulation Reward

The stable thresholds for food, water, and brain-stimulation reward over months of testing indicate that stable inputs to dopamine neurons from the MFB and from PPT cholinergic neurons are more critical for these rewards than the highly plastic inputs from the forebrain via glutamate receptors. Many electrode sites in the lateral hypothalamus near the fornix also elicit feeding, as well as brain-stimulation reward. The stimulation-elicited feeding sites are a smaller subset of the more medial MFB sites. Thresholds for brain-stimulation reward in these medial MFB sites are strongly influenced by food-related signals, including food deprivation, and the feeding-inhibiting neuropeptides leptin and cholecystokinin. These results suggest that brain-stimulation reward can activate pathways important for food sensitivity, for food seeking, and for food-related rewards; besides, MFB stimulation activates many different groups of axons, and consequently involves many different motivational signals in the activation of rewarding effects, in all likelihood.

Genes and Brain-Stimulation Reward

Brain-stimulation is useful to map rewarding inputs to dopamine systems, especially from MFB reward sites. In particular, brain-stimulation reward has been used to study hypothalamic and mesopontine systems and transmitters needed for dopamine-neuron and dopamine-receptor activation.

Dopamine Receptor Genes

Of the dopamine receptors, both D1 and D2 dopamine receptor families have been found to contribute to brain-stimulation reward. Selective blockers of these two main types of dopamine receptor reduce bar pressing (an effect on motor performance) and, in some cases, reduce the sensitivity of rats to brain-stimulation reward (an effect of reward sensitivity that is independent of performance).

Of the five dopamine receptor genes, two are of the D1 type (D1 and D5 genes) and three are of the D2 type (D2, D3, and D4) with all subtypes expressed in varying amounts in the VTA, substantia nigra, nucleus accumbens, and other dopamine terminal regions. In particular, the D2 dopamine receptor knock-out mouse shows excellent bar-pressing performance, but decreased reward sensitivity, requiring about 2 times more MFB stimulation to achieve similar response rates as wild-type control mice. These D2 knock-out mice show normal potentiation of brain-stimulation reward by amphetamine, but greatly reduced or reversed potentiation in response to

morphine. These findings indicate that the D2 dopamine receptor subtype is important for brain-stimulation and morphine-activated rewarding inputs to dopamine functions, but not to amphetamine-activated dopamine outputs. By contrast, the D1 dopamine receptor knockout mouse shows impaired bar-pressing performance in a brain-stimulation reward task.

Acetylcholine Receptor Genes

Many cholinergic receptor genes have been cloned and mapped in the brain. In particular, five muscarinic and nine nicotinic receptor genes have been identified (excluding four nicotinic subunits found on muscles and two in the cochlea that have not been found in the mammalian brain). Four muscarinic receptor subtypes and nine nicotinic receptor subtypes have been found in the ventral tegmental region. Of the four muscarinic subtypes, however, only the one for the M5 muscarinic receptor gene is expressed by dopamine neurons (as indicated by M5 messenger RNA), with messenger RNA for the M3 muscarinic receptor associated with nondopamine neurons. M2 and M4 muscarinic receptors are also found in VTA/SN, without mRNA for these two receptor subtypes, suggesting that these receptors are expressed on axon terminals of neurons projecting from other brain regions.

The M5 muscarinic receptor in VTA has been found most critical for sensitivity to brain-stimulation reward in rats. Specifically, messenger RNA for the M5 receptor was gradually removed by infusing a complementary DNA (called an ‘antisense oligonucleotide’) into the VTA for 6 days, leading to a reduction in the M5 receptor. As the M5 mRNA was removed from the VTA, the sensitivity of the rat to brain-stimulation reward was gradually reduced. Removing the M5 receptor in this manner reduced sensitivity in a way similar to nonselective muscarinic receptor blockers in VTA. When the antisense oligonucleotide infusion was stopped, allowing production of more M5 receptors, the sensitivity of the rat to brain-stimulation reward quickly returned.

When the M5 gene was removed completely in a genetically engineered M5 knock-out mouse, the mouse was less sensitive to morphine tested by dopamine activation, by locomotor activation, or by conditioned place preference. Furthermore, the M5 muscarinic receptor was needed for sustained activation of dopamine neurons by muscarinic receptors in VTA. Therefore, the M5 receptor subtype appears to be most critical for rewarding inputs to dopamine neurons from the brain stem. Of the nicotinic receptor genes, the beta-2 and alpha-4 subtypes have been shown to be most important for nicotine self-administration and conditioned place preference in knockout mice.

Brain-Stimulation Reward and Social Behaviors

Rats and mice communicate by way of high-frequency calls (termed ‘ultrasonic vocalizations’) that humans cannot hear. Mice make calls in the 30–110 kHz range in social situations where rewards, such as food in female mice, or sex, or amphetamine in male mice, are anticipated. M5 knockout mice show many fewer 30–110 kHz ultrasonic calls than wild-type mice in response to female mice, to amphetamine, or to palatable food odors. These findings suggest that the M5 receptor is needed for reward-induced social communications.

Brain-stimulation reward has recently been shown to activate similar 40–70 kHz ultrasonic vocalizations in male rats. These calls occur most often before the bar pressing begins, when the rat anticipates the entry of the bar, as signaled by a conditioned stimulus. These ultrasonic calls are similar to the calls evoked by amphetamine, by sex, by social play, or by tickling in rats, indicating that the calls are activated by rewards, and depend in part on dopamine, and in part on social communication.

In conclusion, the discovery of rewarding brain stimulation provided a major impetus to understanding neural substrates of emotion and learning. Presently, brain-stimulation reward is used to distinguish neural systems, transmitters, and receptors mediating several categories of drug reward, natural reward, and social behavior.

Stress and Drug Craving

Glossary

Autonomic nervous system – The autonomic nervous system is the part of the peripheral nervous system that acts as a control system, maintaining homeostasis in the body. These activities are generally performed without conscious control or sensation and affect heart rate, digestion, respiration, salivation, perspiration, the diameter of the pupils, urination, and sexual arousal. Although most of the actions of the autonomic nervous system are involuntary, some, such as breathing, work in tandem with the conscious mind.

HPA axis – The hypothalamo-pituitary-adrenal (HPA) axis is a complex set of direct and feedback interactions among the hypothalamus, the pituitary gland, and the adrenal glands. The interactions among these organs constitute the HPA axis, a major part of the neuroendocrine system that controls reactions to stress and regulates a variety of physiological processes, including digestion, the immune system, mood and emotions, sexuality, and energy storage and expenditure.

Mesocorticolimbic dopaminergic system – The mesocorticolimbic dopaminergic system is one of the neural pathways in the brain that links the ventral tegmental area (VTA) in the midbrain to the nucleus accumbens and amygdala (in the limbic system) and the medial prefrontal cortex. This pathway is thought to be involved in producing pleasurable feelings and is often associated with reward and desire. Therefore, this pathway has also been implicated in many neurobiological theories of addiction.

Reinforcement – Reinforcement is an increase in the strength of a response following a change in the environment (e.g., the delivery of a food pellet to a laboratory rat following the pressing of a response lever). The environment change contingent upon the response is called a reinforcer (e.g., food in the proceeding example). It is the strength of the response that is reinforced, not the organism.

Stress – Stress is an emotional and physical response to threats from the outside world. According to the pioneering neuroendocrinologist Hans Selye, stress is defined as the nonspecific response of the body to any demand placed upon it to adapt, whether that demand produces pleasure or pain.

Introduction

The relationship between stress and drug craving and relapse is not a novel concept; this phenomenon has been known to the lay public for many years. An excellent example can be found in the 1980 movie *Airplane* (Paramount Pictures, Hollywood, CA). Air traffic controller Steve McCroskey (played by Lloyd Bridges) is responsible for the safe landing of a pilotless passenger airliner in this comedy feature. As more mishaps befall the stricken aircraft, McCroskey is heard to say, "Looks like I picked the wrong week to quit drinking." This was subsequently followed by smoking, amphetamines, and sniffing glue, which was an undeniable reference to the stress of the situation increasing McCroskey's desire to use these substances. In general, addictive drugs (including alcohol, cigarettes, and psychomotor stimulants) tend to alter activity within the primary mediator of stress in the body, the hypothalamo-pituitary-adrenal (HPA) axis. Thus, it should come as no surprise that scientists and clinicians alike have reported a connection between substance abuse and the HPA axis. Recovering addicts often claim that their addiction was under control until they were faced with what they perceived as a stressful life situation. Obviously, drug addiction is a much more complex physical and psychological phenomenon than a simple cause and effect based on HPA axis activation. However, increasing evidence suggests that an addict's belief that his or her drug of choice provides relief from stress or control over life's stressors has a biological basis. This article reviews the evidence for a physiological basis underlying the role of stress and the HPA axis in drug craving and relapse.

Stress and the HPA Axis

Stress is perceived differently by different individuals, and individual responses to stressors are just as varied. However, people generally tend to focus on the negative ramifications associated with exposure to stress. For example, some individuals might complain about stress on the job, stress from dealing with family or friends, or stress related to a traumatic event, and in each case they would likely describe the unpleasant impact the stressor produced, which could include problems such as sleeping, increased anxiety, ulcers, heart disease, depression, or other more serious psychiatric disorders. However,

despite popular belief, stress does not have to be exclusively associated with negative events. The modern definition of stress and its implication for disease was developed by the pioneering neuroendocrinologist Hans Selye, who defined stress as the nonspecific response of the body to any demand placed upon it to adapt, whether that demand produces pleasure or pain. Therefore, positive events can be just as stressful to the body as negative events. Accordingly, stress can result from the loss of a loved one or from a marriage or birth of a child, a job promotion or the loss of a job, moving into a new house or losing one's home, or any number of events that impact upon an individual's daily life.

Stressors produce an activation of two functionally related biological systems, the sympathetic nervous system and the HPA axis. The activation of these systems makes it possible for an individual to cope with or adapt to an environmental event through the production of a stress response or the stress cascade. The stress-induced activation of the sympathetic nervous system, mediated through the neurotransmitter norepinephrine, results in an increase in heart rate, a rise in blood pressure, a shift in blood flow to skeletal muscles, an increase in blood glucose, a dilation of the pupils, and an increase in respiration. This automatic response, also called the 'fight or flight' response, makes it possible for the individual to face the stressor or attempt to escape from it and occurs below the level of consciousness. In reality, however, people cannot run away from many of life's stressors but instead must learn to adapt to both external and internal environmental changes. During positive events, an individual may believe that his or her increased heart rate represents feelings of happiness and joy, while an increased heart rate resulting from a negative event may be associated with anger or fear. Many abused substances also produce changes in the activity of the sympathetic nervous system, and these effects are felt differently by different individuals. One person may relish the increased heart rate (or rush) produced by cocaine while the same autonomic response may cause another individual to experience feelings of panic.

The HPA axis consists of a complex, well-regulated interaction between the brain, the anterior pituitary gland, and the adrenal cortex. The initial step in the activation of the HPA axis is the neuronal-regulated secretion of the peptide corticotropin-releasing factor (CRF). Although CRF is distributed in a number of brain regions, it is those CRF-containing neurons localized in the medial parvocellular subdivision of the paraventricular nucleus (PVN) of the hypothalamus projecting to the external zone of the median eminence that initiate HPA axis activity. These neurons release the peptide into the adenohypophyseal portal circulation in a circadian manner or in response to neuronal stimulation. The interaction of CRF with CRF₁ receptors located on

anterior pituitary corticotrophs results in the synthesis of proopiomelanocortin (POMC), a large precursor protein which is proteolytically cleaved to produce several smaller biologically active peptides, including β -endorphin and adrenocorticotropin hormone (ACTH). Vasopressin is also released from the parvocellular neurons of the PVN and produces synergistic effects on ACTH release. POMC-derived ACTH diffuses through the general circulation until it reaches the adrenal glands. There it stimulates the biosynthesis of adrenocorticosteroids, most notably the glucocorticoids, cortisol (in humans), and corticosterone (in rats), which results in their secretion from the adrenal cortex. Two types of adrenocorticosteroid receptors have been identified, both of which bind corticosterone. The type I mineralocorticoid receptor has a higher affinity for corticosterone and is usually fully occupied at basal concentrations of the hormone. This receptor also displays a high affinity for the mineralocorticoid, aldosterone. In contrast, the type II glucocorticoid receptor has a lower affinity for corticosterone and is more likely to be occupied when plasma corticosterone is elevated (e.g., during stress). This receptor also has a high affinity for the synthetic glucocorticoid, dexamethasone. The HPA axis is finely tuned through negative feedback processes from circulating cortisol at the level of the anterior pituitary and the PVN.

However, glucocorticoid receptors are also localized in brain regions above the hypothalamus, including the hippocampus, the limbic system (e.g., amygdala and bed nucleus of the stria terminalis), and the prefrontal cortex, suggesting that these higher brain centers are involved in the psychological stress response and may alter HPA axis responding. It is relevant to point out that these same higher brain centers have also been implicated in drug reward, and that both stress and addictive drugs produce a similar excitation of dopamine in these brain regions. As stated above, addictive drugs also tend to alter activity within the HPA axis. Cocaine and other psychomotor stimulants increase HPA axis activity, as does cigarette smoking and alcohol intoxication and withdrawal. Heroin users typically exhibit a hyporesponsive HPA axis with decreased plasma cortisol.

Stress and Vulnerability to Drug Addiction

There is a growing clinical literature describing the link between stress and addiction. One group of individuals who appear to be at greater risk for substance abuse are combat veterans, especially those suffering from post traumatic stress disorder (PTSD), and a number of studies have identified individuals with the dual diagnosis of combat-related PTSD and substance abuse. Veterans with PTSD typically report a higher lifetime use of nicotine, alcohol, cocaine, and heroin than veterans screening

negative for PTSD. However, people exposed to stressors other than combat, such as an unhappy marriage, dissatisfaction with employment, or harassment also report increased rates of addiction. Sexual abuse, trauma, and sexual harassment are also more likely to produce symptoms of PTSD and alcoholism and/or other addictions in women than in men. Adolescents are especially susceptible to social stressors and traumatic life events, and exposure to these stressors can significantly impact their substance use. Examples of such events range from childhood sexual abuse or other childhood trauma to the inability to effectively cope with the demands produced by everyday family or social stressors.

Prevalence estimates suggest that rates of substance abuse among individuals with PTSD may be as high as 60–80%, while the rates of PTSD among substance abusers are between 40% and 60%, indicating that there is a clear relationship between PTSD and increased substance use. One explanation for the high concordance between PTSD (and related disorders) and drug addiction (i.e., dual diagnosis) is the self-medication hypothesis. According to this hypothesis, a dually diagnosed person uses the abused substance to cope with tension associated with life stressors or to relieve or suppress symptoms of anxiety, irritability, and depression resulting from a traumatic event. Others may also engage in substance abuse to manage symptoms of anxiety and/or depression that may be unrelated to a specific life event.

Drug Relapse

Exposure to external cues or triggers previously associated with drug use can induce craving and relapse in recovering addicts. A better understanding of how these cues contribute to the precipitation of relapse may lead to the development of more effective and efficient strategies for the treatment of addiction. Accordingly, the development of animal models that reflect many of the salient features of relapse in humans has received considerable attention. One well-studied animal model of relapse involves a reinstatement procedure. Using this model, rats are trained to self-administer a given drug. Once stable self-administration is observed, the rats are subjected to repeated extinction whereby responding is no longer reinforced by the delivery of the drug or to a period of abstinence from drug availability. Once extinction has been successful or the period of abstinence has been reached, the rats are exposed to various events in an attempt to reinstate drug-seeking behavior.

In humans and nonhumans, the acute re-exposure to the addictive drug itself (i.e., drug priming) is a potent event for provoking relapse to drug seeking. This drug-induced reinstatement has been observed for stimulant and opiate self-administration. Exposure to stress, or

simply the presentation of stress-related imagery, is another event that induces craving and relapse in humans. In rats, exposure to stress in the form of intermittent electric footshock has been reported to reinstate heroin- and cocaine-seeking behavior without affecting food-seeking behavior. Pretreatment with the corticosterone synthesis inhibitor ketoconazole can block the stress-induced reinstatement of cocaine seeking and the plasma corticosterone response to electric footshock, suggesting an important role for corticosterone in the ability of this stressor to reinstate cocaine-seeking behavior in rats.

The ability of cues previously paired with cocaine self-administration to reinstate extinguished cocaine-seeking behavior has also been investigated. In these experiments, responding during reinstatement testing results in the contingent presentation of a tone and house light cue that had been paired with cocaine delivery during self-administration training, which reliably reinstates extinguished cocaine-seeking behavior. Conditioned increases in plasma corticosterone are evident during cocaine extinction as well as during reinstatement. However, while plasma corticosterone returns to basal levels by the end of the session during extinction, it remains elevated through the end of the 2-h session during reinstatement, suggesting a potential relationship between HPA axis activation and cue-induced cocaine seeking. In humans, exposure to drug-related cues also increases plasma cortisol and ACTH and activates the sympathetic nervous system, suggesting an important involvement of the HPA axis and the sympathetic nervous system during drug cue-induced cocaine craving. In animal studies, pretreatment with ketoconazole reverses the conditioned cue-induced reinstatement of extinguished cocaine-seeking behavior and also blocks the conditioned increases in plasma corticosterone observed during reinstatement, which further underscores a role for the HPA axis in this behavior. In other studies, pretreatment with oxazepam or alprazolam also prevents the cue-induced reinstatement of extinguished cocaine seeking, suggesting that benzodiazepines may be useful in combating craving and relapse induced by environmental triggers associated with cocaine use.

CRF₁ receptor antagonists have been reported to decrease the stress- and cocaine-induced reinstatement of extinguished cocaine-seeking behavior in rats. Pretreatment with the CRF₁ receptor antagonist CP-154,526 also reduces the ability of conditioned cues to reinstate extinguished cocaine seeking. Another model of cue-induced cocaine seeking is based on the observation that animals will continue to respond for days during extinction when presented with cues that had been previously paired with cocaine. In such studies, rats are trained to self-administer cocaine, and, when responding stabilizes, saline is substituted for cocaine and the animals are tested for extinction. Other rats are allowed to

self-administer cocaine for an additional 30 days, and extinction is tested once again. CP-154, 526-treated animals respond significantly less than vehicle-treated animals during extinction on the first day of testing and also after 30 days of self-administration training, demonstrating a reduction in cocaine seeking. Interestingly, CP-154,526 does not suppress plasma corticosterone, suggesting that the effects of this compound are acting, in part, independently of the HPA axis and are likely mediated at sites located outside of the hypothalamus. However, these data do underscore an important role for CRF in the ability of environmental cues to stimulate cocaine-seeking behavior in rats.

The HPA Axis, Prefrontal Cortex, and Addiction

Cocaine stimulates HPA axis activity, which indicates that this system has the potential to influence many of the neurochemical and behavioral effects of the drug. The acute administration of cocaine dose-dependently increases plasma concentrations of corticosterone, ACTH, and β -endorphin in rats. Cocaine also stimulates the release of ACTH and cortisol in humans and nonhuman primates by increasing the peak amplitude of secretory pulses of these hormones without altering pulse frequency, suggesting that these increases are driven by hypothalamic CRF. However, although the HPA axis is involved in addiction, there are data that suggest that many of the effects of the so-called HPA axis drugs are mediated through sites located outside of the hypothalamus. For example, pretreatment with a CRF receptor antagonist does not produce reliable, reproducible effects on plasma corticosterone, and there is evidence that the prefrontal cortex, or more specifically the medial prefrontal cortex, may function as an interface between the HPA axis and the central nervous system. One series of experiments that supports this hypothesis involves the effects of cocaine on benzodiazepine receptor binding. Chronic, daily injections of cocaine result in differential effects on central benzodiazepine receptor binding in various regions of the rat brain. In general, cocaine decreases binding in terminal fields for the mesocorticolimbic dopaminergic system, while increasing labeling in terminal fields for the nigrostriatal system. Statistically significant decreases in binding in the medial prefrontal cortex and increases in the ventral tegmental area (VTA) are still observed for up to 2 weeks following the final injection of cocaine, suggesting that benzodiazepine receptors in mesocorticolimbic dopaminergic system may be especially sensitive to the effects of the drug. These cocaine-induced changes in binding appear to be mediated, at least in part, through the effects of the drug on dopaminergic neuronal activity since intraventricular

injections of 6-hydroxydopamine (6-OHDA) attenuate or reverse these effects. Continuous exposure to cocaine can also alter benzodiazepine receptor binding in various structures of the rat brain.

Some of the major symptoms associated with cocaine withdrawal often include severe anxiety, restlessness, and agitation, further suggesting that benzodiazepines may be useful for alleviating these negative symptoms during the early stages of withdrawal. These drugs are also useful in the emergency room for the treatment of some of the medical complications associated with cocaine intoxication since convulsions are often apparent following an acute overdose. These seizures can be treated with intravenous diazepam. Interestingly, the number of benzodiazepine receptors in platelets from chronic cocaine users is augmented when compared to those obtained from alcoholics or normal controls. In addition, peripheral benzodiazepine receptors labeled with [³H]PK11195 are decreased in neutrophil membranes from the blood of male inpatients following 3 weeks of cocaine abstinence. These data indicate that benzodiazepine receptors may mediate some of the biological effects of cocaine in humans. Since benzodiazepines are effective in reducing cocaine self-administration and the cue-induced reinstatement of extinguished cocaine seeking, benzodiazepines may also be useful in the treatment of cocaine addiction.

In rats, cocaine-induced increases in ACTH and corticosterone can be blocked by pretreatment with the CRF antagonist α -helical CRF9-41, by immunoneutralization of CRF with an anti-CRF antibody, or by bilateral electrolytic lesions of the PVN, indicating that these increases are also mediated by the cocaine-induced release of CRF from parvocellular neurons in the PVN. It has been reported that cocaine administration also increases hypothalamic CRF mRNA and alters CRF receptor binding measured autoradiographically in various regions of the rat brain. These data suggest that the complex relationship between cocaine reinforcement and corticosterone secretion may ultimately result from actions on extra-hypothalamic CRF.

Ketoconazole-induced changes in cocaine self-administration and reinstatement do not always correspond with decreases in plasma corticosterone either, which suggests that other mechanisms must be underlying these behavioral effects. Interestingly, significant increases in CRF content in the median eminence are observed after the acute administration of ketoconazole. Acute, repeated, and chronic treatment with ketoconazole also significantly increase CRF content in the medial prefrontal cortex, but do not consistently affect the peptide in other brain regions. Since the medial prefrontal cortex and CRF have been implicated in the neurobiology of cocaine addiction, CRF-induced alterations in dopaminergic neurotransmission may play an important role in

this peptide's effects on cocaine responsiveness. Accordingly, the effects of the CRF₁ receptor antagonist CP-154,526 on cocaine-induced dopamine overflow in the nucleus accumbens and medial prefrontal cortex have been measured using *in vivo* microdialysis. Rather than decreasing dopamine content as initially expected, CP-154,526 actually enhances the cocaine-induced increases in dopamine in the medial prefrontal cortex and the rostral part of the nucleus accumbens without altering these increases in dopamine in the rest of the nucleus accumbens. Ketoconazole produces a similar augmentation of cocaine-induced increases in dopamine overflow in the medial prefrontal cortex. These data implicate prefrontal cortex dopamine in the ability of CRF-receptor antagonists and the corticosterone synthesis inhibitor ketoconazole to attenuate cocaine seeking in rats. Taken together, these data suggest that ketoconazole, as well as CRF receptor antagonists and benzodiazepines, may affect cocaine reward, at least in part, through interactions with dopamine and CRF within the medial prefrontal cortex.

The neurochemical and neuroendocrine responses to cocaine have been measured during response-contingent and response-independent cocaine administration in rats. In these studies, male rats are divided into triads of three rats each: one rat is selected as the self-administration rat, while the other two rats are designated as the yoked-cocaine and yoked-saline rats, respectively. Self-administration rats are trained to self-administer cocaine, and each infusion is accompanied by an identical simultaneous cocaine infusion to the yoked-cocaine rat and saline to the yoked-saline rat. Baseline corticosterone in the medial prefrontal cortex was low and stable in all groups prior to the start of the self-administration session and remained stable throughout the entire experiment in the yoked-saline rats, suggesting that the procedure itself was not unduly stressful. Medial prefrontal cortex corticosterone was significantly elevated in microdialysates from the self-administration rats during cocaine self-administration, while corticosterone was increased significantly more in the medial prefrontal cortex of the yoked-cocaine rats. These data suggest that corticosterone in the medial prefrontal cortex may mediate the differences between cocaine reward (in the self-administration rats) and the more aversive aspects of cocaine (in the yoked-cocaine rats), further highlighting the role for this brain region in addiction and suggesting that the medial prefrontal cortex may also serve as an interface between the central nervous system and the HPA axis.

In humans, exposure to cues associated with cocaine induce craving and result in changes in blood flow and metabolic activity in the orbitofrontal cortex and the dorsolateral and anterior cingulate cortices, which loosely correspond to the prefrontal cortex in rats. Increases in glucose metabolism using ¹⁸F fluorodeoxyglucose were

observed in the dorsolateral cortex and medial orbitofrontal cortex after the presentation of cues associated with cocaine when compared to neutral cues. In a more recent study, increases in glucose metabolism were found in the right superior frontal gyrus in the dorsolateral prefrontal cortex and the left lateral orbitofrontal cortex. In contrast, glucose metabolism in the left medial prefrontal cortex and the ventromedial frontal pole decreased after the presentation of cocaine-associated cues, and interviews with the subjects about cocaine use produced increases in metabolism in the orbitofrontal gyrus, but not in the frontal cortex or cingulate gyrus. Both the anterior cingulate cortex and the dorsolateral prefrontal cortex were activated after the subjects watched a cocaine-related video as measured by blood oxygenation using functional magnetic resonance imaging (fMRI). In a more extensive study, the activation of the left dorsolateral cortex as well as the left anterior cingulate cortex and the left posterior cingulate cortex were also identified using fMRI. Finally, cerebral blood flow, measured using ¹⁵O-labeled water, increased in the anterior cingulate cortex, but not in the orbitofrontal cortex, in research subjects after internally generated craving or following the presentation of a cocaine-related video. Taken together, these data highlight the importance of the frontal cortex in cocaine craving in humans, and taken with the preclinical data reviewed above, these data further suggest that the prefrontal cortex may mediate the induction of craving resulting from the cue-induced activation of the HPA axis.

Conclusion

Drug craving is a complex phenomenon. The cues or triggers that stimulate craving and the relapse to drug use do so, at least in part, through an activation of the HPA axis and prefrontal cortex using CRF, cortisol, norepinephrine, dopamine, gamma aminobutyric acid (GABA), and likely a host of other mediators. The continued investigation into how stress and the subsequent activation of the HPA axis impact addiction will likely result in the identification of more effective and efficient treatment for substance abuse in humans. Stress reduction and coping strategies, either alone or in combination with pharmacotherapies targeting the HPA axis, may prove beneficial in reducing cravings and promoting abstinence in individuals seeking treatment for addiction.

Glossary

Drug addiction – The compulsive drug-taking behavior that is maintained due to physical and/or psychological dependence as a consequence of long-term changes in the brain.

Drug craving – The desire for a drug that persists long after dependence has subsided.

Reinforcer – Any natural reward or conditioned stimulus that increases the probability that a particular behavior will be repeated, when the reinforcer is associated with that behavior.

Reward – Something that an animal or individual will work to receive. Some things are naturally rewarding, which means that these items or events have some intrinsic value (e.g., food or sexual activity); other things become rewarding through repeated pairing with natural reinforcers (e.g., money).

Self-administration – In laboratory animals, it is a task where they have a chronic intravenous catheter and they learn to inject a dose of a drug into their veins by pressing a bar or poking their nose into a hole in the chamber wall. The rewarding value of a drug can be determined by the extent that it is self-administered.

Sensitization – The progressive increase in the effect of a drug with repeated exposure to the same dose of the drug.

This article begins with brief descriptions of the reward system, followed by how the stress system and reward system interact. Finally, the article concludes with a brief discussion of sex differences in stress and reward.

Reward

A ‘reward’ is defined as something that an animal or individual will work to receive. Some things are naturally rewarding, which means that these items or events have some intrinsic value (e.g., food or sexual activity); other things become rewarding through repeated pairing with natural reinforcers (e.g., money). A ‘reinforcer’ is any natural reward or conditioned stimulus that increases the probability that a particular behavior will be repeated, when the reinforcer is associated with that behavior. With all rewards, an animal must first learn that something is

rewarding. Food preferences are learned by eating the food, or in some species through interaction with an individual that has eaten a novel food. Sexual experience results in changes in motivational and consummatory aspects of sexual behavior in both males and females. Other stimuli acquire rewarding properties by association with external or internal primary reinforcers.

Our understanding of the neural basis of reward began over 50 years ago when Olds and Milner reported that rats would press a bar to receive electrical stimulation in certain areas of the brain. From these pioneering studies, it was concluded that there are ‘rewarding’ areas in the brain or ‘pleasure centers’ of the brain. With subsequent research it became generally accepted that the reinforcing properties of intracranial self-stimulation, drugs of abuse, and natural rewards are mediated by activation of the ascending dopamine (DA) pathway, and in the absence of DA these things are not rewarding. Nevertheless, it is clear that DA is not the only mediator of reward. As summarized in the 2007 work of Becker and Meisel, “In general, activation of dopamine release in the nucleus accumbens is an internal cue that tells an animal that something desired is available (or is soon to be available). We conclude, as others have, that this dopamine signal is associated with enhanced incentive salience ... of the desired stimulus. Glutamate and GABA neurons modulate dopamine release, providing input related to context and motivational state. GABA and endogenous opioids also provide information about the hedonic value of the stimulus.” This is generally true for food reward and drugs of abuse, although there are subtle differences.

Stress Hormones Regulate Reward Systems

As discussed previously, exposure to stimuli that threaten homeostasis (i.e., stressors) activates autonomic, behavioral, and neuroendocrine systems that permit the organism to respond to the threat. The hypothalamic–pituitary–adrenal (HPA) axis is exquisitely responsive to stress exposure and its activation is critical for the response to the current threat. Stressors induce activation of neural systems that result in the release of corticotropin-releasing hormone (CRH) and other stress-related peptides, which result in the release of corticosterone (CORT) from the adrenal cortex. In the brain, CORT and CRH influence anxiety-related behaviors, memory

and other cognitive functions, and the effect of drugs of abuse on subsequent drug-taking behavior.

Of particular interest to the reward system, stress can activate or inhibit cocaine- and amphetamine-regulated transcript (CART) and orexin (ORX). These peptides act in the amygdala, ventral tegmental area (VTA), and nucleus accumbens (NAcc), among other brain regions, where they modulate the response of the stress system to subsequent challenges (i.e., habituation and/or sensitization) and interact with the reward system. Conversely, drugs of abuse are stressful and induce an increase in the secretion of stress hormones and related neuropeptides. A schematic diagram of how the stress system and reward system interact is presented in **Figure 1**.

As mentioned above, when stressful stimuli activate the HPA axis a number of behaviors are affected, including anxiety-related behaviors, memory and other cognitive functions, drug-taking behavior, and feeding behavior. For the purposes of this review, we focus on drug-taking behavior as a model behavior for discussing interactions among stress and reward.

Stress and Drug Abuse

In humans and nonhumans, it is widely accepted that the rewarding aspect of drugs of abuse are due to the ability of these drugs to activate the neural system characterized in **Figure 1** as the ‘reward’ system. The ascending DA system and its targets are part of a motivational system that regulates responses to natural reinforcers (e.g., food, drink, and sex) and drugs of abuse. Importantly, activity in the ascending DA system is also modulated by the neural responses to stressors, and the effect of drugs of abuse and the neural stress response interact in a way that can influence the initiation of drug-taking behavior.

Animals and many humans will rapidly learn to self-administer psychomotor stimulant drugs (e.g., cocaine, amphetamine (AMPH), and methylphenidate) and opiates, at least in part due to their ability to increase DA in the NAcc. It is also apparent from animal models of drug abuse that the neural stress response influences the reinforcing effects of these drugs of abuse. This is due to both acute and long-term effects of drugs of abuse on the stress axis. First, drugs of abuse induce activation of the HPA axis to induce an increase in CORT release. CORT, in

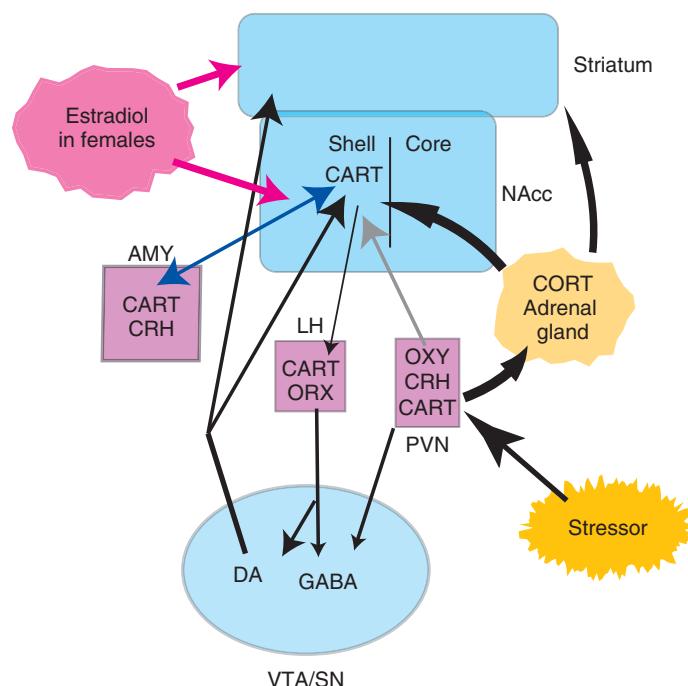

Figure 1 Interactions between the reward system and the stress system. The stress system interacts with the mesolimbic DA systems through input from the PVN to the NAcc shell and from the AMY to the NAcc shell, as well as through the release of CORT that feeds back to the NAcc where it enhances CART and DA release, and to the striatum where DA release is augmented. CRH and OXY also act in the VTA to enhance DA release. CART-containing neuronal terminals are found in the VTA and to a lesser extent in the substantia nigra (SN), and many CART-containing cells and processes are found in the NAcc shell. Most CART input to the VTA/SN derive from neurons in LH where CART may play a role in integrating food and drug reward through stimulation of DA neurons directly or indirectly through inhibition of GABA neurons. In the NAcc, DA terminals are found on CART neurons (GABAergic medium-spiny output neurons), suggesting that DA also influences CART. CART synapses in the NAcc indicating that CART can influence NAcc output. In addition, estradiol in females acts in the striatum and NAcc to enhance stimulated DA release. There are also sex differences in the stress system as described in the text, resulting in greater CORT in females under basal conditions and in response to stress.

turn, acts in the NAcc and the striatum at glucocorticoid receptors to influence neuronal activity and drug-taking behavior. With repeated exposure to the drug, there are long-term changes both in the neural system mediating the reinforcing effects of the drug and in the stress system.

The animal models used as behavioral indices of the neural changes associated with drug abuse that are used most frequently are ‘sensitization’ and drug ‘self-administration.’ Sensitization is the progressive increase in the effect of a drug with repeated exposure to the same dose of the drug. In other words, the more doses of a drug an individual is exposed to, the greater is the behavioral response to the drug – the individual has become ‘sensitized’ to the drug. The neural processes associated with sensitization are thought to be related to the neural basis of drug craving, or the desire for a drug that persists long after dependence has subsided. Drug self-administration in animals is a task where animals have a chronic intravenous catheter and they can learn to inject a dose of a drug into their veins by pressing a bar or poking their nose into a hole in the chamber wall. Both, self-administration of drugs of abuse and sensitization induced by repeated drug treatment, are modulated by the increase in glucocorticoid levels induced by drug treatment.

Animals that cannot mount a stress response due to removal of the adrenal gland neither learn to self-administer drugs nor do they show behavioral sensitization; conversely, CORT enhances acquisition of cocaine self-administration. If endogenous CORT is elevated in male rats or mice due to repeated stressful encounters with a dominant male prior to self-administration (i.e., social defeat), they will acquire self-administration of cocaine more rapidly and take more cocaine. Animals will also exhibit greater behavioral sensitization to psychomotor stimulants following the stress of social defeat. On the other hand, administration of a glucocorticoid receptor antagonist attenuates the motivation to self-administer cocaine. These findings, and others, support the idea that one way in which drugs of abuse induce neural changes that result in addiction, in susceptible individuals, is through activation of the stress axis and the glucocorticoid receptors in particular. Drug-taking behavior also results in long-term changes in the stress response. For example, prior cocaine self-administration enhances the effect of restraint stress on increases in plasma CORT. Thus, exposure to drugs of abuse enhances the HPA response to stressful stimuli, and prior stress enhances drug-taking behavior.

The response to stress may also impact individual differences in the response to drugs of abuse. When experimentally naive rats are exposed to the mild stress of a novel environment, some rats exhibit high rates of exploratory locomotion, and these animals are known as high responders (HRs); other rats, known as low responders (LRs), exhibit low rates of locomotor activity in a

novel environment. In addition, HR rats will seek out a novel and varied environment over an environment to which the rats have become habituated. Importantly, the rate of novelty-stress-induced locomotion predicts the subsequent behavioral responses of these animals to drugs such as AMPH and cocaine. HR rats exhibit higher rates of AMPH- and cocaine-induced locomotor activity, and will self-administer these drugs at lower doses than will LR rats.

HR rats have a prolonged CORT response after exposure to a novel context compared with LR rats. On the other hand, administration of exogenous glucocorticoid induces LR animals to self-administer AMPH, but reduces self-administration in HR animals. Similarly, social defeat enhances acquisition of self-administration of cocaine in LR rats, but reduces drug taking in HR rats. These results suggest that there is an optimal amount of CORT that will enhance drug-taking behavior. Since HR rats have a greater endogenous increase in CORT than do LR rats, when CORT is enhanced through either investigator administration or social stress, the HR rats are exposed to excessive CORT and this inhibits drug taking. The LR rats, with a more ‘optimal’ increase in CORT after prior stress or exogenous CORT, experience enhanced drug taking. This effect may be mediated by a direct effect of glucocorticoids on the striatum and NAcc, or through an enhanced effect of the drugs to induce an increase in DA, or both. Thus, these and other findings support the idea that one way in which drugs of abuse induce neural changes that result in drug abuse, in susceptible individuals, is through activation of the stress axis.

Stress and Drug Addiction

Maintenance of compulsive drug-taking behavior, or ‘addiction,’ in humans and nonhuman animals is thought to be due to long-term changes in the brain that are induced as a consequence of exposure to drugs of abuse. Induction of these long-term changes is another way in which the stress axis and reward system interact. In the paraventricular nucleus (PVN), CRH-containing neurons are known to project to the NAcc and VTA where they regulate the activity of dopaminergic and γ -aminobutyric acid- (GABA-)ergic neurons, and this CRH activity is thought to impact drug-taking behavior in addicted individuals. In animal models, as a consequence of repeated drug taking on an extended access schedule, a pattern of drug taking that might be seen with a cocaine addict, the central CRH system (CRH neurons projecting to the VTA and NAcc shell) is hypothesized to be overactive. This overactivity is thought to contribute to compulsive drug-taking behavior and addiction; hence, when a CRH-1 receptor antagonist is given to an animal that is already self-administering cocaine, the intake of cocaine is

reduced in a dose-dependent manner. This can be seen with a number of schedules of reinforcement, but is seen most dramatically with animals that are avidly taking drugs in over a period of 3–6 h day⁻¹ or animals on a progressive ratio schedule (where each dose of the drug requires the animal to work harder for the next drug dose).

CART, co-localized with glutamate in a subpopulation of lateral hypothalamus (LH) neurons, is another potential regulator of both the stress response and drug-taking behavior. CART protein is increased by cocaine and AMPH in the shell of the NAcc, the PVN, the LH, and the central nucleus of the amygdala (ceAMY) as well as in a number of other brain regions and the sympathetic nervous system. With chronic activation, CART in the NAcc (and perhaps in other brain regions) is thought to serve as a compensatory agent to downregulate changes in the NAcc associated with drug taking. In the VTA, CART stimulates DA neurons and inhibits GABA neuronal activity. Thus, activation of CART may help to decrease susceptibility to addiction.

Finally, ORX co-localized with glutamate in neurons in the LH, which project to the VTA, also plays a role in mediating the interface between stress and drug abuse and, in particular, the neuro-adaptations associated with compulsive drug-taking behavior. CRH stimulates the release of ORX, and this neural circuit is thought to be critical for the induction of sensitization to cocaine, activation of the reward circuitry, and drug seeking during withdrawal. Thus, convergence of stress and reward interactions occurs at the mesolimbic DA neurons at the level of the cell bodies and terminals, for acute and long-term adaptation to repeated drug exposure.

Sex Differences in Stress and Reward

Sex Differences in Drug Abuse in Humans

Adult men are 2–3 times more likely than women to have a drug abuse/dependence disorder; however, this current gender difference is thought to reflect historical differences in opportunity, rather than sex differences in vulnerability to drug abuse. The male predominance in drug use may be waning, as data collected in the past 5 years in the USA indicate that among males and females of high school age, there is no longer a sex difference in drug-taking behavior. Among individuals who use drugs, more females are using cocaine and other psychomotor stimulants than males. There are also sex differences in the rate of escalation of drug use, with women tending to increase their rate of consumption of alcohol, marijuana, opioids, and cocaine more rapidly than do men. The sex differences in the psychomotor stimulants are the best studied, and women begin using cocaine or AMPH earlier in life and enter treatment at earlier ages than men.

Women also have more severe cocaine use at intake and more severe dependence than men. Furthermore, once addicted to a drug, women can find it more difficult to quit than men do.

Animal Models of Sex Differences in Drug Use

Basic research on the role of sex and ovarian hormones in the neurochemical and behavioral responses to acute and repeated exposure to drugs of abuse also finds sex differences and may provide insight into the biological causes of sex differences in drug abuse. The acute behavioral response to psychomotor stimulants in rodents can reflect both the sex differences and the modulation role of gonadal hormones in males and females. Research on rodents and humans indicates that the behavioral effects of drugs of abuse and, the psychomotor stimulants, in particular, are both sexually dimorphic and modulated by the gonadal steroid hormones.

Sex differences have been reported during all phases of the addiction process as assessed using various self-administration paradigms. When a low dose of drug is used, intact or ovariectomized (OVX) female rats acquire cocaine self-administration at a faster rate than do intact or castrated (CAST) males. Estradiol treatment enhances acquisition of cocaine self-administration in OVX female rats, but not in males; and the estradiol antagonist, tamoxifen, when given to intact females, inhibits acquisition. Therefore, there are inherent sex differences independent of circulating gonadal hormones in the acquisition of cocaine self-administration, with females being more vulnerable than males. Furthermore, estradiol enhances acquisition in females, but not in males.

Once animals are reliably taking cocaine, if female rats are given a choice between two doses of cocaine, females in estrus prefer higher doses of cocaine compared with females in other phases of the estrous cycle or male rats. If rats are housed in self-administration chambers 24 h a day and then given access to drug in limited times during the day, female rats 'binge' for a longer initial period of time, take more cocaine over a 7-day access period, and show a greater loss of diurnal control over cocaine intake than do males. Furthermore, estradiol treatment increases the initial binge length and the total amount of cocaine self-administered. These results show that estradiol influences both cocaine self-administration under high access conditions and the motivation to take cocaine.

The effects of estradiol on the motivation to take cocaine has also been demonstrated when animals are responding to low doses of cocaine under a schedule in which the number of responses required to obtain a cocaine infusion progressively increases. Under this 'progressive ratio schedule,' intact female rats reach much higher final ratios than do males, indicating that females are more motivated to obtain cocaine. Females also

worked harder for access to cocaine during the phase of the estrous cycle when estradiol was elevated. When estradiol treatment is given to OVX rats, it enhances responding on a progressive ratio schedule at some doses of cocaine. Thus, there are sex differences in the motivation to take cocaine, and 'estradiol enhances the motivation' to take cocaine. Sex differences have also been observed under reinstatement testing conditions designed to parallel relapse in humans, with females exhibiting a greater susceptibility to reinstatement of responding for cocaine after prolonged abstinence.

Sex Differences in Stress and Drug Abuse

In rodents and humans, there are sex differences in activation of the HPA axis that can play a role in behavior and physiology. For example, in female rats, both basal and stress-induced CORT secretions are more pronounced than in males. Furthermore, HPA secretions vary across the estrous cycle in the rat. Females in proestrus or estrus show elevated basal and stress-induced CORT concentrations relative to diestrous animals. Similarly, women show greater adrenocorticotropic hormone (ACTH) and cortisol responses in the luteal phase (when estradiol and progesterone are elevated) compared with the follicular phase (when estradiol is slowly rising). Females are also less sensitive to suppression of the HPA axis by the synthetic glucocorticoid, dexamethasone, than are males. Sex differences and ovarian hormones also affect the central neural circuits regulating neuroendocrine and behavioral stress responses, as indicated by stress-induced c-fos messenger RNA (mRNA) expression. Proestrous and estrous females show attenuated cortical and hippocampal induction of c-fos relative to males or diestrous females, while luteal-phase women demonstrate impaired glucocorticoid feedback relative to the follicular phase. In males, testosterone attenuates stress-induced CORT and ACTH secretion, and inhibits CRH gene expression in PVN neurons controlling the HPA-axis response. If the HPA axis is enhancing the response to drugs of abuse, establishment of drug-taking behavior, and subsequent neural changes resulting in addiction, sex differences in the HPA axis may play a role in the enhanced susceptibility of females to drug abuse.

Finally, there is greater stress-induced activation of CART in the PVN of female rats, compared to males. CART mRNA expression in the NAcc is sexually dimorphic, with males having higher basal expression than estradiol-treated females. On the other hand, females have higher basal expression of ORX precursor expression in the hypothalamus than male rats. Therefore, if CART decreases drug-taking behavior and ORX enhances drug-seeking behavior, as previously discussed, these hormones may also play a role in sex differences in drug abuse. One could postulate that females exhibit less

suppression of drug-associated behavior during initial drug exposure due to lower CART activity. If females also have greater basal ORX activity, the lower CART response coupled with enhanced ORX may underlie the more rapid escalation of drug-taking behavior in females and lead to the more rapid onset of addiction in females compared to males. This intriguing possibility needs to be explored further.

Summary

This brief discussion has shown how the neural systems mediating stress and reward are intimately intertwined. Agents that activate the reward system, such as drugs of abuse, also activate the neural stress systems. Activation of the stress system can be necessary for some of the reinforcing effects of drugs of abuse. Conversely, the stress system can also inhibit the reward system. Sex differences and individual differences in the stress system and the reward system affect how they interact. For example, females have a greater stress response and are more likely to acquire self-administration of drugs of abuse, with more rapid escalation of drug-taking behavior. In addition, long-term changes in both the stress and reward systems that occur during repeated exposure to drugs of abuse result in sensitization of each neural system and alter how the two systems interact in a sexually dimorphic way.

Glossary

Catalepsy – Nervous condition characterized by muscular rigidity and fixity of posture irrespective of external stimuli, as well as decreased sensitivity to pain.

Endocannabinoids – Endogenous agonists of cannabinoid receptors. Endocannabinoids are derived from long-chain polyunsaturated fatty acids. The family of endogenous agonists for CB₁ receptors is larger than initially thought. The first-discovered and best-studied endocannabinoids are anandamide (*N*-arachidonoyl-ethanolamine) and 2-arachidonoyl-glycerol (2-AG). Newly proposed endocannabinoids are 2-arachidonylglyceral ether (noladin, 2-AGE), O-arachidonoyl-ethanolamine (virodhamine), and *N*-arachidonoyldopamine (NADA). The physiological functions for these compounds have not yet been established.

Hemopressin was recently identified as an endogenous CB₁ receptor antagonist.

G-protein-coupled receptors (GPCRs) – A large protein family of transmembrane receptors that sense molecules outside the cell and activate intracellular signal-transduction pathways and, ultimately, cellular responses. Most processes of signal transduction involve ordered sequences of biochemical reactions inside the cell, which are carried out by enzymes, activated by second messengers, resulting in a signal-transduction pathway. Such processes are usually rapid, lasting on the order of milliseconds in the case of ion flux, or minutes for the activation of protein- and lipid-mediated kinase cascades.

GTPgammaS (GTP γ S, guanosine 5'-O-[gamma-thio]triphosphate) – Nonhydrolyzable G-protein-activating analog of guanosine triphosphate (GTP). Its 35-S-labeled radioligand [³⁵S]GTP γ S is used to evaluate the functional activity of G-protein-coupled receptors.

Immunohistochemistry – The process of localizing proteins in cells using the principle of antibody binding to specific antigens in biological tissues. For immunohistochemical evaluation of receptor localization, an antibody is developed that selectively binds to the C- or N-terminal regions of the receptor. The antibody is typically tagged with a fluorophore and, thus, the antibody distribution in tissue can be visualized by fluorescence analysis.

Nociception – The neural processes of encoding and processing noxious stimuli and is produced in the

peripheral and central nervous system by stimuli that have the potential to damage tissue. This activity is initiated by nociceptors (also called pain receptors) that can detect mechanical, thermal, or chemical stimuli. Once stimulated, a nociceptor transmits a signal along the spinal cord, to the brain. Nociception triggers a variety of autonomic responses and may also result in the experience of pain.

Orexigenic – Increasing or stimulating the appetite.

Psychoactive (or psychotropic) drugs – Chemical substances that act primarily upon the central nervous system to alter brain function, resulting in temporary changes in perception, mood, consciousness, and behavior. These drugs may be used recreationally – to purposefully alter one's consciousness – or therapeutically as medication. Because psychoactive substances bring about subjective changes in consciousness and mood that the user may find pleasant (e.g., euphoria) or advantageous (e.g., increased alertness), many psychoactive substances are abused, that is, used excessively, despite risks or negative consequences. With sustained use of some substances, physical dependence may develop, making the cycle of abuse even more difficult to interrupt.

Radioligand binding – Evaluates the distribution of a selective receptor ligand (agonist or antagonist) that has been tagged with a radioactive moiety such as tritium [³H]. Radioligand distribution is typically evaluated by apposing prepared brain slices with X-ray film that, thus, produces a density image of the radiotracer presence throughout the tissue.

Cannabis Δ9-THC Content, Use, and Pharmacokinetics

Among the 66 different types of cannabinoids found in extracts of the plant *Cannabis sativa*, three are known to be psychoactive: Δ9-tetrahydrocannabinol (Δ9-THC), Δ8-THC, and Δ9-tetrahydrocannabidiol. Of these, Δ9-THC is the principal psychoactive component with Δ8-THC and Δ9-tetrahydrocannabidiol being 50–70% and 25% as potent. Cannabis also contains non-psychotropic cannabinoid acids that are decarboxylated to Δ9-THC. Other constituents of the plant include

cannabidiol (CBD) and cannabinol that are nonpsychoactive and do not bind to CB₁ or CB₂ receptors.

The highest concentration of Δ9-THC in the cannabis plant is in the oil obtained from the leaves and flowers, with decreasing amounts found in the stems, roots, and seeds. Marijuana prepared from dried flowers and leaves has Δ9-THC concentrations ranging from 0.5% to 5%. Hashish, a dried sticky resin of the flowers from the female plant, can contain 15–20% Δ9-THC, while chemically extracted hash oil has the highest Δ9-THC content of any marijuana preparation (50–60%).

Cannabis leaves are typically smoked like a cigarette or in a pipe (often a water pipe, or ‘bong’), though it also produces psychotropic effects after oral administration (e.g., prepared in foods or as a tea). Humans very rarely inject cannabis extracts intravenously. Δ9-THC can be detected in plasma within seconds after inhalation of cannabis smoke with 10–40% bioavailability depending on the experience of the smoker. Peak plasma concentrations are reached 3–10 min after inhalation and are typically in the range of 70–160 ng ml⁻¹. Due to its lipophilic nature Δ9-THC and related compounds are rapidly cleared from blood and deposited in fatty tissues, with plasma levels falling <20 ng ml⁻¹ within 30–60 min after smoking. Bioavailability is lower following oral consumption (6–7%), and the rise and fall of plasma Δ9-THC levels are delayed with this route of administration. Δ9-THC accumulates in fatty tissues and accordingly the elimination half-life for Δ9-THC is estimated to be in the range of 20–60 h, with metabolites present for longer times (elimination half-life of 5–6 days). Elimination is faster in heavy long-term users as compared with non-users, though acid metabolites of Δ9-THC can be detected in urine for up to 27 days in long-term users.

Cannabinoid Receptors

Cannabinoid research has experienced major breakthroughs over the last 25 years since the discovery of receptors for Δ9-THC and related cannabinoid substances. The cannabinoid receptor type 1 (CB₁ receptor) was the initial cannabinoid receptor to be characterized. CB₁ receptor distribution was first mapped in rat brain through autoradiographic imaging of the radioligand [³H]CP-55,940 that binds with high affinity to CB₁ sites. Subsequently, the CB₁ receptor was cloned from rat cerebral cortex, then from the human brain and testis, and finally from the mouse brain. Based on this knowledge, antibodies were developed that target the C- or N-terminal regions of the receptor and these were used for immunohistochemical mapping studies. The overall pattern of CB₁ receptor distribution revealed by radioligand binding and immunohistochemistry is remarkably similar.

CB₁ receptors are G-protein-linked and couple to the inhibitory Gi/o class of G proteins. CB₁ receptors are among the most abundant G-protein-coupled receptors in the brain and are mainly localized to axons and nerve terminals and are largely absent from neuronal soma or dendrites. The predominant presynaptic localization is consistent with the CB₁ receptor influence on neurotransmitter release. Functional CB₁ receptors are also found in intracellular vesicles.

In both animals and humans CB₁ receptors are regionally expressed in brain with a pattern consistent with the behavioral effects produced by cannabis. CB₁ receptors are present in very high density in areas involved in motor coordination and function (cerebellum and basal ganglia) with dense expression also in areas involved in learning and memory (hippocampus), emotionality (amygdala), cognitive information processing (cerebral cortex, particularly frontal areas, etc.), reward and motivation (mesolimbic and mesostriatal areas), and food intake (hypothalamus and limbic system). CB₁ receptors in the brainstem and spinal cord may participate in nociception, though the relatively low expression of CB₁ receptors in these regions may account for the low levels of lethality with cannabinoids. The distribution of cannabinoid-activated G proteins (as measured by [³⁵S]GTPγS autoradiography) generally parallels CB₁ receptor-expression density, although evidence suggests receptor density does not necessarily predict receptor signaling efficiency. CB₁ receptor expression has also been detected in astrocytes and oligodendrocytes, and glial cells have been shown to produce and release endogenous cannabinoid compounds.

CB₂ receptors are expressed in the spleen, tonsils, and immune cells (B cells, monocytes, and T cells) indicating a role in immune function. The extent of CB₂ expression in the brain has been controversial as initial studies failed to find appreciable levels of CB₂ receptor expression in the brain tissue. However, CB₂ receptor mRNA expression and immunoreactivity have been shown in glial and neuronal cells in a number of rat brain regions, and CB₂ receptor mRNA and protein has been found in rat, ferret, and mouse brainstem neurons. CB₂ receptors are also expressed in perivascular microglial cells of the human cerebellum. The functional influence of CB₂ receptors in the brain is presently unknown.

Studies on CB₁ and CB₂ receptor knock-out mice suggest there may be several additional cannabinoid receptors. For example, a variety of plant, synthetic, and endogenous cannabinoids bind to and activate the orphan G-protein-coupled receptor 55 (GPR55), which is expressed in the brain and various peripheral tissues in humans and rodents, leading to recent suggestions that GPR55 is a cannabinoid receptor. Endogenous cannabinoids such as anandamide can also produce effects through modulation of ion channels, an example of

which is the transient receptor potential vanilloid type 1 (TRPV1) receptor. However, these ion channels are generally not considered cannabinoid receptors, *per se*.

Endogenous Cannabinoids

In the early 1990s, two derivatives of arachidonic acid were identified and characterized as being endogenous ligands for cannabinoid receptors. These substances are *N*-arachidonylethanolamide (AEA; anandamide) and 2-arachidonoyl glycerol (2-AG). Subsequently, other possible endocannabinoids have been proposed such as noladin ether (arachidonyl glycerol ether), viroldhamine, and *N*-arachidonoyl-dopamine (NADA), although the natural occurrence and functional influence of these other compounds remains unclear. AEA and 2-AG are characterized by different structures, different biosynthetic and degradation pathways, and somewhat distinct pharmacological effects (although similar to Δ9-THC, both AEA and 2-AG exert agonist effects at CB₁ receptors). Endocannabinoids are lipophilic neuromodulators and are not stored in synaptic vesicles, but rather appear to be synthesized primarily on an 'as needed' basis through increased neuronal activity. The pharmacology of these endogenous ligands is similar to Δ9-THC, though clear differences in the behavioral effects of endocannabinoids and synthetic or plant-derived cannabinoids have been documented.

The endogenous cannabinoid system exerts prominent modulatory effects on a variety of behaviors and may be involved in a number of movement disorders, psychiatric disorders, problem eating and obesity, and addictive disorders. Despite the obvious overlap in between plant-derived, synthetic, and endogenous cannabinoid substances the present article concentrates on the behavioral effects produced by Δ9-THC.

Behavioral Effects of Δ9-THC

In view of the widespread presence of cannabinoid receptors and their ligands, it is not surprising that cannabinoid signaling can modify virtually every mode of behavior. Indeed, no single behavioral parameter is specifically influenced by cannabinoids. The effects of cannabis and cannabinoid receptor ligands on behavior and cognition in animals and humans are reviewed below and a summary of these findings can be found in Table 1.

In the early 1990s, Billy Martin and colleagues developed a battery of behavioral tests as an *in vivo* assay for evaluating cannabimimetic effects. Collectively, these procedures were shown to provide a sensitive index of a drug affinity and efficacy at centrally located cannabinoid receptors. The full battery of behavioral tests includes a

Table 1 Similar effects of cannabis/Δ9-THC in rodents and humans

fourfold behavioral evaluation in mice (the 'tetrad'), drug discrimination and catalepsy test in rats, static ataxia tests in dogs, and an evaluation of operant suppression in monkeys. For practical reasons, however, most evaluations use only parts of the battery, and many studies simply employ the mouse tetrad.

The Mouse Tetrad Test

The mouse tetrad consists of four simple evaluations, which may be measured in sequence in the same animal. As discussed below, the four evaluations are of spontaneous motor activity, catalepsy, hypothermia, and analgesia. Δ9-THC and synthetic cannabinoid agonists such as WIN 55,212-2 and CP55,940 produce characteristic disruptions in each of these measures and the effects of each of these ligands are reversed by the CB₁ antagonist Rimonabant (SR141716A), providing good evidence of CB₁-related mechanisms. Endogenous cannabinoids such as AEA and 2-AG induce effects similar to Δ9-THC though some differences have been documented. The most notable difference is that AEA-induced hypothermia, analgesia, and catalepsy are not reversed by SR141716A administration.

The effects of Δ9-THC and related cannabinoids on 'spontaneous activity' (or hypomotility) are determined in an open field. Behavior is typically monitored for a 10-min period, and is performed either by manual observation or by digital scanning.

'Catalepsy' is assessed either through the ring-immobility test or the bar test. The ring-immobility test was developed by Pertwee and colleagues, and measures the amount of time in which the mouse is immobile after placement on a 5.5 cm metal ring fixed 16 cm above a table top. The criterion of immobility is defined as the absence of all voluntary movements, including whisker movement (but excluding respiration). In the bar test, a metal bar is fixed horizontally above a cage floor. The animal's forepaws are placed on the bar and the length of time during which the mouse maintains the initial position is measured.

Hypothermia is typically measured by a telemeter.

The fourth assay in the tetrad is analgesia. Systemically administered Δ9-THC and synthetic cannabinoids have antinociceptive and antihyperalgesic effects in a variety of animal models of acute and inflammatory pain. Δ9-THC produces antinociceptive effects both in phasic (e.g., tail-flick and hot-plate tests) and tonic (e.g., stretching) nociceptive tests. Substantial evidence suggests that the antinociceptive effects of Δ9-THC are mediated, at least in part, through activation of CB₁ receptors which are present in central nervous system (CNS) sites associated with the transmission and processing of nociceptive information (spinal cord, thalamus, periaqueductal gray, rostroventromedial medulla, dorsal-root ganglia, afferent-fiber terminals, etc.). For example, the analgesic effects of Δ9-THC and many synthetic CB₁ agonists are prevented by the CB₁ receptor antagonist SR141716A. In addition, the antinociceptive response to Δ9-THC is largely reduced in CB₁ receptor knock-out mice. However, some studies have found that Δ9-THC continues to exert some antinociceptive actions in CB₁ knock-out mice tested in the hot-plate and formalin tests. This suggests that Δ9-THC-induced analgesia is not mediated exclusively by CB₁ receptors.

There is evidence for an interaction between cannabinoid and opioid mechanisms in analgesia. Δ9-THC and morphine have been found to act synergistically in tests of acute and chronic inflammatory pain, and this synergism can be blocked by either CB₁ (SR141716A) or opioid (naloxone) antagonists. Intrathecal Δ9-THC administration can induce the release of endogenous opioids (most likely dynorphin) that stimulate both δ- and κ-opioid receptors. Moreover, subchronic Δ9-THC administration increases both prodynorphin and proenkephalin gene expression in rat spinal cord, and Δ9-THC-induced analgesia is attenuated in prodynorphin knock-out mice. Interestingly, co-administration of low-dose Δ9-THC has been reported to prevent tolerance to opioid-induced analgesia, suggesting that low-dose Δ9-THC combination therapy may reduce the need to escalate opioid doses for maintenance of analgesia.

Feeding and Appetite

Cannabis is well known to stimulate appetite even in previously sated human subjects, and laboratory studies since the 1970s have demonstrated that Δ9-THC stimulates feeding in a variety of animal models. The hyperphagic effect of Δ9-THC in rats is remarkably potent and can induce overconsumption even in animals that are sated. The effect of cannabinoids appears to be selective for high-fat or sweet-high-fat diets, and in laboratory animals cannabinoid-induced increases in food intake are not observed in animals given only standard rat chow. The orexigenic effects of Δ9-THC and synthetic and endogenous cannabinoids are mediated through CB₁ receptors as demonstrated by the ability of the CB₁ receptor antagonist Rimonabant (SR141716A) to block cannabinoid-induced food consumption. Under certain circumstances, administration of the antagonist itself can reduce appetite and body weight. A commonality among hypotheses of cannabinoid-induced feeding is that CB₁ receptor stimulation increases sensitivity to the sensory properties of foods, thereby increasing the salience or incentive value of food.

Cannabinoid effects on feeding behavior are likely mediated through mechanisms in both the central and peripheral nervous systems. In the CNS, the hypothalamus has long been recognized to play a key role in feeding and weight regulation. Intra-hypothalamic cannabinoid-agonist administration induces eating, and cannabinoid activity in the hypothalamus varies as a function of changes in nutritional status and the expression of feeding behaviors. Further, rodents genetically prone toward obesity (e.g., Zucker rats, ob/ob and db/db mice) are characterized by defective leptin signaling (leptin is an appetite-suppressing hormone) and increased endocannabinoid levels in the hypothalamus, and treatment of normal rodents with leptin decreases hypothalamic endocannabinoid levels. CB₁ receptors are colocalized with appetite-regulating hormones such as cocaine–amphetamine-regulated transcript (CART), melanin-concentrating hormone (MCH), and corticotropin-releasing factor (CRF) in the paraventricular nucleus (PVN) of the hypothalamus. There is also evidence of functional interactions between cannabinoids and the orexigenic peptide orexin A, most likely through interactions between the hypothalamic CB₁ and orexin OX₁ receptors. Elements of the limbic forebrain also play an important role in the motivational effects of food consumption, and the shell subregion of the nucleus accumbens is another highly sensitive site for cannabinoid-induced feeding behavior. Finally, recent evidence suggests an important functional interaction between the endogenous cannabinoid and opioid systems in the modulation of the rewarding properties of food. For example, the hyperphagic effects of Δ9-THC are reversed by the nonselective opioid-receptor antagonist

naloxone. Moreover, behaviorally inactive subthreshold doses of naloxone and Rimonabant produce a profound synergistic anorectic action. CB₁ and opioid receptors are colocalized in a number of regions involved in the regulation of feeding, most notably the PVN of the hypothalamus, and increased feeding induced by intra-PVN morphine administration is reversed by Rimonabant.

Cannabis Intoxication, Reward, and Dependence

In humans, Δ9-THC produces behavioral effects characteristic of both sedative-hypnotic and psychedelic drugs. Subjective accounts of cannabis intoxication in humans vary considerably, depending on the dose of the drug, environment, history of use, and expectations of the user. The high is characterized by enhanced mental associations, a sharpened sense of humor, a distorted sense of time, increased appetite, and a relaxed, calm, dreamlike state. Users typically note anxiolytic effects of marijuana, although increased anxiety is not uncommon. Psychedelic-like perceptual effects are sometimes noted following high-dose administration, along with decreased motivation and impaired cognitive functioning. This collection of acute behavioral effects produces a complex state most often characterized as euphoric, and this is believed to be a primary motivating factor for repeated drug use. Evidence for positive reinforcing effects of Δ9-THC in laboratory animals has been produced using a variety of behavioral paradigms including drug discrimination, brain-stimulation reward, conditioned place preference, and intravenous self-administration.

Discriminative stimulus effects

Drug discrimination procedures in animals evaluate drug-induced interoceptive stimulus conditions (or subjective effects) perceived by the subject in the context of interoceptive stimulus effects produced by other drugs in similar or different drug classes. Animals are typically trained to lever press for food reinforcement using a two-lever operant chamber. During training, food reinforcements are obtained by responding at one of the levers in sessions following drug administration, while reinforcers are earned by responding at the other lever in sessions following vehicle administration. In subsequent tests, the animals receive either the training drug at a different dose or a different drug, and lever selection is monitored as an index of whether the pretreatment produces a discriminative stimulus effect similar to the training drug.

Cannabinoid drugs show a pharmacological specificity in the drug-discrimination procedure. Only drugs that activate CB₁ receptors fully generalize to the THC-training stimulus in animals trained to discriminate Δ9-THC from saline. Similarly, training-drug-appropriate responding is produced

by Δ9-THC administration in animals trained to discriminate synthetic CB₁ agonists (such as WIN 55,212-2 and CP 55,940) from saline. The discriminative stimulus effects of Δ9-THC and synthetic CB₁ agonists can be competitively blocked by pretreatment with the CB₁ receptor antagonist SR141716A (Rimonabant), further demonstrating that cannabinoid discrimination is mediated by CB₁ receptors. No cross-generalization has been observed with a wide variety of drugs from different classes including opioids, psychostimulants, psychedelics, antipsychotics, and anticonvulsants. Partial generalization to Δ9-THC has been observed with diazepam, phencyclidine (PCP), and methylenedioxymethamphetamine (MDMA). However, the partial generalization of diazepam to Δ9-THC is not blocked by SR141716A and from this it was suggested that the generalization is mediated by non-CB₁ modulation of γ-aminobutyric acid (GABA-ergic) signaling. In general, the observations made in the drug-discrimination paradigm indicate that the interoceptive effects of Δ9-THC are mediated through CB₁ receptor activation.

Brain-stimulation reward

In 1954, Olds and Milner reported that rats will repeatedly lever-press to receive an electrical stimulation of the medial forebrain bundle, which is a component of the brain reward circuit. Subsequent work has shown that the sensitivity to brain stimulation (as indexed by the threshold level of stimulation frequency or current delivery that produces positive reinforcing effects) can be used to evaluate the function of the reward circuit. For example, most major drugs of abuse dose-dependently decrease the threshold for brain-stimulation reward (e.g., enhance the function of the reward circuit). A limited number of studies have evaluated cannabinoid-induced alterations in brain-stimulation-reward thresholds, and the results have not been entirely consistent. Low Δ9-THC doses (1–1.5 mg kg⁻¹) decrease brain-stimulation-reward thresholds in Sprague Dawley (SD) and Lewis rats, though this effect is not observed in Fisher rats. Moreover, in Lewis rats the synthetic CB₁ receptor agonist CP 55,940 does not alter stimulation-reward thresholds at doses comparable to Δ9-THC doses that reduce thresholds. Interestingly, brain-stimulation-reward thresholds are elevated during withdrawal from a single Δ9-THC administration suggesting a withdrawal-associated deficit in the function of the reward circuit.

Conditioned place preference

The conditioned place-preference paradigm is a classical conditioning procedure that evaluates drug-related reward/aversion effects. In the conditioning procedure, animals are confined to a distinct environment following drug administration or are confined to an adjacent compartment that differs in color, size, or texture following vehicle administration. Conditioning is produced through a number of treatment/environment-pairing sessions. On

the final test day, no injections are administered and the animal is allowed to freely explore both compartments. The relative time spent in the drug-paired versus saline-paired compartments is used as an index of the rewarding or aversive effects of the drug treatment.

Most drugs abused by humans increase the time spent in the drug-paired environment (i.e., produce a place preference) in a manner dependent on drug dose and the postadministration environmental conditioning period. Δ9-THC produces both place preference and place aversion in rats and mice, depending on the dose and experience of the animals. Place aversions are more commonly reported, and have been observed with acute administration of moderate to high Δ9-THC doses. Similar profiles have been observed with synthetic cannabinoid agonists such as CP 55,940, WIN 55,212-2, and HU 210. In general, place preferences are observed following low-dose Δ9-THC administration or following pre-exposure to the drug prior to environmental conditioning. Interestingly, two studies demonstrate that the CB₁ receptor antagonist SR141716A (Rimonabant) produces place preference, though an equal number of reports have found that this compound induces no significant place preference or aversion.

Self-administration

Nearly every drug that is abused by humans also maintains operant self-administration behavior by nonhuman subjects under controlled laboratory conditions. This has been repeatedly demonstrated for psychostimulants, opioids, nicotine, ethanol, and other abused substances. However, cannabinoids have long been considered an exception to the correspondence between drugs abused by humans and those that maintain operant self-administration in animals. Several different research groups have made unsuccessful attempts to demonstrate reliable, persistent, dose-related, and drug-specific self-administration of Δ9-THC or synthetic cannabinoid agonists by laboratory animals. Although early studies reported intravenous Δ9-THC self-administration by food-restricted rats, drug intake decreased to placebo levels when the food restriction was discontinued. Several reports have demonstrated the self-administration of synthetic CB₁ agonists such as WIN 55,212-2, CP 55,940, and HU-210 both in rats and mice, although in some cases chronic diet restriction was shown to be a necessary condition for these effects. Moreover, most of these rodent studies did not evaluate the persistent maintenance of drug-taking behavior over time.

Several studies from the Goldberg laboratory have demonstrated long-term stable operant Δ9-THC self-administration by squirrel monkeys that were not diet restricted. Initial experiments were performed in monkeys with a prior history of cocaine self-administration, though subsequent work demonstrated the initiation and

maintenance of intravenous Δ9-THC self-administration behavior in experimentally naive monkeys. Clinically relevant Δ9-THC doses were employed in these studies, and steps were taken to ensure complete solubilization of the drug in the self-administered solution. This is of import as early animal studies employed relatively high drug doses that were not fully solubilized in the self-administered solution. These drug suspensions were of low concentration and thus required large injection volumes delivered at slow infusion speeds, conditions that have been shown to adversely affect the reinforcing effects of a drug by intravenous administration.

Other factors may also underlie the difficulty in establishing operant cannabinoid self-administration in laboratory animals. It is well established that response-reward associations necessary for operant drug-taking behavior are facilitated by a rapid onset and dissipation of the drug's pharmacological effects. However, Δ9-THC and other cannabinoid agonists produce prolonged pharmacological and behavioral effects whose onset is delayed from initial administration, and this may preclude the necessary association between the operant task required for drug infusion and the resultant psychoactive effects of the drug. In addition, the apparent aversive effects of cannabinoids (as demonstrated in place-conditioning paradigms) and motor-depressant effects of these drugs may also confound the acquisition and maintenance of operant self-administration.

During the past 30 years, a substantial number of clinical studies have evaluated Δ9-THC self-administration by humans. When given a choice, experienced marijuana smokers prefer marijuana cigarettes with greater Δ9-THC content over those with lesser Δ9-THC content. Moreover, several (but not all) studies have provided evidence that experienced marijuana users titrate their smoking behavior according to the Δ9-THC content, and a Δ9-THC concentration-effect in the subjective ratings of intoxication has been shown in several studies.

Mechanisms for the rewarding effects of cannabinoids

The neuronal circuits known to be involved in mediating the rewarding aspects of most abused drugs originate with a subgroup of dopamine (DA) neurons located in the ventral tegmental area (VTA). These DA neurons possess axons that target GABAergic medium spiny neurons located in the nucleus accumbens (NAcc) that send reward-relevant information to the ventral pallidum (VP), back to the VTA and to other structures. The VTA, NAcc, and VP are interconnected via reciprocal axon collaterals that are critical for the performance of reward-relevant behaviors. These brain reward nuclei also receive glutamatergic and GABAergic inputs,

whose functional integrity is necessary to observe drug-related reward behavior.

Δ9-THC and several synthetic CB₁ receptor agonists increase the firing rate and burst activity of DA cell bodies in the VTA, likely through a CB₁ receptor-dependent inhibition of GABA release in the VTA (thereby diminishing inhibitory control over DA cell firing) and this is thought to contribute to the rewarding effects of Δ9-THC and other cannabinoid agonists. Increased NAcc DA levels are also believed to partially mediate the rewarding effects of several other classes of abused drugs.

It has become apparent that many abused drugs, including cannabinoids, also exert reward-relevant neurochemical effects that are not reliant on dopaminergic neurotransmission. For example, the CB₁ agonist WIN55,212-2 reduces GABA release onto NAcc medium spiny neurons, resulting in the disinhibition of GABAergic output to the VTA, VP, and other target structures. However, cannabinoids also inhibit glutamate release onto NAcc medium spiny neurons, which likely results in reduced activation of these GABAergic output neurons. The relative contribution of the CB₁ receptor modulation of GABAergic and glutamatergic synaptic transmission to the output of the NAcc is presently poorly understood and likely relies on the behavioral circumstances under which each system predominates.

Dependence and withdrawal

For many years, cannabis was not considered to be an addictive drug. This was based on difficulty in establishing cannabinoid self-administration by laboratory animals and the fact that abstinence from cannabis use was not associated with obvious physical withdrawal symptoms either in humans or animals. However, views on this subject have changed dramatically in recent years and it is now accepted that cannabis dependence is a clinically observable phenomenon, and that a substantial percentage of users meet the *Diagnostic and Statistical Manual*, Version-IV (DSM-IV) criteria for substance abuse and substance dependence. Marijuana appears to produce dependence less readily than most other illicit drugs and recent studies indicate that 9% of those who try marijuana eventually develop dependence on the drug, as compared with 15% of people who try cocaine and 24% of those who try heroin. Because cannabis use is much more common than the use of other illegal drugs, cannabis dependence is estimated to be twice as prevalent as is cocaine or heroin dependence.

Recent studies in humans have shown that a reliable and clinically significant withdrawal syndrome occurs in cannabis users during drug abstinence. Withdrawal symptoms are observed in a substantial percentage of heavy users (16%) and include craving for cannabis, decreased appetite, weight loss, sleep disturbances, restlessness, irritability, anxiety, anger, and aggression. The onset of

these symptoms typically occurs within 1–3 days of drug abstinence, with peak effects observed at 2–6 days' abstinence with most symptoms abating after 2 weeks of abstinence. However, some clinicians suggest that a protracted withdrawal period exists for up to 18 months that is characterized by intermittent cognitive deficits and sleep disturbances.

Cannabinoid withdrawal has also been characterized in rats and mice. In these studies, a withdrawal state is typically precipitated by the administration of a CB₁ receptor antagonist, which induces a behavioral syndrome that includes wet-dog shakes, scratching, face rubbing, arched back, ptosis, ataxia, and hunched posture. This withdrawal syndrome has been observed following repeated administration of not only Δ9-THC, but also synthetic CB₁ receptor agonists such as WIN 55,212-2 and CP 55,940. Although mild somatic withdrawal symptoms have been observed during abstinence from WIN 55,212-2, spontaneous somatic signs of withdrawal have not been observed during Δ9-THC abstinence. However, some motivational indications of Δ9-THC withdrawal have been reported such as elevations in brain-stimulation-reward thresholds.

Cognitive Function

Long-standing clinical evidence suggests that cannabis use can compromise cognitive or 'executive' functions. Executive functioning comprises cognitive processes such as attention, behavioral flexibility, decision making, inhibitory control, planning, time estimation, and working memory. High levels of CB₁ receptor expression are found in the human cerebral cortex, hippocampus, and basal ganglia. Heavy cannabis use by humans is associated with abnormal frontal cortical function and neurocognitive deficits including impairments in attention, inhibitory control, certain forms of impulsive behavior, decision making, and/or cognitive flexibility that are thought to be associated with altered prefrontal cortical function. Neuroimaging studies have found cannabis-induced alterations in the function of prefrontal (orbitofrontal) cortex, hippocampus, and components of the basal ganglia, and it has been proposed that neural dysfunction in these regions contributes to a loss of inhibitory control that propels continued cannabis use.

Attention

It has long been recognized that acute challenge or prolonged cannabis use impairs attentional processing in humans. Although there have not been many examinations of this issue using laboratory animals, a few recent preclinical studies are consistent with these long-standing observations in humans. For example, chronic intermittent treatment of laboratory rats with Δ9-THC impairs visuospatial attention in a lateralized-reaction-time task

and similar effects have been observed in this task following acute challenges with the CB₁ receptor agonist WIN 55,212-2. Effects of cannabinoids on attentional capacity have also been evaluated using the 5-choice serial-reaction-time task (5-CSRTT), which is a procedure that requires subjects to scan a horizontal array of five spatial apertures for the location of a very brief visual target stimulus. Animals are tested in a large number of discrete trials, thereby taxing attentional capacity. Decreased accuracy in the 5-CSRTT has been observed following a 2-week period of high-dose Δ9-THC administration, though performance on this task was not altered following acute administration of the synthetic CB₁ agonist WIN 55,212-2. The difficulty of the 5-CSRTT can be varied by altering the brightness, duration, or frequency of the target visual stimulus; the stimuli can be made temporally and spatially unpredictable (similar to a nonpaced version of the continuous-performance task); and distracting stimuli (e.g., bursts of white noise) can be introduced. These manipulations can increase the sensitivity of this task for detecting attentional deficits and this may be a useful approach for future work characterizing the effects of repeated Δ9-THC administration on attentional capacity.

Inhibitory control

Impulsivity and compulsive stereotyped behavior have emerged as potentially major contributing factors in drug dependence. Heavy cannabis use by humans is associated with abnormal frontal cortical function and certain forms of impulsive behavior thought to be associated with altered prefrontal cortical function. Acute challenges with Δ9-THC and marijuana have been shown to increase impulsive responding in the stop-signal task (e.g., impaired ability to inhibit ongoing behavior) and heavy cannabis users have been found to have specific deficits in the ability to balance rewards and punishments, as evidenced by their preference for immediate rewards despite the incurrence of costly losses in a gambling task. From these observations, it has been argued that cannabis users may choose immediate gratification in the form of continued drug use without careful consideration of negative consequences, thereby perpetuating abuse and dependence. In rodent tests, acute administration of the CB₁ agonist WIN 55,212-2 mildly impairs response inhibition in the stop-signal task although alterations in performance of the delayed-discounting task have not been observed following acute WIN 55,212-2 administration.

Time estimation

In humans, marijuana or Δ9-THC use reportedly makes time appear to pass more slowly. In laboratory tests, subjects typically overestimate the amount of elapsed time, or produce shorter-than-appropriate intervals when asked to signal a period of elapsed time. In laboratory animals, Δ9-THC and WIN 55,212-2 shortens the

response interval in rats trained to respond for food reward using a fixed-interval schedule and similar underestimations of time passage are observed in the time-discrimination and time-estimation procedures.

Working memory

It is well established in humans that acute and chronic intoxication with cannabis produces an impairment of short-term memory, particularly as assessed in tests that depend heavily on attention. Animal studies have also found that Δ9-THC and synthetic cannabinoids induce deficits in short-term memory as determined in delayed-matching and -nonmatching tests, and radial arm maze performance. It is likely that these effects are produced through cannabinoid-induced alterations in hippocampal function. CB₁ receptors are expressed in high densities in the hippocampus, and are positioned in a manner that allows a potent influence both on GABA and glutamate release in hippocampal circuits. Memory formation is thought to involve the processes of long-term potentiation (LTP) and long-term depression (LTD) at glutamatergic synapses in the hippocampus. Cannabinoids appear to inhibit the induction of both LTP and LTD by reducing glutamate release to below the level needed to activate N-methyl-D-aspartic acid (NMDA) receptors (a requirement for LTP and LTD). The CB₁ modulation of the function of hippocampal GABAergic interneurons may be to control oscillatory electrical activity at frequencies important for synchronizing pyramidal cell activity.

Behavioral flexibility

Adaptive behavior (e.g., flexibility) relies heavily on the ability to modify behavior in response to transient changes in the predictive relevance of environmental stimuli. This ability – variously termed strategy-shifting, behavioral flexibility, and attentional set-shifting – requires both the learning of new stimulus-response relationships and the suppression of responses that have been appropriate previously but are no longer so. In humans, set-shifting ability is commonly measured with the Wisconsin Card Sorting Task (WCST). Tests of this nature have revealed that set-shifting ability is impaired in certain disease states, such as schizophrenia, and in individuals with frontal lobe damage providing evidence of deficits in cognitive flexibility which limits behaviors in these individuals to constrained, inflexible repertoires. In a similar manner, heavy cannabis use by humans is associated with decreased mental flexibility, increased perseveration, and a reduced ability to shift attention. In a laboratory task requiring subjects to alternate between two response options in order to maximize monetary gains, marijuana dose-dependently impaired the ability to switch behavioral responses, thus resulting in loss of monetary gains. Deficits in the performance of the WCST have also been observed in adults and adolescents who are

heavy cannabis users. Few studies have evaluated the effects of cannabinoids on behavioral flexibility in rodents, and the literature in this regard is inconsistent. Acute Δ9-THC has been found to impair intradimensional, but not extradimensional, learning in rats. In contrast, the synthetic CB₁ agonist HU-210 reportedly impairs extradimensional learning and the CB₁ antagonist SR141716A improves extradimensional learning. The onset of cognitive deficits as a function of the amount and duration of cannabis use has not been characterized and it is not known how long deficits persist following cessation of cannabis use. In addition, it is not known whether the deleterious effects of cannabis are more or less pronounced in adolescent or adult users.

Neural mechanisms for the cognitive effects of cannabinoids

Although the neurochemical mechanisms through which cannabis affects cognitive function have not been fully characterized, some insight into the neural processes underlying this effect of cannabis use can be gleaned from the distribution of brain CB₁ receptors and human neuroimaging studies. High levels of CB₁ receptor expression are found in the human cerebral cortex, hippocampus, and basal ganglia. Heavy cannabis use by humans is associated with abnormal frontal cortical function and neurocognitive deficits, including impairments in attention, inhibitory control, certain forms of impulsive behavior, decision making, and/or cognitive flexibility that are thought to be associated with altered prefrontal cortical function. Neuroimaging studies have also revealed cannabis-induced alterations in the function of prefrontal (orbitofrontal) cortex, hippocampus, and components of the basal ganglia, and it has been proposed that neural dysfunction in these regions contributes to a loss of inhibitory control that propels continued cannabis use.

As reviewed above, cannabinoids have clear, though generally mild, effects on a variety of cognitive functions. However, it has been less clear whether more severe deficits in cognitive function develop over the course of years of heavy cannabis use by humans, or in animals treated for prolonged periods of time with the drug. Some studies in long-term very heavy cannabis users (10–20 joints per day for more than 10 years) failed to show any significant difference between users versus nonusers using a battery of tests of cognitive function. Several other reports have shown deficits in the performance of complex cognitive tasks in long-term cannabis users, although the available evidence does not suggest that these deficits are more severe than those observed after initial drug use. Thus, there is presently little evidence suggesting a sensitization of the cognitive impairing effects of Δ9-THC with long-term continuous cannabis use. It is likely that neural adaptations develop in response to long-term frequent cannabis use, such as a

downregulation of cannabinoid receptor expression or function. These adaptations may serve to maintain relatively normal function in the presence of relatively high Δ9-THC levels maintained during ongoing cannabis use. It is possible such neural adaptations contribute to cognitive impairments when brain Δ9-THC levels decline during cannabis abstinence. However, cognitive function during acute or prolonged abstinence from cannabis use has not been well characterized in either human or animal studies. Finally, few studies in humans have sought to determine whether abnormalities in cognitive function observed in long-term marijuana smokers result from long-term cannabis exposure or were preexisting factors that may have contributed to drug use.

Psychiatric and Cognitive Disorders

Schizophrenia and psychosis

Following the ingestion of large doses of cannabis (typically in food or drink), a form of drug-induced psychosis can occur. This condition is characterized by delusions of being controlled by an outside force, grandiose identity, persecution, thought insertion, auditory hallucinations, altered perceptions, and emotional blunting. Because of the overlap between these symptoms and those present in paranoid schizophrenia, this has led to the suggestion that cannabis use can precipitate schizophrenia. Many studies have evaluated a potential relationship between cannabis use and psychosis. For example, in a prospective study of nearly 2500 German individuals in the age range of 14–24 years, it was found that cannabis use at baseline testing was associated with an increased incidence of psychotic symptoms at follow-up. A 14-year study in a similarly aged Dutch population concluded that cannabis use predicts future psychotic symptoms in individuals who did not have such symptoms before they began using cannabis. Probably the strongest evidence for a linkage comes from a Swedish study in which detailed records obtained on entry into the Swedish army were used for following up on subsequent medical history over a 15-year period. In this study, the relative risk of schizophrenia in those who had used cannabis was 2.4 times greater than in the nonusers, while in 'heavy users' (more than 50 episodes of cannabis use) the relative risk increased to 6.0. While these and related results provide support for a linkage between cannabis use and schizophrenia, a causal relationship between cannabis use and long-term psychotic illness remains unproven.

Depression and anxiety

Most studies evaluating the effects of cannabis use on psychiatric conditions have focused on psychosis, and far fewer have investigated a potential link with more common affective disorders such as bipolar disorder (BD), depression, and anxiety. However, various studies

have shown that a range of pathological conditions – including depressive, bipolar, and anxiety disorders – and the degree of their comorbidity are significantly associated with cannabis use and the progression to cannabis-use disorder.

Longitudinal studies suggest a modest association between early-onset regular or problematic cannabis use and later BD or depression. For example, a recent evaluation of nearly 5000 subjects found that cannabis use at the initial evaluation was significantly correlated with the incidence of manic symptoms during follow-up evaluations over the course of 3 years. This association between cannabis use and mania was independent of the incidence of psychotic symptoms, and manic symptoms at baseline did not predict the onset of cannabis use during follow-up. Similar studies have reported that rates of major depressive disorder are increased in individuals seeking treatment for cannabis dependence and that heavy cannabis use is associated with two- to fourfold greater likelihood of depressive symptoms and suicidal ideation as compared with individuals who do not use cannabis. A number of studies have found a modest association between early-onset regular cannabis use and later depression. Of the studies that examined a linear trend across cannabis-use frequencies, four have reported a consistency in the ‘dose–response’ effect of cannabis use and depression outcomes and one report observed that lifetime DSM, Version III, revised (DSM-III-R) cannabis dependence was associated with a 3.4 times increased risk of major depression. Further, in monozygotic twin studies, a cannabis-dependent twin was found to be more likely to have major depression disorder, suicidal ideation, and attempted suicide than is their non-cannabis-dependent co-twin. At least two hypotheses have been forwarded to explain the possible association between cannabis use and depression. For example, long-term heavy cannabis use may induce neuroadaptations in neurotransmitter signaling that results in an increased likelihood of depressive symptoms. Alternately, evidence suggests that regular and early-onset cannabis use is associated with social difficulties that are themselves risk factors for the development of depression (e.g., reduced educational success, increased unemployment, and crime).

It has long been recognized that acute cannabinoid administration can produce biphasic and bidirectional effects on affective state, depending on the mode of administration, dose, tolerance, and a variety of environmental and individual factors. Thus, under certain circumstances, cannabis can exert anxiolytic, antidepressant, and hypnotic effects while, at higher doses, it can produce dysphoric reactions, anxiety, panic, paranoia, and psychosis. Similar biphasic effects of natural and synthetic cannabinoid agonists on anxiety-like behaviors have been reported in rats and mice. Increased anxiety has been

observed in most, but not all, prospective studies of cannabis use in healthy volunteers, and cannabis use is associated with increased anxiety in young adults independent of the use of additional illicit drugs.

CB_1 receptors are expressed in high density in the amygdala, hippocampus, anterior cingulate cortex, and prefrontal cortex that are key regions in the regulation of anxiety. The mechanisms contributing to the dose-related differences in cannabinoid-induced anxiety-like behavior have not been characterized. It is possible that varied behavioral effects are produced by the activation of CB_1 receptors versus novel non- CB_1 cannabinoid-sensitive receptors, or that there is a region-specific difference in CB_1 receptor sensitivity or coupling to G_s and G_i proteins. In this regard, it is interesting that one of the constituents in cannabis –CBD – possesses anxiolytic and potentially anti-psychotic properties that are not mediated through CB_1 receptors. Moreover, the anxiolytic effects of CBD are not biphasic or bidirectional even at high doses.

Transition to Addiction

Glossary

Intravenous self-administration – An operant behavior measured in experimental animals. A behavioral response, a nose-poke or a lever press, is followed by a drug injection (the reinforcer) through a chronic indwelling catheter. Maintained self-administration has been reported for most of the drugs that humans abuse.

Progressive ratio schedule – A schedule whose goal is to measure the efficacy of a reinforcer to maintain an operant behavior. It is a measure of the strength of the operant behavior. It is also commonly interpreted as a measure of the motivation of the subject for the reinforcer. In the case of self-administration, the method consists in increasing response requirement (fixed ratio) after each drug injection. The maximum fixed ratio (FR) a subject will complete to receive a drug injection is called the break point and is the variable that is classically used to estimate the subject's motivation for the drug.

Reinforcing effect – In the context of operant behavior, a reinforcer is a consequence that causes a behavior to occur with greater frequency. A positive reinforcing effect occurs when a behavior (response) is followed by a favorable stimulus (positive reinforcer) that increases the frequency of that behavior. Negative reinforcing effect occurs when a behavior (response) is followed by the removal of an aversive stimulus (negative reinforcer) thereby increasing that behavior's frequency.

The DSM-IV describes five possible behavioral alterations characterizing loss of control (**Table 1**) that can be grouped into three main categories: (1) a difficulty to limit drug use and drug seeking (items 3 and 4), (2) an apparent strong motivation for the drug (items 5 and 6), and (3) maintenance of drug use despite consciousness of negative consequences. In conclusion, while in the DSM-III transition to addiction was considered as the appearance of changes in drug effects (tolerance and withdrawal), in the DSM-IV, it is characterized by changes in the modality of drug taking (loss of control over drug intake).

It took over 10 years for the scientific community to integrate and adopt this drastic conceptual change in the clinical vision of addiction. Today, drug addiction or dependence is consensually defined as a chronic relapsing disorder characterized by compulsive drug use. Drug addiction is, indeed, an absence of control over drug taking and drug seeking, which is associated with a high probability to relapse even after prolonged periods of withdrawal. Transition to addiction consequently corresponds to the shift from controlled, nonpathological drug use to compulsive drug intake.

Two Theoretical Frameworks for Explaining Addiction

The voluntary intake of drugs of abuse is a behavior largely conserved throughout phylogeny. Thus, the preference for drug-associated environments or learning of tasks reinforced by drugs has been found in several species, including worms, honeybees, rodents, and nonhuman primates. Voluntary intake of drugs has been studied in animals since 1962, thanks to the development of the intravenous self-administration model.

Based on this model in animals and on clinical observations in humans, two main theoretical frameworks have been proposed to explain the transition to addiction: the drug-centered and the individual-centered theories. These two theories have been grounded, respectively, on two commonly admitted clinical observations. First, transition to addiction occurs only after prolonged drug use. Second, addiction is observed only in a limited number of drug users.

Drug-centered theories of addiction are the most followed by experimental researchers. They have guided research and therapy design over the past 40 years. According to these theories, transition to addiction results from the psychopharmacological changes in drug effects

Introduction

Definition and Characteristics of Addiction

The clinical definition of drug addiction (or drug dependence) considerably evolved from the early 1980s to the mid-1990s as testified by profound revisions of the reference manual of psychiatry, the *Diagnostic and Statistical Manual of Mental Disorders* (see **Table 1**). In the DSM-III in 1980, addiction was defined as tolerance to the drug and/or withdrawal symptoms when drug use was stopped. By contrast, with the DSM-IV in 1994, tolerance and withdrawal can be present but are no longer necessary criteria. In the DSM-IV, behavioral symptoms related to an absence of control over drug taking and drug seeking must be present in order to make a diagnosis of addiction.

Table 1 Evolution of diagnostic criteria for drug addiction

<i>DSM III diagnosis for drug addiction (1980)</i>	<i>DSM IV diagnosis for drug addiction (1994)</i>	<i>Main symptoms (DSM IV 1994)</i>
<i>At least one of these two criteria</i>	<i>Three out of these seven criteria</i>	
1. Tolerance	1. Tolerance	Alterations in drug effects (no longer exclusive)
2. Withdrawal	2. Withdrawal	
	3. Substance is used more or for longer periods than intended	1. Difficulty to limit drug use and drug seeking
	4. Persistent desire to or unsuccessful efforts to cut down	
	5. Considerable time spent in obtaining the substance or using, or recovering from its effects	Behavioral symptoms: absence of control over drug use and drug seeking
	6. Important social, work, or recreational activities given up because of use	2. An apparent strong motivation for the drug
	7. Continued use despite knowledge of problems caused by or aggravated by use	3. Continued use despite knowledge of problems caused by or aggravated by use

that result from chronic drug use, such as tolerance, sensitization, conditioning, and withdrawal. These visions of addiction have been reinforced by behavioral observations showing that the longer the exposure to a drug, the greater the amount of drugs taken by animals. The discovery of very significant neurobiological alterations at molecular, cellular, synaptic, or network levels following chronic drug intake have also strengthened these theories.

The individual-centered theory posited 20 years ago has received less attention. This theory was initially based on the clinical observation that transition to addiction only occurs in 15–35% of drug users. According to this theory, transition to addiction results from a pathological response to the drug, which, in turn, depends on the biological phenotype of the drug user. Several experimental observations have strengthened the hypothesis of the existence of a drug-vulnerable phenotype. Indeed, in rodents, large differences in vulnerability to developing drug use have been observed between individuals of outbred rodent strains as well as by comparing different inbred mice strains.

Since individual vulnerability to developing drug intake is observed in both humans and animals, an interesting question is how drug-centered theories have been and still are the leading theories of addiction. This has been achieved by a series of criticisms and alternative

explanations of the individual differences observed in humans and in animals. Concerning human studies, it has often been hypothesized that individual risk in vulnerability to addiction is underpinned by contingent factors, such as drug availability or peer pressure, irrespective of a particular biologically drug-vulnerable phenotype. In other words, some individuals have a greater risk of developing addiction simply because they are more likely to be exposed to the drug. Concerning individual differences observed in animals, it has also been proposed that they are due to uncontrolled contingent factors such as experimental error and/or to specific experimental conditions, such as very low doses of accessible drug. For this reason, it has been proposed that individual differences are irrelevant in real-world conditions, where drug doses can be freely titrated by the individual. This idea has also been reinforced by statements from leading figures in the field that even in animal studies using the right experimental conditions, for example, high unitary doses of drugs, individual differences do not exist.

Research in animals during the past 20 years has finally set all these criticisms to rest and demonstrated that individual vulnerability to drugs does exist and is due to an underlying biological phenotype that increases the reinforcing effects of drugs in certain individuals. First,

individual differences are not due to uncontrolled experimental contingencies. In fact, they can be predicted by relevant drug-independent behaviors, such as behavioral response to stress and anxiety- and impulsivity-related behaviors. Second, individual differences in drug use also exist when animals have exactly the same access to drugs and are maintained over the entire range of doses that can be explored in animals. Importantly, dose-response studies have shown that individual differences in drug intake are due to differences in drug efficacy and not to differences in drug sensitivity. Differences in sensitivity could be irrelevant in the real world owing to the absence of limitation in drug dose. In contrast, differences in efficacy might also predict a higher vulnerability in the real-world conditions since they imply that, whatever be the dose, some individuals will take a larger quantity of drugs and will be more prone to drug use. Finally, research on the biological substrates of these differences has now revealed some of the biological alterations determining the higher vulnerability to take drugs in certain individuals, and that this biological predisposition can be genetically determined or stress induced.

In conclusion, we now know that certain individuals are more prone to develop and maintain intake of large amounts of drugs because of specific biological phenotypes. It is also refreshing to observe that leading groups in the field, which have denied the relevance of individual differences and discarded them as irrelevant or not existing, have started finding them and studying them.

Experimental Models of Transition to Addiction

Most preclinical research has tended and still tends to assimilate increased drug use to drug addiction. However, as first argued by Andrea Heyne and Jochen Wolffgramm in the early 1990s and as clearly described in the DSM, taking drugs is not the landmark of the clinical diagnosis of addiction. Indeed, for clinicians, even an increased or escalating drug use does not prove addiction. The drug user has to express specific behavioral deficits attesting loss of control over drug use, such as maintenance of drug intake despite negative consequences.

For these reasons, one of the major challenges of addiction research in recent years has been to develop models for studying not only changes in drug intake but also the transition between controlled and compulsive drug use.

To model human addiction, a reasonable approach seems to adequately model symptoms of addiction, evaluate these symptoms repeatedly over an extended period of drug use, and consider results at the individual level so as not to discard potential individual differences. In other words, building a model that has true face validity with

the clinical reality and that consequently targets the drug-directed behaviors considered as addiction in humans. Over the past 10 years, a few teams have investigated addiction-like behaviors in rodents. Our research group developed a multisymptomatic model for investigating the transition to addiction, taking the abovementioned constraints into account. Four monosymptomatic models were also developed considering specific addiction-like behaviors. Both types of models are discussed below.

The Multisymptomatic Model

Intravenous cocaine self-administration was used as a model of drug use. Adult male 10-week-old Sprague-Dawley rats were used as subjects. The choice of an outbred strain was deliberate to mimic the human situation and to assess potential individual differences. The rats are allowed to self-administer cocaine intravenously at a relatively high dose (0.8 mg kg^{-1} per infusion) for 2 h on a daily basis.

Assessing addiction-like symptoms and transition to addiction

It clearly appears from the clinical definition that behavioral differences between drug users and addicts might be best revealed in challenging conditions; to obtain drugs, addicts are willing to overcome barriers that users are not prepared to overcome. Therefore, besides the daily training protocol of cocaine self-administration, rats are episodically challenged to assess addiction. Cocaine use severity is assessed by using three behaviors resembling one or more of the seven DSM-IV criteria for addiction: (1) high motivation for the drug, measured by a progressive ratio schedule of reinforcement; (2) inability to refrain from drug seeking even if the drug is not available, measured by active responding during periods of signaled drug nonavailability; and (3) drug use despite negative consequences, measured by resistance to footshock-induced punishment during cocaine self-administration.

To detect an eventual transition from controlled use to addiction, the rats are trained for intravenous cocaine self-administration over a much longer period of time (over 80 sessions) than that classically used in the monosymptomatic models (no more than 40 days). After early, intermediate, and late training (20, 40, and 70 sessions), cocaine addiction severity is evaluated by testing the rats for the three addiction-like symptoms.

Performing an individual diagnosis

In humans, the diagnosis of addiction is performed by counting the number of DSM diagnostic criteria met by a drug user; a positive diagnosis is made when at least three out of the seven criteria are present. Addicts can also be assigned a score on a scale of severity (addiction

severity scale or ASI), which depends on the number of diagnostic criteria met by the patient, comorbidities, and addiction-induced social impairments. To take into account the possible individual dimension of addiction, we used a qualitative DSM-like diagnosis and a quantitative ASI-like diagnosis as in humans.

For the qualitative diagnosis, animals are ranked for each addiction-like behavior independently. When a rat has a score in the 35th highest percentile of the population, it is considered positive for this addiction-like criterion. This allows us to separate our sample of rats into four groups according to the number of positive criteria met (zero to three) and to identify two very different subpopulations, 0crit and 3crit rats, which model nonaddicts and addict drug users, respectively. The 1crit and 2crit rats could either represent specific stable cocaine-use-related troubles or intermediate steps toward addiction.

For the quantitative diagnosis, the three scores are computed into an addiction score for each rat after normalization. This score quantifies cocaine addiction severity and can be useful to establish potential correlations with neurobiological or other behavioral variables.

Transition to addiction depends on individuals, not on drug intake

After short or intermediate exposure to cocaine (up to 40 days), qualitative diagnosis of addiction did not make it possible to identify addicted (3crit) rats. After prolonged cocaine use, however, transition to addiction occurred in some rats. Indeed, after late training, some rats were positive for the three addiction-like criteria, while their behavior after early training was similar to that of the other rats and, in particular, to that of nonaddicted (0crit) rats. Furthermore, like human addicts, 3crit rats had a high propensity to relapse even after a long period of withdrawal. Finally, the percentage of 3crit animals (17%) was very similar to the percentage (15–20%) of human cocaine users diagnosed as addicts. Strikingly, these individual differences were not dependent on the amount of drug intake, since animals that did or did not develop addiction-like behavior had an identical intake of cocaine during the baseline training protocol. However, when having extended access to the drug (5 h in a row), the drug intake of addicted rats rapidly became higher than that of nonaddicted (0crit) rats, further showing the difficulty of these individuals to limit their drug use.

Similar results were obtained using the quantitative ASI-like diagnosis. The calculated addiction score proved to be linearly related to the number of addiction-like criteria met using the DSM-like qualitative diagnosis. The 0crit rats were the only group with a negative addiction score, confirming their resistance to addiction. The 3crit rats were the only group with an addiction score above one standard deviation, confirming their

vulnerability to addiction, while the 1crit and 2crit rats showed intermediate addiction scores.

These findings confirmed that addiction results from an interaction between a prolonged exposure to drug and a vulnerable phenotype, which, importantly, is present also in laboratory animals. This observation opens up new perspectives for the understanding of the dynamics of the addiction process and may be helpful for understanding the different factors involved in the maintenance of controlled drug use or the development of addiction, depending on the individual.

Monosymptomatic Models of Transition to Addiction

Other models studying only one addiction-related behavior have been proposed as a model of transition to addiction. Like the multisymptomatic one, two of these models are based on the DSM-IV diagnostic criteria of addiction focusing, respectively, on adverse consequences or motivation for the drug.

The other two models, on the contrary, do not directly derive from the diagnostic criteria of addiction. One of these models focuses on relapse and, in particular, on the development of craving. Although relapse is a consequence and not a diagnostic criterion of addiction, this model is extremely interesting. It specifically allows modeling of a counterintuitive clinical observation, that is, the fact that the probability to relapse does not decrease but increases after drug discontinuation is initiated.

The last model focuses on the escalation of drug intake that is observed when animals are given longer daily access to drugs. This model is the most far from the clinical diagnosis of addiction since escalation in drug intake is not a clinical sign of addiction in the DSM-IV but a phenomenon often but not obligatorily associated with addiction. Studies on escalation in drug intake have, however, the merit to be the first to attempt to model addiction and to put forward the idea that one should study more than just standard intravenous self-administration.

In conclusion, monosymptomatic models are very heterogeneous, being more or less close to the clinical definition of addiction. These models present the advantage to demand a lower workload than the multisymptomatic model and, consequently, allow for a large range of neurobiological investigations. However, they also have a few drawbacks: (1) they explore only one dimension of the clinical diagnosis of loss of control on drug intake; (2) they are usually studied using shorter periods of drug exposure than those needed for addiction-like behavior to strongly appear; (3) they poorly integrate the individual dimension, although this seems to have been corrected in recent studies from some of these groups.

Transition to Addiction: Psychobiological Basis

In the search for etiological factors of addiction, clinical, and epidemiological studies have focused on psychological dimensions, such as impulsivity or reactivity to stress, and on addiction-associated pathologies such as anxiety or depression. Although variable results have been obtained, associations between addiction and/or sustained drug use and these traits or pathologies have been found. However, in human studies, it is difficult to assess whether a certain behavioral trait is a consequence or a potential cause of the development of addiction. Animal models have now somewhat clarified the relationships between addiction and other behavioral traits.

Response to Stress

Exposure to stressful life events has been consistently evoked in epidemiological studies as a risk factor for human drug addiction. Experimental studies support this hypothesis. Twenty years ago, our research group demonstrated that in rodents, as in humans, certain individuals (high responders, HRs) show a higher vulnerability to develop voluntary drug intake than other (low responders, LRs) more resistant subjects. Vulnerable subjects display enhanced sensitivity to the reinforcing effects of drugs of abuse, self-administering larger amounts of drugs over a wide range of doses. This enhanced vulnerability can be predicted by a greater behavioral reactivity to a stress (locomotor activity in a novel environment) and can be induced by life events and, in particular, by stressful experiences occurring during adulthood or at an early stage of development.

Locomotor response to novelty, however, has been shown to be unrelated to the vulnerability to develop addiction-like behavior. Transition to addiction has the same incidence in both HR and LR rats and once addiction has developed, nonaddict (0crit) and addict (3crit) rats do not differ for locomotor response to novelty. Whether the development of addiction-like behavior in rodents can be influenced by stressful life events remains an open question.

Impulsivity

Poorly conceived, disadvantageous decisions and behaviors characterize impulsivity. This personality trait, however, could be composed of multiple components, including behavioral disinhibition, intolerance for delayed reward, and impaired ability to consider the consequences of behaviors. In humans, incidence of high impulsivity is much higher in drug addicts than in the normal population. There is also a high comorbidity

between drug addiction and disorders characterized by impulsive behavior, such as attention-deficit/hyperactivity disorder (ADHD). In animals, impulsivity might also predict vulnerability to drug use. However, only some components of this complex trait seem related to drug sensitivity. For example, intolerance for delayed reward could predict vulnerability to cocaine use, whilst behavioral disinhibition as measured by the inability to wait and sample predictive stimuli before responding might not. Thus, HR and LR rats, which are, respectively, vulnerable and resistant to psychostimulant use, differ in a DRL task, but do not in the task measuring the inability to wait and sample predictive stimuli before responding.

In the context of transition to addiction, impulsivity, in particular, behavioral disinhibition, is not associated with cocaine addiction but could predict its development. The inability to wait and sample predictive stimuli before responding predicts the vulnerability to shift from controlled to compulsive cocaine use. Transition to addiction mostly occurs in rats showing the highest level of impulsivity prior to cocaine use. It is noteworthy that this specific test, as stated above, fails to predict vulnerability to develop drug use. However, once addiction is developed, addict (0crit) and nonaddict (3crit) rats do not differ for behavioral disinhibition as measured in extinction conditions. Continued responding under extinction conditions is also considered a measure of behavioral disinhibition and impulsivity. Extinction allows for the measurement of persistence of responding to the drug. During this procedure the drug is withdrawn, but is still signaled as available.

Anxiety

Anxiety and drug addiction is a frequently described comorbidity, and whether anxiety precedes or follows addiction remains a question of debate. In rodents, cocaine use and withdrawal from drug use might produce anxiety. Concerning anxiety as a predictive factor for cocaine use, conflicting results have been obtained, that is, increased or reduced anxiety predicting vulnerability to cocaine use. Concerning addiction *per se*, anxiety is likely not a consequence of addiction in rats; addict (3crit) and nonaddict (0crit) rats do not differ with regard to anxiety as measured in an elevated plus maze. Whether anxiety in drug-naïve rats could precede transition to addiction remains to be investigated.

Pattern of Drug Use

Cocaine addiction often emerges with new patterns of use that accelerate drug delivery to the brain. These new patterns include increases in intranasal dosage or switch to new routes of administration, such as smoking or intravenous injections. Experimental studies have shown that

the speed of drug infusion might influence cocaine-induced neurobiological adaptations as well as motivation to drug use. What about transition to addiction?

Despite identical opportunity to self-administer cocaine in all rats, transition to addiction is specifically preceded by the early development of a burst-like pattern of use. Early after the rats start to self-administer cocaine (less than 20 sessions) and although future addicts (3crit) and nonaddicts (0crit) take the same amount of drug, future 3crit rats spontaneously self-administer cocaine faster than future 0crit rats. In summary, a fast pattern of cocaine use appears as an early symptom of the transition to addiction. Whether this behavior is a mere early symptom of the development of addiction or is causally related to it remains to be determined.

In conclusion, different behavioral traits seem to be associated with the vulnerability to develop and maintain drug intake and with the development of addiction. Higher behavioral response to stress, anxiety-like behaviors, and certain dimensions of impulsivity have been shown to be associated with increased drug intake or to predict vulnerability to drug use. By contrast, none of these behaviors seems to predict the development of addiction-like behaviors. Only the pattern of drug intake and certain forms of impulsivity seem to predict the development of addiction.

A Unified Vision of Addiction

Using pertinent animal models, it now appears possible to reconcile the two major theories of addiction and to integrate the experimental and clinical perspectives. Thus, the major hypotheses driving experimental research consider the degree of exposure to drugs as the key factor leading to addiction. On the contrary, clinical visions of drug abuse have progressively shifted from the role of drug exposure to that of the higher vulnerability to drugs of certain individuals. Our unified vision of addiction sees this pathology as the result of drug/individual interactions along a two-step process.

Addiction results from the interaction between (1) the degree of exposure to drugs, because addiction-like behavior appears only after extended access to drug and (2) the degree of vulnerability in the exposed individual, because addiction-like behaviors appear only in a few subjects, despite a similar drug intake in all subjects. It is, therefore, the interaction between the exposure to drug and a vulnerable phenotype, not one or the other factor in itself, which seems to determine the development of addiction.

Addiction is a two-step process in which each step is subsumed by a different type of vulnerability. The first step is the one that brings an individual to acquire and maintain a sustained drug intake for a prolonged period of time. This is a necessary step because addiction-like

behavior develops only after prolonged drug intake. Phenotypes such as a higher vulnerability to stress, anxiety, and certain forms of impulsivity predispose to sustained drug use probably by increasing the appetitive effects of drugs. In other words, drugs have higher reinforcing effects in certain individuals that will then be more prone to acquire and maintain drug intake. However, to shift from sustained drug use to addiction, an individual also needs a second addiction-prone phenotype. The psychobiological basis of this phenotype, which could include a certain dimension of impulsivity, still remains uncertain and needs much more research effort.

Transition to Addiction: Neurobiological Basis

Little is known to date of the biological basis underlying the development of addiction. Thus, as we have seen, theories of addictions have evolved and pertinent behavioral models have become available only recently. For this reason, most of the knowledge available today concerns the neurobiological effects of repeated exposure to drugs and the biological basis of vulnerability to developing sustained drug use.

The relevance of knowledge on the neurobiological effects of repeated exposure to drugs to our understanding of addiction is uncertain for two main reasons. First, most of this research has been performed using short-term drug exposure, that is, drug-induced modifications have been studied well before addiction-like behavior appears. Second, most of these studies have been performed on small groups of animals without taking individual differences into account. Since most individuals exposed to drugs, even for prolonged period of time, do not develop addiction, it is very likely that our knowledge concerns neurobiological adaptations that protect from addiction and not those that determine it.

More pertinent for the addiction process is our knowledge on the biological basis of individual vulnerabilities. However, this knowledge exclusively concerns the first step of the addiction process, that is, that leading to acquire and maintain sustained drug use. Over the past 20 years, biological determinants of vulnerability to psychostimulants and alcohol use have been intensively studied by our group and a few others. This research has led to a consistent conclusion: vulnerability to drug use, which is spontaneously present in some individuals (HR rats) or induced by stress in others, involves an interaction between mesencephalic dopaminergic (DA) neurons, one of the major substrates of the reinforcing effects of drugs, and glucocorticoid hormones, one of the major biological responses to stress. The activity of the DA projection to the nucleus accumbens is higher in

drug-vulnerable subjects than in resistant ones. This increase in DA activity appears to depend on glucocorticoid hormones. Thus, by activating the glucocorticoid receptors in the nucleus accumbens, glucocorticoids enhance the DA response to drugs of abuse and increase the propensity to self-administer drugs.

Clearly, this is not the only neurobiological substrate proposed in the literature. Koob and Le Moal, Robinson and Berridge, Hyman *et al.*, Everitt *et al.*, Kalivas *et al.*, and Shaham and Hope proposed differently elaborated and theoretically valid hypotheses of the mechanisms leading to addiction. However, the interaction among stress, glucocorticoid, and dopaminergic neurons is the only substrate that can be considered as a pathophysiological mechanism of vulnerability to drugs within the framework of classical experimental medicine. In this conceptual framework, already clearly stated by Claude Bernard, a biological factor or a biological chain of events can be considered a pathophysiological mechanism when (1) changes in its activity can be correlated with the predisposition of vulnerable subjects, (2) known etiological or predisposing external conditions modify the activity of such a factor, and (3) opposite manipulations of such a factor can induce and reverse the pathology. These three conditions have been convincingly and extensively demonstrated only for the interaction between stress, glucocorticoid, and dopamine that consequently stands as the only known pathophysiological mechanism of vulnerability to initiate and maintain a sustained drug intake.

Our knowledge is more restricted concerning the pathophysiological mechanisms of the addiction-prone phenotype. Thus, we are still completely lacking the most important knowledge: What are the neurobiological changes that, during prolonged drug intake, appear specifically in a few individuals and lead them to addiction? As the investigative tools and the appropriate experimental models to address this question are now available, we are confident that the answer will surely be found in the coming years.

Glossary

Adaptive model or individual-centered model –

Individual differences exist prior to the first exposure and contribute to the propensity to use drugs or to enter into the addiction cycle. These individual differences are attributable to inherent or acquired vulnerabilities. This model is validated by clinical observations and research.

Comorbidities – Epidemiological studies and clinical observations state that most (if not all) individuals who will succumb had, prior to exposure to the addictive objects, a ‘proaddictive phenotype,’ observable psychopathological and behavioral pathologies, and emotional pain. Drug use is a response to these sufferings.

Epigenetics – Refers to the regulation of various genomic functions, including gene expression, that are elicited by heritable (in some cases), but potentially reversible, changes in DNA methylation and various modifications of histones. Epigenetic mechanisms correspond to biological traces left by environmental insults and lead to vulnerabilities and individual differences.

Exposure model or drug-centered model – Drugs (and addictive objects in general) are the primary and unique causes of addiction, in which only the use of addictive substances (or objects) induces addiction. This model is widely used in laboratory research.

Genetic factors – In psychiatry and non-Mendelian diseases, there is no specific gene for addiction but rather only susceptibility or vulnerability genes that participate indirectly to the disorder.

Vulnerability – A construct that covers all the fields of medicine. After a period devoted to description of symptoms and diagnoses, the next step was to identify the pathophysiological bases of the diseases, and then (now) to find the causes, and find a cure. Predictive medicine will be the last step, that is, to discover markers and prodromic states of vulnerabilities. Some vulnerabilities are specific for a given class of disease, others are, in the state of our knowledges, nonspecific.

Introduction

The main goal of current research on addiction is to understand the neuroadaptive mechanisms within specific neurocircuits that mediate the transitions between occasional, controlled drug use, abuse or harmful use, and finally the loss of behavioral control over drugseeking and drug taking that defines addiction as a chronic relapsing disease. However, epidemiological data and everyday clinical practice highlight considerable individual differences at each step of the process. For a given drug, a small percentage of users become addicted. Approximately 15.6% (29 million) of the US adult population will engage in nonmedical or illicit drug use at some time in their lives, with approximately 3.1% (5.8 million) of the US adult population going on to drug abuse and 2.9% (5.4 million) progressing to addiction on illicit drugs. For alcohol, 51% (120 million) of people over the age of 12 were current users, 23% (54 million) engaged in binge drinking, and 7% (16 million) were defined as heavy drinkers. Of these current users, 7.7% (18 million) met the criteria for substance abuse or dependence on alcohol. For tobacco, 30% (71.5 million) of people aged 12 and older reported past-month use of a tobacco product. Furthermore, 19% (45 million) of persons in the US smoked every day in the past month. Of the 15- to 54-year-olds, 75% had used tobacco at some time in their lives, with 24.1% meeting the criteria for addiction. In other words, some individuals are more at risk than others and even some are resilient. They display an inherent predisposition, propensity, or proneness to enter into or succumb to addiction and relapse at one or more stages of the addiction spiral.

The underlying reasons of this vulnerability have not raised extensive research, especially at the experimental and animal levels. Conversely, drugs also have effects that depend on the intrinsic and differential hazard of the drugs. The number of individuals meeting the criteria for addiction on a given drug as a function of ever having used the drug varies between drugs. Recent data derived from the National Household Survey on Drug Abuse showed that the percentage of subjects addicted to a given drug, of those who ever used, decreases in the following order: heroin > cocaine > marijuana > alcohol.

The percentage of users with addiction or abuse for heroin is 57.4%, cocaine 25.6%, and marijuana 15.6%.

Vulnerability refers to an inherent trait or acquired state of psychobiological nature for which an object (here a drug) that is neutral by nature and by essence not addictive becomes reinforcing and addictive. This occurs because of its conjunction with a specific individual, or one who is vulnerable. Most often, vulnerability is revealed empirically *a posteriori*. Clinical and experimental research has been aimed the past few years at revealing markers of vulnerability and predicting its consequences.

The origin of vulnerability are numerous and interactive and include genetic and environmental factors and aversive life events. All have left psychological and physiopathological traces in the organism. Vulnerability participates in psychopathological syndromes and comorbid factors diagnosed in most of the psychiatric disorders. Each individual has his or her own history that uniquely contributes to the entrance into the addiction process. However, such a view based on clinical observations and studies contrasts with most of the experimental investigations and raises methodological considerations about animal and biological models and the neuroscience of addiction in general.

Methodological Considerations: Individual-Centered versus Drug-Centered Approaches

The field of addiction research shares the same basic biopsychosocial frameworks with most of the psychopathological

and behavioral disorders. Contributing factors relate to individual history and are multifactorial: living conditions, education, stressful life events, genetic/environment interplay, comorbidities, etc. One or a combination of factors contributes to psychobiological traits or states that render the subject intrinsically more vulnerable. Such an individual-centered approach (**Figure 1**) places the individual at the focal point of research and interest.

Addiction is a behavioral disorder occurring in a vulnerable phenotype. This adaptive perspective is based on predisposition and explains why subjects are at risk. The intrinsic predisposed state determines the neuroplasticity induced by the drugs. To understand and detect the sources of vulnerability would lead to a predictive medicine and toward prevention and detection of such vulnerable subjects and psychosocial interventions. Translation from the real world and from clinical psychiatry to the laboratory must discover and develop models that will present for elucidation, (1) gradual individual differences from the resilient to the most vulnerable phenotypes, (2) a transition to misuse only for some animals prone to enter in to the disease process, and (3) the main symptoms of the disease at the end of the process. An individual-centered approach is basically a historic approach. Patients and animals are considered different and more or less vulnerable because of their past, developmental characteristics, or genetic background. The sequences of the process are represented in **Figure 2**.

This paradigm contrasts with classic pharmacological approaches (e.g., drug-centered or exposure model) based on acquired drug-induced neuroplasticity vulnerability.

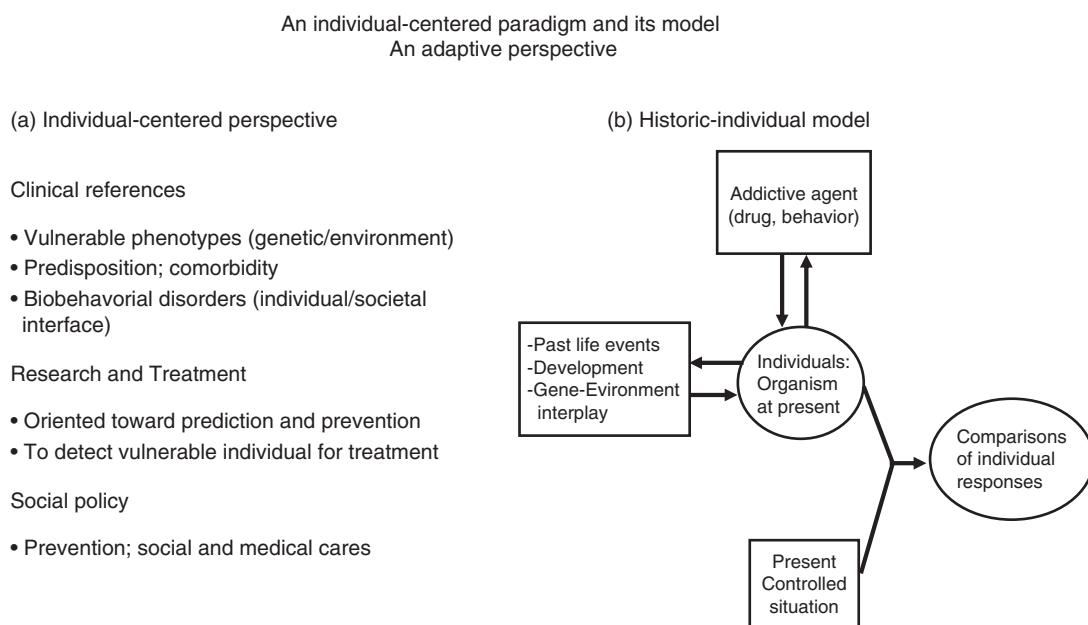

Figure 1 An individual-centered research perspective (a) to a historic-individual animal model (b), considering individuals as different from the point of view of their past life events, developmental characteristics, and genetic background. Individual comparisons require nonparametric statistics. Figure 2 A given drug or behavior (e.g., eating, gambling, and sex) is addictive because of its exposure to a vulnerable individual (1) who will be prone to repeat the drug use (2). Drug use then will induce neuropharmacological and neurotoxicological effects and profound neuronal changes (3) and then addiction (4). A, B, C, and D: Process sequence. Reproduced from Le Moal M (2009) Drug abuse: Vulnerability and transition to addiction. *Pharmacopsychiatry* 42: S42–S55, with permission from © Georg Thieme Verlag Stuttgart, New York.

Here, drug abuse is, in many ways, an iatrogenic disorder, and both research and therapeutics are oriented toward understanding pharmacological drug properties, toxicological actions on brain substrates, and counteracting these effects by other pharmacological means. This paradigm is largely dominant in laboratory research. Animals are considered not in relation with their past (i.e., ahistoric models) but rather with the amount of drug taken (**Figure 3**). Individual differences are hidden under statistical standard errors or considered as protocol artifacts.

These two research interests and practices have their own logic and necessities and are complementary. Discovering the neuroplasticities induced by drugs is important. These neurobiological changes explain the transition from impulsive to compulsive behaviors and loss of control. A trivial observation is that frequent drug usage or the repetition of specific behaviors, combined with the intrinsic dangerousness of each drug (e.g., gambling, eating, and sex), is addictive by itself, leading to compulsive disorders and loss of control.

The characterization of such vulnerabilities in laboratory settings has been rather recent. Research has demonstrated that it was possible to show in rats: (1) marked individual differences in the development of psychostimulant self-administration, (2) differential propensity to drug taking predicted by individual reactivity to novelty, a robust and permanent trait, and (3) a significant positive correlation between the magnitude of reactivity and the amount of the drug self-administered during an acquisition session. Subsequent research

demonstrated that rats allowed short access (1 h per daily session) to a psychostimulant maintained low, stable, and controlled intake for many weeks, whereas long access (6 h) drug intake gradually escalated over days, with increased early drug loading, suggesting an increase in hedonic set point. Here the gradual transition from use to abuse correlated with the amount of drug taken. However, possible individual differences within groups were not investigated in their studies. More recently, it was demonstrated that three of the essential diagnostic criteria (i.e., loss of control, resistance to punishment, and motivation for drug) appeared over time in rats trained for months to self-administer cocaine. Interestingly, only 17% of the animals presented the three criteria and 41% no criterion (i.e., resilience), demonstrating significant individual differences in the propensity to become addicted.

Genetic Factors Involved in Vulnerability

Genetic factors are generally proposed to contribute to individual differences in vulnerability to initiating use of addictive substances and in vulnerability to shift from use to addiction. Genetic research in addiction, as well as in psychiatry in general, has been controversial.

Genetic contributions to addiction have long been postulated, and these can result from complex genetic differences that range from alleles that control drug metabolism to hypothesized genetic control over drug

A drug-centered paradigm and its model
An exposure perspective

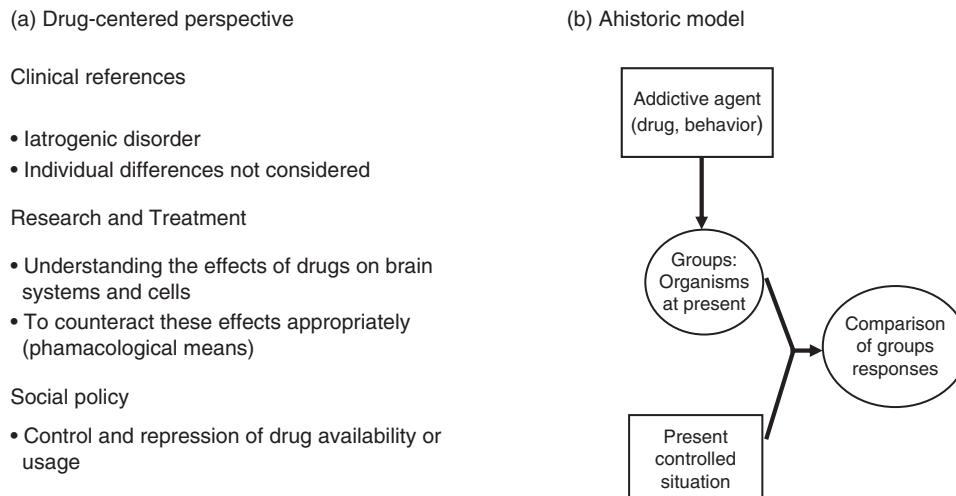

Figure 3 A drug-centered research paradigm (a) to an ahistoric animal model (b) with group comparisons and parametric statistics. The subjects are not considered from their individual characteristics – they are equal or similar. sensitivity and environmental influences. Complex genetic influences are those that are genetic but are not due to single-gene effects that produce Mendelian inheritance patterns. The classical approaches to complex trait genetics have been the examination of co-occurrence or comorbidity for the trait in monozygotic versus dizygotic twins, reared together or apart, and in analogous family studies with other types of biological relatives. Twin and adoption studies can provide researchers with estimates of the extent of genetic influences, termed heritability (i.e., the proportion of observed variation in a particular trait that can be attributed to inherited genetic factors in contrast to environmental factors). Using such estimates, genetic studies have demonstrated that genetic factors can account for approximately 40% of the total variability of the phenotype. In brief, and to summarize a great amount of studies, heritability estimates for drug dependence are for cocaine 44% (male) and 65% (female); opiates 43% (male); marijuana 33% (male) and 79% (female); tobacco 53% (male) and 62% (female); and alcohol 49% (male) and 64% (female). The specificity and selectivity of these data, however, are questionable. First, no ‘gene for’ exists when the various psychiatric traits and behavioral pathologies are considered. Genes have contributory roles in influencing individual variations in the liability of those traits, and the genetic effects are weak and indirect, and not causal for a given addiction. Gene variation has been shown to partially underlie complex personality and physiological traits, such as impulsivity, risk taking, and stress responsivity, as well as a substantial proportion of vulnerability to addictive

diseases. Second, evidence suggests substantial genetic and environmental nonspecificity across addictive behaviors. Genetic vulnerabilities for drugs or other types of addictions are shared with many other behavioral traits. Moreover, no evidence has specifically demonstrated genetic factors that increase risk to abuse substance A but not substances B, C, and D. A combination of environmental and genetic influences is shared between diseases. Poly-drug use is widespread, raising the additional possibility for a general addictive tendency or a general nonspecific vulnerability linked to comorbid factors. Third, addiction depends initially on individual’s decision to use an addictive substance (under the assumption that the choice of a person is not heritable) and wide variations in addictive liability are observed across time and space. Fourth, addictions are theoretically preventable by law, religious beliefs, and individual choices, imagining that a genetic shift accounts for the various drug epidemics observed over the past 40 years. Fifth, most individuals who succumb to addiction share comorbid disorders, such as impulsivity, externalized behaviors, anxiety, and dysphoria. An individual’s socio-economic status also is a decisive factor in initiating drug use, and psychosocial influences are integral to the syndrome.

Over the past few years, genetic background and, particularly, gene/environment interactions have received renewed interest by taking into account epigenetic mechanisms. These mechanisms account for many stable changes attributable to environmental events (and drugs) and subsequent psychiatric symptoms. Epigenetics exert lasting control without altering the genetic code, the

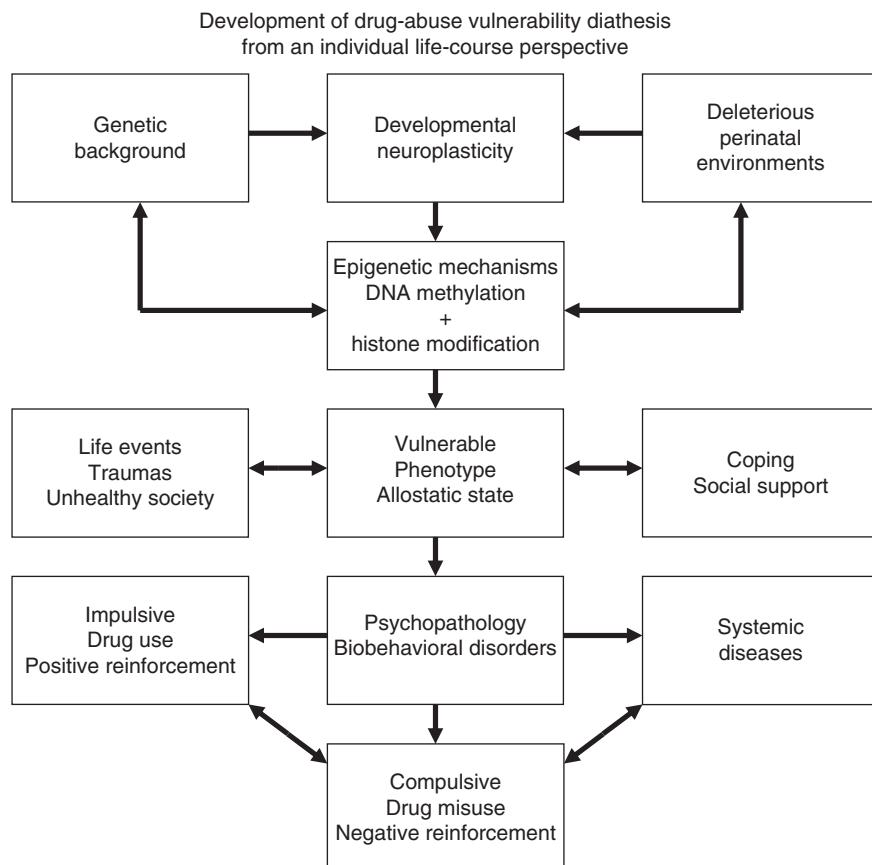

Figure 4 Development of drug-abuse vulnerability diathesis from an individual life-course perspective. Reproduced from Le Moal M (2007) Historical approach and evolution of the stress concept: A personal account. *Psychoneuroendocrinology* 32: S3–S9 (with modifications).

DNA sequence. Epigenetic changes affect chromatin modifications and methylations that occur at the carbon-5 position of cytosine in CpG nucleotides and impact chromatin packaging of DNA by posttranslational histone modifications and nucleosomes remodeling. Importantly, these epigenetic changes have not only been demonstrated in disease susceptibility, but also may be heritable. Heritable environmentally induced epigenetic modification may underlie reversible transgenerational alterations in phenotype. Epigenetic mechanisms correspond to biological traces left by environmental insult, which eventually lead to vulnerabilities (Figure 4).

Disrupted Development and Stressful Life Events

In humans, children of mothers who experienced stress during gestation display alterations in motor and cognitive development, increased anxiety, anomalies in brain and neuroendocrine function, and increased risk of developing a range of physiological and behavioral abnormalities. Extensive data from animal studies parallel

these findings. Moreover, offspring of rat mothers exposed to maternal restraint stress during the last week of gestation have a highly significant response to drugs and are prone to initiate drug use. These behavioral pathologies are linked to enduring stress axis dysregulations, among many other neurochemical changes. Prenatal stress-induced changes are reversed by postnatal handling or adoption. During infancy, disrupted maternal care, early adverse experience, and childhood sexual or physical abuse are important factors associated with a vulnerability to substance initiation and abuse. The prevailing view is that stressors influence the development of neural and neuroendocrine systems to regulate the expression of responses to stress and reinforcement processes. These clinical observations are consistent with results obtained in nonhuman primate models of disrupted maternal care. Infant rhesus macaques peer-reared, rather than mother-reared, exhibit neurobehavioral dysfunctions as adults, such as increased fear and anxiety and limbic–hypothalamic–pituitary–adrenal axis hyperreactivity following stressful situations, and they consume more alcohol than mother-reared offspring. Notably, however, acute social separation stress increases

alcohol consumption in mother-reared animals to the level of their peer-reared counterparts. Excessive alcohol intake correlates positively with plasma cortisol levels in peer-reared rhesus macaques and negatively with 5-HIAA concentrations in cerebrospinal fluid. A functional variant of the rhesus serotonin transporter-linked polymorphism has been shown to interact with rearing condition and gender to influence the adrenocorticotropic hormone response to stress, suggesting differential sensitivity to stress dependent on a gene/environment interaction. In rodents, disrupted maternal care with repeated episodes of maternal separation during the first 2 postnatal weeks provokes the same endocrine, functional, and behavioral disorders that are causal in adulthood for the individual differences in susceptibility to drug self-administration. Glucocorticoids interact directly with dopamine transmission. However, these deleterious effects resulting from maternal separation and isolation rearing of infants lead to disruptions in a variety of reward-related behaviors and neurotransmitter systems in adulthood. These effects also include reduced 3,4-dihydroxyphenylacetic acid (DOPAC)/dopamine turnover in the frontal cortex (but a larger turnover in ventral striatum) and increased self-administration of a variety of abused drugs. Enriched environments, by contrast, have been shown to decrease the propensity to initiate drug intake. Disrupted development and stress depend also on early aversive social experiences that are defined largely by social and economic disadvantages to contribute to adult psychopathologies and drug-abuse vulnerability.

Age and Gender Influences

Effects of Age and Early Drug Exposure

Adolescence (12–25 years of age) is characterized by pronounced changes in behavior with increased risk taking (e.g., hazardous driving, unprotected sex, and substance abuse), novelty and sensation seeking, social interactions, high activity and play behaviors accompanied with low levels of anxiety regarding the potential for harm, reduction in reward sensitivity, sensitivity to stress, strong emotional states, and mood instability. Self-regulatory executive functions are still maturing during adolescence, and impulsivity is supposed to normalize at the end of this period with the appearance of reasoning and planning abilities. These behavioral characteristics correlate with changes in cortical development. The prefrontal cortex and the limbic system undergo prominent reorganization, myelination, neuronal plasticity, and structural rearrangements. Sexual and stress neurohormonal systems and major neurotransmitter systems also undergo similar changes. Behavior and brain maturation interact, and the resulting traits are deeply influenced by

appropriate environments, particularly self-regulation abilities, executive function stabilization, and impulsivity control. Sociologic changes in Western societies, including individualism, early autonomy of children and adolescents, disrupted family environments, and the disappearance of social and civic connections and traditions during the second part of the twentieth century, have led to early and uncontrolled drug experiences. For example, among the US high school students, 12% of eighth graders (13–14 years of age), 22% of 10th graders, and 28% of 12th graders reported heavy episodic drinking within the past 2 weeks. According to the National Institute of Drug Abuse, 82% of adolescents have tried alcohol by the time they reach their senior year in high school. For college students, 44% binge drink every 2 weeks, and 19% are frequent binge drinkers, having more than three binge drinking episodes per week. Thus, adolescents are often drinking large quantities of alcohol. Drug taking during critical periods of cortical development may lead to increased vulnerability to drug abuse and dependence and to life-long changes in executive functions. Drug actions interfere with cortical remodeling. Persons first intoxicated at the age of 16 or younger were more likely to become heavy drinkers and 2–3 times more likely to develop substance dependence on alcohol. Similarly, persons who smoked their first cigarette during the age of 14–16 were 1.6 times more likely to become dependent than those who initiated at a later age. Others have argued that regular smoking during adolescence raises the risk for adult smoking by a factor of 16 compared to nonsmoking during adolescence. Most smoking initiation occurs during the transition from junior high school to high school (14–15 years of age). The age at which smoking begins influences the total years of smoking, the number of cigarettes smoked in adulthood, and the likelihood of quitting. When prevalence of lifetime illicit or nonmedical drug abuse and substance dependence was estimated for each year of onset of drug use from ages 13 and younger to 21 and older, early onset of drug use was a significant predictor of the subsequent development of drug abuse over lifetime. Drugs included sedatives, tranquilizers, opioids other than heroin, amphetamines, cocaine and crack cocaine, cannabis, heroin, methadone, hallucinogens, and inhalants. In general, the lifetime prevalence of dependence among those who started using drugs under the age of 14 years was 34%; this percentage dropped to 14% for those who started using at age 21 or older.

In adolescents, stages and pathways of drug involvement have been proposed in which initiation begins with legal drugs (e.g., alcohol and tobacco) and the involvement with illicit drugs occurs later in the developmental sequence. Marijuana is often cited as the bridge between licit and illicit drug. However, although this sequence is common, it does not represent an inevitable progression.

Only a very small percentage of youth progress from one stage to the next and on to later stage of addiction. Again, previous aversive experiences are responsible of their vulnerability.

Influence of Gender

Clinical and epidemiological data are now accumulating to suggest increased vulnerability to substance dependence in women. Gender differences have been reported across all phases of the dependence process, including initiation, maintenance, withdrawal, and relapse. Males and females report dissimilar motives for drug use. Females experience different subjective effects, including greater severity of withdrawal, and progress more rapidly than do men through more addictive routes. Moreover, women are more sensitive than men to stress disorders and trauma, and a link has been demonstrated between stress hormone, subsequent comorbidities, and vulnerability to substance use and abuse. Menstrual cycle phase modulates reward-related neural function in women, demonstrated by magnetic resonance imaging (MRI) techniques, with augmented reactivity of the reward system during mid-follicular phase when estrogen is unopposed by progesterone. A correlation between brain activity and gonadal steroid levels reveals that the activity in the amygdala–hippocampal complex is positively correlated with estradiol level. These data provide neurobiological foundations for understanding their impact on vulnerability to drug abuse and psychiatric comorbidity, including hormonally mediated mood disorders.

Analogous differences are observed in animals and data concur with findings, indicating that estrogen is a main factor influencing the enhanced vulnerability to initiation and relapse of drug abuse. Moreover, basal dopamine levels in the frontal cortex are dependent on the phase of the estrous cycle and attributable to the effect of ovarian steroid hormones. These data confirm MRI investigations performed in humans.

Comorbidity: Epidemiological Data

Proaddictive phenotypes depend upon multicausal factors and are heterogeneous by nature. A classic assertion is that the initiation is more associated with social disadvantage and developmental and environmental factors, whereas the transition to misuse and addiction are more associated with neurobiological factors. However, no separation exists between mental-behavioral events and their neurobiological translation (and vice versa; i.e., the magnitude of one impact on the magnitude of another). For most practitioners in addiction medicine, a normal individual will not become addicted, whereas psychopathological traits can be detected most of the times

prior to drug misuse. Patients recognized that they were not normal before drug use and that drugs were not the problem but rather a solution. Here, again, opposite positions are found in the literature. Researchers and public policymakers describe certain drugs or objects (game of chance) as addictive, tacitly implying that the cause of addiction resides in the properties of drugs or other objects. In fact, clinicians recognize that individuals who have been or who will be diagnosed with an addiction problem exhibit, prior to the onset of addiction symptoms, one or more other observable manifestations of biobehavioral pathologies, such as symptoms of another psychiatric disorder or dysfunctional behavior patterns. Individuals are concerned with lifetime comorbidity. The existence of *DSM-IV* disorders in the general population is not uncommon. Lifetime prevalence estimates are as follow: 28.8% for mood disorders; 20.8% for impulse-control disorders; 24.8% for substance use disorders; 24.6% and additional various other biobehavioral disorders: 46.4%. The median age of onset is much earlier for anxiety and impulse disorders (11 years) than for substance use (20 years) or mood disorders (30 years). Lifetime prevalence estimates were higher in a recent cohort than in earlier ones. When prevalence is estimated over a 12-month period, the percentage are the following: anxiety (18.1%), mood disorder (9.5%), impulse control disorder (8.9%), substance use disorder (3.8%), and any disorder (26.2%). Considering the severity of the cases, 22.3% were considered as serious, 37.3% as moderate, and 40.4% mild. Moreover, 55% had only a simple diagnosis, 22% two diagnoses, and 23% three or more diagnosis. Not surprising is that the strongest associations are found with mood, anxiety, conduct and personality disorders. Data from the International Consortium in Psychiatry Epidemiology that assessed approximately 30 000 subjects revealed that approximately 35% of the sample with drug dependence met lifetime criteria for a mood disorder, about 45% met criteria for an anxiety disorder, and 50% met criteria for either conduct or antisocial personality disorder. More recent data on 12-month prevalence of comorbidity in 43 000 respondents showed similar results: 21–29% for comorbidity of mood disorders, 22–25% for anxiety disorders, 32–70% for personality disorders.

An adaptive-clinical view of addiction focuses on the factors leading to vulnerability to addiction. The core focus of this approach is on developmental difficulties, emotional disturbances, structural factors, personality organization, and the building of the self. Two critical elements (disordered emotions and disordered self-care) and two contributory elements (disordered self-esteem and disordered relationships) have been identified, and have evolved into a modern self-medication hypothesis, in which individuals with substance use disorders take drugs as a means of coping with painful and threatening

emotions. In this conceptualization, individuals experience states of subjective distress and suffering or alexithymia and have feelings that are overwhelming and unbearable. Drug use is viewed as an attempt to medicate such a dysregulated affective state. The suffering of the patient is deep-rooted in disordered emotions characterized at their extremes by either an unbearable painful affect or a painful sense of emptiness. Interestingly, such self-medication may be drug specific. Patients may have a preferential use of drugs that fits with the nature of the painful affective states that they are self-medicating. Opiates might be effective in reducing psychopathological states of violent anger and feelings of rage. Others suffering from anhedonia, anergia, or lack of feelings, will prefer the activating properties of psychostimulants. Some who are flooded in their feelings, or cut off from feelings, will welcome repeated moderate doses of alcohol or depressants as medicine to express feelings that they are not otherwise able to communicate. Thus, in some cases, the subjects attempt to relieve painful feelings; others attempt to control or express feelings. The common element to this hypothesis is that each class of drugs serves as an antidote to dysphoric states and acts as a replacement for a defect in the psychological structure of such individuals. The paradox is that the choice of drugs with which to self-medicate will later by itself perpetuate the problem by facilitating entry into the addictive spiral, thereby continuing a life revolving around drugs.

General Conclusions

A significant proportion of the population takes drugs of abuse once or several times in their lifetime. Many individuals maintain repeated recreational use, but only a few develop the chronic relapsing disease named addiction. Who will succumb and why is it relevant to the problem of vulnerability? Laboratory research has only recently explored individual differences of these vulnerable phenotypes and genotypes predisposed to take drugs. The various origins of vulnerabilities have been reviewed from genetic to disrupted development and education, and stressful life-events perspectives. Most individuals who will succumb to addiction have a pro-addictive phenotype characterized by various psychopathological manifestations and emotional pain, possibly with underlying epigenetic mechanisms. Vulnerability remains a protean construct. More research is needed to understand if vulnerability is specific to drug abuse or nonspecific and relevant to psychopathology in general.

Glossary

Compulsive buying disorder (CBD) – Frequent buying episodes or impulses to buy that are experienced as irresistible or senseless. The spending behavior and impulses lead to personal distress, social, marital, or occupational dysfunction, and to financial or legal problems. The excessive buying behavior does not occur exclusively during episodes of mania or hypomania.

Compulsive Buying Scale (CBS) – A well-validated seven-item screening instrument for CBD. CBS-total scores can be calculated from the responses to the seven items through a regression formula. Lower scores on the scale indicate higher levels of compulsive buying.

Compulsive hoarding – Acquisition of and failure to discard a large number of possessions that appear to be useless. Living places are cluttered. Hoarding causes significant distress or impairment in functioning.

Impulse control disorders – A group of impulsive behaviors that have been included in the *Diagnostic and Statistical Manual*, Fourth Edition, Text Revision (DSM-IV-TR). These disorders are characterized by an inability to resist the impulse to perform an action that is harmful to one's self or others. The diagnostic category consists of the following disorders: trichotillomania, intermittent explosive disorder, pathological gambling, kleptomania, and pyromania.

Impulse-control disorders, not otherwise specified (NOS) – The NOS category comprises impulse-control disorders that do not meet the criteria for any specific impulse-control disorder or for another mental disorder having features involving high impulsivity and low impulse control.

Compulsive buying disorder (CBD) is a culturally bound excessive behavior wherein affected individuals engage in excessive buying. Historically, about one century ago, Kraepelin and Bleuler described the phenomenon termed 'oniomania' as a clinical entity in their psychiatric textbooks. Although the phenomenon

has received increasing attention in both consumer and psychiatric research, it has largely been ignored in clinical practice.

Phenomenology

Compulsive buying is characterized by shopping and spending behavior that seems out of one's control, wherein unnecessary items or large numbers of items are purchased. Individuals with CBD are preoccupied with buying impulses. They shop for longer periods of time and spend more money than intended. Repeated efforts to stop the excessive buying are unsuccessful, despite the negative consequences. The shopping episodes are typically preceded by negative feelings of tension, depression, anxiety, or boredom. Shopping typically leads to a short-term improvement in affect (i.e., a sense of relief, pleasure, well-being, and power), while the long-term negative consequences of the buying behavior are largely ignored. When the buying episode ends, most individuals experience guilt and shame. Typically, the purchased items are not used, but instead are hidden, hoarded, given away, or forgotten. These maladaptive patterns are at first minimized, then rationalized or dissimulated, and eventually produce further substantial negative psychological, social, occupational, and financial consequences. Sometimes, the pathological purchasing behavior also leads to legal problems. The extent of the shopping episode (i.e., amount of time spent shopping, amount of money spent during buying episodes), the negative consequences of the consumer behavior, and the stress individuals suffer from their behavior differentiate compulsive buying as a unique psychiatric entity when compared to occasional, unnecessary purchases. The excessive shopping behavior does not occur exclusively during periods of mania or hypomania. The following case example illustrates the behavioral excess.

Case Example

Anne, a 22-year-old student, suffers from repetitive, pre-occupying thoughts of buying. Her debt has increased substantially because of her purchases of clothes,

decorations, and cosmetics. Anne always enjoyed shopping and while buying her new purchases she imagined how attractive she would look wearing her new clothes and how other people would admire her. Her closets are overflowing with her purchases, which for the most part she does not use. In fact, many of the items are unwrapped and still have the sales tags on them. She cannot enjoy the purchases. Instead she feels depressed, ashamed, and angry with herself because of her uncontrolled shopping habits. It frightens her that she rarely uses what she buys and can hardly remember acquiring all of the items she had. Anne bought nearly the entire clothing line of one specific brand name. Her boyfriend and her parents, who have supported her financially in the past, are ashamed and refuse to offer financial help to her. Arguments are frequent between Anne and her family because Anne hides her purchases and lies to her family about her finances. In addition, she cannot pay the rent for her apartment because of her debts. Over the last few weeks, she has tried to stay at home and avoid shopping. However, she cannot resist the urge to visit the Internet homepage of different clothing companies several times daily.

Diagnosis and Assessment

Preliminary operational criteria for CBD were based on similar DSM-III-R criteria for impulse-control, obsessive-compulsive, and substance-use disorders.

Several questionnaires and diagnostic interviews have been developed to identify CBD (**Table 1**). The most widely used instrument in empirical studies is the Compulsive Buying Scale (CBS). For clarification purposes, a diagnostic interview should be administered in addition to a CBD questionnaire. To measure severity and clinical change in persons with CBD, the Yale-Brown Obsessive-Compulsive Scale-Shopping Version (Y-BOCS-SV) is recommended.

Epidemiology

Current research suggests that CBD is common in maturing consumer societies. Using the CBS in a national representative sample survey, researchers estimated the United States lifetime prevalence of CBD at 5.8%. German representative studies reported a point prevalence of CBD in Germany of about 7%. It should be noted that the use of only questionnaires is a limitation in these studies, and could result in an overestimation of CBD because of a response bias. Even so these findings demonstrate the high propensity to engage in compulsive buying in population-based samples.

There is also evidence that CBD has increased in prevalence in the past few decades. In Germany, two representative population-based surveys investigating CBD were conducted 10 years apart (1991 and 2001). In the first study, 1% of the East German population and 5.1% of the West German population were identified as having CBD. Ten years later the percentages had increased, with 6.5% of the population in East Germany and 8% of the population in West Germany reporting compulsive buying.

Clinical surveys suggest that women are more frequently affected by CBD than men, with the percentages of women in treatment-seeking samples being about 90%. However, population-based studies have not confirmed this gender difference. In fact, these population-based studies have found a near equal percentage of women and men in their surveys. Given these findings, it appears that CBD may not only affect women and that other gender-related factors (e.g., in propensities for treatment seeking) may influence the composition of clinical samples.

Psychiatric Comorbidity

Previous research indicated that CBD may be associated with elevated rates of *Diagnostic and Statistical Manual*,

Fourth Edition, Text Revision (DSM-IV-TR) Axis I disorders. Comparison of treatment-seeking individuals with CBD in Germany and the United States showed that almost all participants in both samples met criteria for at least one lifetime Axis I disorder. A few controlled trials were conducted comparing psychiatric comorbidity among individuals with and without CBD. Some researchers have reported elevated frequencies of lifetime mood disorders among those with CBD. Others have found higher frequencies of lifetime anxiety, substance-use, binge-eating, and impulse-control disorders. Another study described only substance dependence as occurring more frequently among patients with CBD. In a German study, treatment-seeking women with CBD showed significantly higher frequencies of affective, anxiety, and eating disorders compared to a nonclinical control group.

Two studies have assessed personality disorders among persons with CBD. One study found that 59% of 46 compulsive buyers met DSM-III-R criteria for at least one personality disorder. The most frequently identified Axis II disorders were obsessive-compulsive, avoidant, and borderline personality disorders. A second study reported that, compared to community controls, individuals with CBD presented with a significantly higher frequency of any personality disorder (73%), most commonly avoidant, depressive, obsessive-compulsive, and borderline personality disorder. Further, 23% of the CBD sample described at least one further impulse-control disorder, most frequently intermittent explosive disorder.

A strong link has been observed between CBD and compulsive hoarding. Previous findings have indicated that many patients with CBD suffer from high levels of compulsive hoarding. In one investigation, it was observed that about two-thirds of a treatment-seeking CBD sample reported substantial hoarding. In addition, CBD patients exhibiting hoarding reported more severe compulsive buying and obsessive-compulsive symptoms and presented more frequently with psychiatric comorbidity, especially current affective, anxiety, and eating disorders.

Because of the high frequencies of psychiatric comorbidity, there exists some skepticism about the recognition of CBD as an independent psychiatric entity. Alternatively, CBD could be conceptualized as an epiphenomenon of other psychiatric disorders. Nonconsideration of CBD as an independent psychiatric condition may result in further neglect and minimization of this disorder in clinical practice. Clinical experiences suggest that CBT typically does not resolve with the successful treatment of comorbid disorders. Because of the psychiatric comorbidity, patients with CBD represent a very heterogeneous patient sample. In summary, these findings could be interpreted to support the idea that a subtyping approach might be useful in classifying CBD. The development of specific therapeutic

interventions for those with CBD who also report comorbid psychiatric disorders may also be indicated.

Etiology

The etiology of CBD appears multifactorial, and models have been suggested based on psychological, social, neurobiological, and cultural influences. Patients with CBD report urges to buy, preoccupation with buying and shopping impulses, and in general increased impulsivity in the sense of acting without thinking. In addition, low self-regulatory resource availability and low self-control are associated with CBD. The negative consequences of CBD are often not considered by those affected. Furthermore, a close association between negative mood states and buying has been found. Using as a model short-term positive and negative reinforcement, compulsive buying is used as a way of escaping from problems and to relieve negative mood states. Individuals with CBD suffer from low self-esteem, and they often describe themselves mostly as socially anxious, depressed, and having decision-making problems.

Consumerism and money attitudes appear to play a key role in the development and maintenance of CBD. For example, younger age and higher materialistic values are associated with compulsive buying. The relationship between narcissism and compulsive consumption appears to be mediated by both low impulse control and high materialism values, and credit card use moderates the effect of money attitudes on CBD. These considerations involving factors influencing the development and maintenance of CBD are schematized in **Figure 1**.

In addition to psychological, social, and cultural influences, the biological model posits serotonergic, dopaminergic, and opioidergic contributions and a role for the brain reward systems. Currently, there is no direct evidence to support these neurobiological hypotheses, and it should be noted that the high comorbidity could influence the specificity of future neurobiological findings.

CBD is probably a culture-specific excessive behavior that occurs in industrialized countries. Technological developments, including television and Internet shopping, allow individuals to buy a vast array of products rapidly. In this cultural context, some authors warn against the labeling and medicalization of the CBD. Indeed, such an approach minimizes the clinical observations that individuals with CBD may suffer significantly from their shopping and buying behaviors, and do not seem to be able to easily stop the behavior. To understand CBD, and to create and validate etiological models and disorder-specific treatment strategies, both the psychological and consumer-research approaches should be considered.

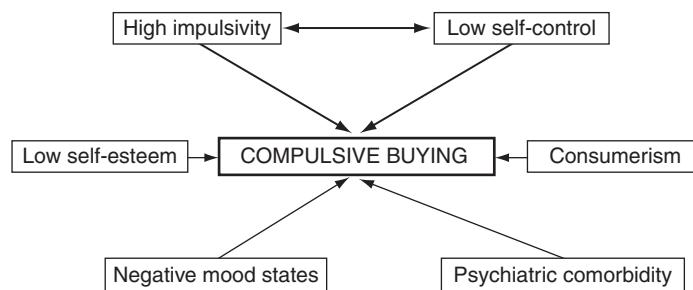

Figure 1 Proposed factors influencing CBD.

Considerations on Classification

The appropriate method of categorizing CBD continues to be debated. According to the preliminary diagnostic criteria, the inclusion of CBD in DSM-IV and ICD-10 as an “impulse control disorder not otherwise specified” is preferred. Some researchers have attempted to examine the link between CBD and obsessive-compulsive spectrum disorders (OCSDs) or addictive disorders. At present, there is a suggestion to create a category called ‘behavioral and substance addictions’ that would include both excessive behavioral disorders and substance-use disorders. The commonalities and a high comorbidity with substance-use disorders, the craving to buy, the sense of lack of self-control, the needs to spend increasing amounts of time shopping or spend increasing amounts of money in order to achieve the desired feelings (i.e., tolerance), and shopping-/buying-related withdrawal symptoms all support the categorization of CBD as an addiction. The similarities in phenomenological features, their courses, and their psychological and social consequences also cannot be ignored. In our experience, however, there exist crucial differences between substance addictions and excessive behaviors. A real dose-increase or tolerance (‘more and more/more often/more expensive’) is seen only in some of the CBD patients treated in our CBT studies. With regard to withdrawal symptoms, the patients describe negative feelings like depressive symptoms, pressure, and restlessness, if they begin to normalize their buying behavior. Detailed behavior analyses show, however, that these negative feelings are usually a matter of the emergence of negative mood states which had been suppressed through shopping behavior. The extent to which these reflect differences between CBD and substance-use disorders requires direct examination.

Treatment

Medication

A few case reports and successful open-label medication trials were reported using antidepressant, anxiolytic, mood stabilizer, anticonvulsant, and opioid antagonist

drugs. Some smaller controlled trials examined the efficacies and tolerabilities of fluvoxamine, citalopram, and escitalopram. These trials have not found superiority for these selective serotonin-reuptake inhibitors over placebo. However, the results are limited by small sample sizes, high dropout rates, and placebo-response rates ranging up to 60%. In summary, data do not support the sole use of any one medication in the treatment of patients with CBD at this time.

Psychotherapy

Some authors have described successful individual psychodynamic psychotherapy treatment and cue exposure plus response prevention for patients with CBD. Moreover, several specific group therapy and self-help approaches have been described.

The effectiveness of disorder-specific, manualized, group CBT was supported in two controlled psychotherapy studies. In both studies, the treatment was specifically aimed at interrupting and controlling the problematic buying behavior, establishing appropriate purchasing patterns, identifying and restructuring maladaptive thoughts and feelings associated with shopping and buying, developing healthy coping skills and communication patterns, and implementing relapse-prevention techniques. In addition, more general sessions about self-esteem, stress management, and problem solving were included. Group participants were expected to complete homework assignments and read and review manual materials regularly as assigned. The psychotherapy treatment focused both on current factors that maintain the excessive buying behavior and on strategies for controlling buying problems. Treatment lasted 10–12 weeks with one 90-min group session per week. Groups were conducted with 5–8 participants. The treatment manuals have been described in detail elsewhere. Further research is needed to determine whether specific individual, group, or family interventions have the most substantial impact on helping individuals with CBD.

Conclusions

CBD is a relatively prevalent disorder, particularly in developed societies. Individuals with CBD often experience significant personal distress and interference in areas of life functioning, including within financial and interpersonal domains. More research is needed into the biological basis of the disorder and more effective preventive and therapeutic strategies.

Glossary

Hyperactive sexual desire disorder – An interest or involvement in normative sexual activity that is so excessive as to cause distress or impairment in functioning.

Hyperphagia – Excessive appetite and excessive consumption of food.

Hypersexuality – Excessive interest or involvement in sexual activity. It is synonymous with hyperphilia.

Hypogonadism – Inadequate functioning of the testes or ovaries resulting in impaired sexual development or withdrawal effects (e.g., premature menopause) in adults and/or defective egg or sperm development leading to impaired fertility.

Nonparaphilic sexual addiction – Sexual thoughts, urges, and behaviors of normative content (but) that are unusually intense and persistent and are associated with distress or impaired functioning. Nonparaphilic sexual addiction (often simply referred to as sexual addiction) has been conceived of as a form of behavioral addiction.

Paraphilia – Powerful and persistent sexual urges, fantasies, or behaviors that involve: nonhuman objects; the suffering or humiliation of oneself or one's partner; or children or other nonconsenting individuals.

Sexual fetishism – Sexually arousing fantasies, sexual urges, or sexual behaviors focused on nonliving objects or on body parts not conventionally viewed as being sexual in nature, considered a paraphilia.

The term impulsive–compulsive sexual behavior, the focus of this article, is more often used to refer to sexual thoughts, urges, and behaviors that are normative in content but occur with such frequency or intensity that they are distressing or cause impairment in functioning. Other terms used to describe this problem include nonparaphilia-related sexual disorders or nonparaphilic sexual addictions, to differentiate them from the paraphilic. Terms such as compulsive sexual behaviors, hyperactive sexual desire disorder, hyperphilia, hypersexuality, sexual addiction, and out-of-control sexual behavior have also been used to describe this disorder. We use the term impulsive–compulsive sexual behavior throughout this article. Although impulsive–compulsive sexual behavior, under one name or another, has been discussed in the scientific literature since the early 1800s, there has been little rigorous research on the topic, so our understanding is limited. This category is not designated as specific disorder in the DSM-IV-TR; however, if an official diagnosis is needed, impulsive–compulsive sexual behaviors can be classified as impulse control disorders, not otherwise specified; or as sexual disorders, not otherwise specified.

Since it is not a formally recognized disorder, there are no official diagnostic criteria for impulsive–compulsive sexual behavior. However, there is some general agreement among experts. Impulsive–compulsive sexual behavior is operationally defined similarly to the paraphilic and to pathological gambling. The impulsive–compulsive sexual behavior diagnosis requires recurrent and intense sexually arousing fantasies, sexual urges, and sexual behaviors with a focus on normative sexual behaviors. It has been proposed that the behavior must have been present for a minimum duration of 6 months. The proposed diagnosis also requires standard DSM criteria of severity (frequency and/or intensity severe enough to cause clinically significant distress or impairment in social, occupational, or other important areas of functioning) and specificity (not due to a medical condition, medication or substance use, or better accounted for by another Axis I or II disorder).

Although the sexual behaviors themselves are normative, it is their excessive and poorly controlled nature that leads to serious problems such as exposure to human immunodeficiency virus and other sexually transmitted diseases, job loss, legal consequences, problems in maintaining romantic relationships or marriage, and unwanted pregnancies. Eli Coleman described seven subtypes of

Impulsive–compulsive sexual behavior refers to sexual thoughts, urges, and behaviors that are extremely difficult to resist. These thoughts and behaviors are generally divided into two types, paraphilic (which involve socially deviant sexuality) and more conventional but excessive sexuality. The paraphilic are better researched and better understood; they involve sexual interests that focus on nonhuman objects, children, or other nonconsenting persons, or the suffering or humiliation of oneself or one's partner. Paraphilic are a recognized category of disorders in the current *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR) and include disorders such as pedophilia, fetishism, exhibitionism, voyeurism, sexual sadism, and masochism among others.

impulsive–compulsive sexual behavior: compulsive cruising and multiple partners, compulsive fixation on an unattainable partner, compulsive autoeroticism (masturbation), compulsive use of erotica, compulsive use of the Internet for sexual purposes, compulsive multiple love relationships, and compulsive sexuality in a relationship. Studies have shown that the most common impulsive–compulsive sexual behaviors are promiscuity, masturbation, pornography dependence, and phone sex, but the use of the Internet for sexual purposes certainly may be increasing.

Based on Alfred Kinsey's concept of total sexual outlet (TSO), the total number of orgasms achieved per week by any means is often used to indicate severity of impulsive–compulsive sexual behavior, with a TSO of 7 per week persistently for at least 6 months usually considered the minimum for the diagnosis. Although a TSO of 7 may seem low as a criterion for hypersexuality, a TSO of 1–3 is typical of males in the general population and most estimates place the percent of males having a TSO of 7 or more at 3–7.5%, though estimates have been as high as 15%. Recall that diagnostic clinical and research criteria also require that the sexual behavior, thoughts, and/or urges need to cause distress or functional impairment.

TSO or the total time spent in sexual activities overall are considered by many to be better measures to use to quantify impulsive–compulsive sexual behavior, as compared to the frequency or time spent in specific kinds of sexual behaviors; however, the amount of time spent seeking sexual activities can also be considerable and problematic. Studies of males with impulsive–compulsive sexual behavior or paraphilic disorders found that the large majority of both groups have a TSO ≥ 7 per week and that the groups do not differ substantially from one another. Males with impulsive–compulsive sexual behavior spend 1–2 h a day occupied by their sexual urges, fantasies, or activities.

Most commonly, impulsive–compulsive sexual behavior is conceptualized either as an impulse control disorder, perhaps on the obsessive–compulsive spectrum, or as a behavioral addiction. Phenomenologically, at least initially, there is an impulsive component (pleasure, arousal, or gratification) at behavioral onset, and a compulsive component that leads to the persistence of the behavior; thus, the phenomenology can fit with either conceptualization. In the next version of the *Diagnostic and Statistical Manual of Mental Disorders* (the Fifth Edition; DSM-V), impulsive–compulsive sexual behavior may be recognized as a specific disorder. One new category under consideration for DSM-V into which impulsive–compulsive sexual behavior may be included is the behavioral and substance addictions. This category could include the disorders currently in the ‘substance-related disorders’ category as well as several putative impulse-control disorders (e.g., gambling addiction, sexual addiction, shopping addiction, and Internet addiction).

Epidemiology and Demographics

There have been no systematic epidemiological studies of impulsive–compulsive sexual behavior. Based on clinical samples, the estimate is that it affects 5–6% of the general population.

Impulsive–compulsive sexual behavior is believed to be approximately 3 times more common in males than females; the paraphilic disorders are rarely diagnosed in females except for sexual masochism, which is about 20 times more common in males than females. Virtually all research on these disorders has been conducted among males and little is known about impulsive–compulsive sexual behavior in females. It may be that the disorder presents differently in males than in females. Some consider females who fantasize about sex and seem to be addicted to romantic relationships to be suffering from impulsive–compulsive sexual behavior, a difference being that males are focused on the physical aspects of sexuality, while females focus more on the relationship.

It seems likely that impulsive–compulsive sexual behaviors, such as paraphilic disorders, begin by late adolescence and peak between ages 20 and 30. Although the severity may wax and wane, it may often be chronic. The typical outpatient in treatment for impulsive–compulsive sexual behaviors is a white, college-educated, employed man, with a middle-class income.

Individuals with impulsive–compulsive sexual behavior have a higher-than-expected rate of childhood sexual abuse; they differ from those with paraphilic disorders in that the latter have a significantly higher rate of childhood physical abuse. Those with paraphilic disorders have also often completed fewer years of education and are more likely to be unemployed or on disability.

Differential Diagnosis

Impulsive–compulsive sexual behavior may be a symptom of medical conditions (such as traumatic brain injury, stroke, epilepsy, and other conditions noted later in this article); in addition, substance intoxication, manic episodes, and schizophrenia may present with impaired judgment and diminished impulse control that may result in excessive sexual behavior. Onset in conjunction with an injury or change in health status, or at later than typical age, should be carefully evaluated for potential contributions from medical conditions.

Sexual obsessions can be a presentation of obsessive compulsive disorder (OCD) but can be distinguished from the obsessions that are part of impulsive–compulsive sexual behavior in several ways. Sexual obsessions in OCD are characterized by being ego dystonic and morally repugnant; the sexual thoughts induce anxiety

and often include uncertainty as to whether the feared sexual behavior may have actually been committed without the patient knowing it. In OCD, the sexual behaviors are not carried out and the compulsive behaviors related to these obsessions are not generally sexual. Rather, OCD patients frequently avoid specific situations or people in order to prevent the feared sexual acts from occurring and they may also perform rituals that are repetitive behaviors of a nonsexual nature meant to prevent or undo the distressing sexual thoughts or fears (such as by confessing to acts that didn't actually occur).

In addition, OCD rituals are not pleasurable activities engaged in for their own sake; rather, they are neutral or often irritating and unpleasant behaviors that are engaged in to reduce anxiety. In contrast, impulsive–compulsive sexual behaviors generally have an element of pleasure, at least initially, although they may lose their pleasurable quality over time; in this regard, they are more similar to addictions and to impulse control disorders such as pathological gambling.

Comorbidities

Individuals with impulsive–compulsive sexual behaviors tend to have multiple additional Axis I disorders. A majority of these males have a lifetime diagnosis of depression, and substantial minorities have lifetime diagnoses of substance abuse, anxiety disorders (especially social phobia), and impulse control disorders (such as pathological gambling, compulsive buying, kleptomania, trichotillomania, pyromania, compulsive exercise, and intermittent explosive disorder). Interestingly, the major comorbidity difference between males with impulsive–compulsive sexual behavior and those with paraphilic disorders is childhood attention deficit hyperactivity disorder (ADHD) (with corresponding ratios of approximately 1:6 vs. as many as 1:2, respectively).

By definition, those with impulsive–compulsive sexual behavior do not also have paraphilic disorders; however, a majority of individuals with paraphilic disorders also have impulsive–compulsive sexual behaviors; a majority report compulsive masturbation and notable minorities report promiscuity and pornography dependence.

Note that these individuals are not necessarily more ill than those with other psychiatric disorders; they simply differ from the general population in the pattern just described. Thus, patients with impulsive–compulsive sexual behavior should be screened for depression, anxiety disorders, other impulse control disorders, and substance abuse.

Neuroanatomical Features

Most knowledge of what brain structures may be involved in aberrant sexual behavior has come from animal

research and from studies of traumatic brain injury and disease processes in humans. As with most complex human behavior, it has become clear from this and other research that neural circuits are as or more important than specific structures or locations. Two circuits most clearly implicated in human sexual behavior are the frontal–striatal and the temporo-limbic circuits. Some conditions can affect either circuit depending on the disease locus; these include traumatic brain injury, stroke, seizures, and dementias. Other conditions may primarily affect only one of these circuits.

Fronto-striatal abnormalities have been linked to increased sexual desire but this seems to be due to general disinhibition rather than sexuality specifically. For example, there are many reports of hypersexuality following traumatic brain injury to frontal regions. Although disinhibition is one common consequence of frontal lesions, not all frontal lesions will result in hypersexuality, and its occurrence cannot be predicted at this time based on the injury site or severity. Likewise, in multiple sclerosis, cases of hypersexuality have occurred with frontal lesions, but those patients may have also had lesions elsewhere. Similarly, hypersexuality may occur in dementias that affect this circuit or in epilepsy with frontal seizures. Striatal disease can also result in hypersexuality (e.g., Huntington's disease, although hyposexuality is more frequent in this disorder).

The frontal lobe is an interesting candidate for a role in impulsive–compulsive sexual behavior because, in addition to being involved in impulse control in general, the orbital frontal cortex is specifically implicated in social cognition, decision making, working memory, and emotional processing, particularly in deficits in recognition of emotional expressions and relative insensitivity to potential consequences. The prefrontal cortex is also critical to the acquisition of moral and social knowledge; injuries in this brain region during childhood have been associated with limitations in this knowledge and deficits in moral reasoning. Injuries that occur after this knowledge is acquired will generally leave the knowledge base intact, but the patient may be unable to behave in accordance with this knowledge.

The single condition most associated with hypersexuality, Kluver–Bucy syndrome, seems to be related to temporo-limbic circuit dysfunction. It results most often from lesions in the amygdala, a temporal lobe structure, but can also result if there is a disruption of the temporo-limbic circuits. Kluver–Bucy syndrome has many symptoms but two of particular interest here, hypersexuality and hyperphagia, may reflect a loss of the ability to discriminate appropriate objects rather than an increase in drive, *per se*. Kluver–Bucy syndrome can result from many different disease processes, including Alzheimer's disease, adrenoleukodystrophy, anoxia or ischemia, carbon monoxide intoxication, herpes simplex encephalitis, limbic encephalitis, multicentric glioblastoma multiforme,

porphyria, progressive subcortical gliosis, Rhett's syndrome, systemic lupus erythematosus, trauma, and temporal lobectomies. Temporal lobe epilepsy and temporal lobe resection treatment of epilepsy have been related to changes in sexuality. The amygdala has been found to be a focal structure in emotion processing, that is where stimuli are given their emotional and motivational significance. Thus, if the amygdala is damaged, objects may lose their prior emotional significance.

It has been theorized that impulsive–compulsive sexual behavior may function similarly to substance addictions, that is, the intense, excessive sexual behavior may bring about changes to neural circuitry that may then perpetuate the behavior, just as the addictive substances may cause changes in neural circuitry.

Neurochemical Features

Strong biological influences are apparent in human sexual functioning, notably on the very basic phases: sexual desire, arousal, and orgasm. Endocrine, neurotransmitter, and neuropeptide influences on these phases have been specifically identified. However, there are also clear environmental/learned influences on sexual desire and behavior, and the relationship between these and biological factors is complex.

Among the endocrine factors that have been implicated, the androgens, in particular, play a role in sexual interest and activity in both males and females. Although there is a relationship between testosterone levels and the frequency of sexual thoughts in adolescent males, in adult males there seems to be no such relationship within a wide range of normal testosterone levels. In addition, hypogonadal and castrated males rapidly lose sexual interest, and this is reversed with testosterone administration. Similarly, females experience a decline in sexual interest as testosterone levels decrease, such as with natural or induced menopause. However, in females, estrogen has little effect on sexual interest while estrogens and progesterone seem to have an inhibiting effect on male sexual interest.

The monoamines (serotonin, dopamine, and norepinephrine) are considered important for human sexual functioning and there is reason to believe that hypersexuality may result from dysregulation of these monoamines. These neurotransmitters modulate sexual motivation. In that sexual side effects are associated with certain medications (antidepressants, psychostimulants, and neuroleptics), the neurotransmitter systems that they target influence sexual motivation and behavior. It has yet to be proven, however, that the monoamines are specifically involved in hypersexuality. Several relevant neurotransmitters are discussed below.

Serotonin

The role of serotonin in sexual functioning is complex and not yet fully understood. Activation of some receptors, such as 5-HT₂, may impair functioning while activation of other receptors, such as 5-HT_{1A}, may facilitate functioning. As noted earlier, medications that enhance central serotonin neurotransmission have dose-dependent side effects, including decreased desire and difficulties with arousal, although the most common sexual side effects are delayed ejaculation and delayed or absent orgasm. The importance of serotonin in sexual motivation and behavior is evident from animal research and records of human injury and disease. In addition, serotonin dysfunction has also been found in a number of other psychiatric disorders characterized by impaired impulse control (e.g., pathological gambling and substance abuse); this may reflect impaired frontal inhibition, which may result in a diminished ability to control desires. Impaired impulse control may result from overstimulated drive and/or impaired inhibition or reward processing.

Dopamine

Dopamine is important in several aspects of male sexuality ranging from basic sexual functioning (e.g., seminal emission and erectile function) to sexual arousal and motivation. The exact role of dopamine in female sexual behavior is less clear. In general, alterations in dopamine functioning may be associated with intense urges that override considerations of the consequences in impulse control disorders. As with serotonin, evidence for the role of dopamine in sexual interest and behavior comes from animal research as well as from observation of naturally occurring human injury and disease. For example, hypersexuality may result when Parkinson's disease is treated with dopaminergic medication. Dopamine is a key part of mammalian reward systems. Certain behaviors such as gambling and sexual arousal may result in a release of dopamine which may then lead to feelings of intense pleasure. Consequently, the dopamine system has been proposed as an important component of behavioral and chemical addictions.

Pharmacological Treatment

No pharmacological agents have been Food and Drug Administration (FDA)-approved for the treatment of impulsive–compulsive sexual behavior, and research on these treatments is limited with no convincing controlled trials in the literature. Given the absence of research and based on the knowledge regarding treatment of other impulse control disorders, it is important to consider

prominent symptoms and comorbidities in choosing a pharmacological approach.

Considerable research has been performed investigating pharmacotherapy and medical treatments of the paraphilic behaviors; however, these treatments are not necessarily appropriate for impulsive–compulsive sexual behavior. Notably, surgical and pharmacological techniques to lower testosterone levels do reduce paraphilic preoccupations, urges, and activities, but may be too drastic and risky to be used in impulsive–compulsive sexual behavior treatment.

Although there are no definitive controlled trials, one placebo-controlled trial, open-label studies, and case reports suggest that serotonin reuptake inhibitors (SRIs) are effective in reducing the symptoms of impulsive–compulsive sexual behavior and/or paraphilic behaviors. The SRIs reported to be effective in impulsive–compulsive sexual behavior include citalopram, clomipramine, fluoxetine, sertraline, and venlafaxine; however, there is no evidence that the SRIs differ from one another in efficacy. In clinical practice, SRIs are one of the first-line treatments for both impulsive–compulsive sexual behavior and paraphilic behaviors. They were initially tried in the hope that their sexual side effects, especially decreased libido but also impaired sexual functioning, would be helpful in impulsive–compulsive sexual behavior. The results have been better than expected in that reduction in impulsive–compulsive sexual behavior symptoms may be a result of their anti-obsessional effects causing a decrease in thoughts and urges, rather than the sexual side effects, which seem to be independent. The best treatment would suppress disturbing and out-of-control sexual drives and behaviors, while leaving other aspects of sexuality intact.

The sexual side effects of selective SRIs (SSRIs) can sometimes be reduced by titrating the dose. In some cases, nefazodone may be worth trying since it has a lower rate of sexual side effects than other SSRIs and there are some reports that it is effective in ameliorating impulsive–compulsive sexual behavior; however, the possibility of liver abnormalities must be considered. In line with the notion of using comorbidities and symptoms to choose a treatment for impulsive–compulsive sexual behavior, SSRIs can be an excellent treatment because depression and anxiety disorders are common comorbidities and SSRIs are effective treatments for these disorders.

Although an open-label trial of divalproex sodium showed no change in paraphilic symptoms, there is some evidence for the use of mood stabilizers (such as carbamazepine, lamotrigine, topiramate, and valproic acid) in impulsive–compulsive sexual behavior. They have been shown to be effective in some other impulse control disorders, such as pathological gambling. These mood stabilizing agents should be considered in patients who

are identified as bipolar or have prominent impulsivity. These drugs can also be used in combination with SRIs.

In line with the conceptualization of impulsive–compulsive sexual behavior as a behavioral addiction, if the SSRIs or mood stabilizers are not effective, opioid antagonists such as naltrexone and nalmefene may be helpful.

Case reports have noted other agents as successful in treating impulsive–compulsive sexual behavior or paraphilic behaviors; these include buspirone, tricyclic antidepressants, and atypical antipsychotics. Particular subgroups may benefit from adjunctive or other treatment. Patients with ADHD and impulsive–compulsive sexual behavior have been successfully treated with SSRIs augmented with the psychostimulant methylphenidate.

As noted, other agents widely used in the treatment of criminal sexual offenders, such as pedophiles, are often considered too drastic for most cases of impulsive–compulsive sexual behavior. These include anti-androgen treatment like medroxyprogesterone acetate and gonadotropin-releasing hormone. These agents may completely eliminate sexual interest.

Since benzodiazepines can be disinhibiting and increase impulsive behavior, they are generally not recommended for impulsive–compulsive sexual behavior, although they can be helpful in emergency situations.

In summary, when selecting a pharmacological treatment, it is probably best to refine the decision based on comorbidity and prominent symptoms. For individuals with depression or anxiety or prominent obsessive symptoms, an SSRI might be a good choice for a first trial. For those with a more addictive symptom profile, opiate antagonists might be tried. Those on the bipolar spectrum or with prominent impulsivity might be started on mood stabilizers. Patients with prominent ADHD symptoms might benefit from stimulants.

Psychological Treatment

Very little research has been conducted on psychological treatments for impulsive–compulsive sexual behavior. Most psychological treatments that have been studied in paraphilic behaviors might be appropriately applied to impulsive–compulsive sexual behavior. In addition, psychological treatment approaches used with behavioral and substance addictions show promise for impulsive–compulsive sexual behavior. Based on these two traditions, the most promising treatments might be 12-step programs, cognitive–behavioral therapy and motivational interviewing.

Treatments based on 12-step programs are widely used; these include Alcoholics Anonymous-type groups such as Sexaholics Anonymous, Sex Addicts Anonymous, Sex and Love Addicts Anonymous, Sexual Recovery Anonymous, and Sexual Compulsives Anonymous. As with Alcoholics Anonymous, there are also groups for

partners and families of those with impulsive–compulsive sexual behavior (co-dependents of sex addicts and S-Anon international family groups). In addition, formal inpatient and outpatient treatment programs also incorporate this approach.

Cognitive behavioral therapy (CBT) is often used. CBT can help individuals identify the triggers for their sexual thoughts, urges, and behavior. It can be useful in training them to manage stress, improve their coping skills, and managing symptoms of depression and anxiety; all these applications of CBT can decrease patients' susceptibility to their impulsive–compulsive sexual behavior. In general, CBT may also be very useful in preventing relapse. There is some evidence that combinations of CBT and 12-step approaches are effective in reducing impulsive–compulsive sexual behavior.

Other similar disorders, such as pathological gambling and substance addictions, respond to 12-step, CBT and motivational interviewing approaches so these approaches seem promising for impulsive–compulsive sexual behavior.

Conclusions

Impulsive–compulsive sexual behavior may be a serious, chronic, and difficult-to-treat disorder with public health and societal consequences. It is similar in many ways to substance addictions and addiction-like disorders such as pathological gambling. Although there has been little research to date on its pathogenesis, some promising treatment options are currently available, including pharmacological and psychotherapeutic approaches. The condition can be difficult to treat and may be even more challenging than similar disorders mentioned since sex is a basic human drive.

Glossary

Diagnostic and Statistical Manual (DSM) – Published by the American Psychiatric Association. In the United States, it is the primary system used to classify and diagnose mental disorders. It is currently in its fourth edition (DSM-IV).

Epiphénomène – A secondary phenomenon that occurs alongside or in parallel to a primary phenomenon, but may not be causally linked to the primary phenomenon.

First line – Preferred, standard, or initially recommended approach; often used in reference to treatment selection.

Impulsive aggression – Also known as reactive or hostile aggression, impulsive aggression occurs in response to angering thoughts. The goal of impulsive aggression is to cause harm to another. This is in contrast to instrumental or premeditated aggression in which anger is not the primary motivator for the aggressive behavior and the aggression is seen merely as a means to an end (e.g., hitting someone to steal their wallet).

Morbid risk – The probability that an individual born into a population or group will develop a disorder.

Selective serotonin reuptake inhibitors (SSRIs) – A class of drugs that increase the amount of serotonin available in the synapse (space between nerve cells) by inhibiting the recapture or reuptake of serotonin by the nerve cells that released the serotonin into the synapse.

individuals who display intermittently violent behavior and who are “generally excitable, aggressive, and over-responsive to environmental pressures” with “gross outbursts of rage or of verbal or physical aggressiveness different from their usual behavior.” In DSM-III, ‘explosive personality’ was codified and operationalized as IED for the first time and assigned ‘clinical disorder’ status under Axis I. The diagnostic criteria, however, were not well operationalized (e.g., criterion A ‘assaultive’ and ‘destructive’ acts had no specific guidelines on which behaviors would satisfy the criteria from a severity, frequency, or time-frame standpoint) and were otherwise problematic. Subjects who were generally aggressive or impulsive in between the ill-defined aggressive episodes were excluded from receiving the diagnosis (criterion C). Since individuals with recurrent, problematic, impulsive aggression are also generally impulsive and aggressive between more severe outbursts, this exclusion ruled out the vast majority (e.g., 80%) of individuals who now would be diagnosed with IED.

With the introduction of the DSM-IV in 1994, the earlier exclusionary C criterion that omitted individuals with chronic aggression problems (effectively excluding most subjects now considered to meet criteria for IED) was removed. Regardless, DSM-IV still lacked objective criteria for the intensity, frequency, and nature of aggressive acts to meet criteria for IED ([Table 1](#)).

Noting the limitations of the DSM-IV criteria for IED, some investigators developed an alternative criteria set that integrated their research findings with DSM conceptualizations of IED ([Table 2](#)) ‘integrated research’ criteria for IED (IED-IR) differ from DSM-IV IED criteria on four key points. (1) IED-IR criteria operationalizes the severity and frequency of aggressive behavior required for the diagnosis. The inclusion of verbal aggression within the IED-IR construct reflects data showing that frequent verbal aggression occurs in over 85% of subjects with physical aggression, that subjects with frequent verbal aggression in the absence of more severe assaultive acts show the same core deficits and impairment as assaultive subjects and that anti-aggressive responses to serotonin reuptake inhibitors are seen in both groups. (2) IED-IR criteria explicitly require the aggressive behavior to be impulsive in nature. This was also informed by research showing psychosocial, biological, and treatment-response characteristics differentiated impulsive and premeditated aggression. (3) IED-IR

Intermittent explosive disorder (IED) is a DSM-IV diagnosis that describes the pathology of people with aggression, typically impulsive aggression. Although aggressive behavior is relatively common, many clinicians and researchers rarely consider the diagnosis of IED when faced with a patient with recurrent, problematic, aggressive behavior. This is notable because IED has been a part of the DSM since its third edition in 1980. Before that, this construct was referred to as ‘passive-aggressive personality (aggressive type)’ and was characterized as “persistent reaction to frustration with irritability, temper tantrums and destructive behavior.” This disorder evolved into ‘explosive personality’ in DSM-II at which time such patients were characterized as being aggressive

Table 1 DSM-IV criteria for intermittent explosive disorder

- A. Several discrete episodes of failure to resist aggressive impulses that result in serious assaultive acts or destruction of property.
- B. The degree of aggressiveness expressed during the episodes is grossly out of proportion to any precipitating psychosocial stressors.
- C. The aggressive episodes are not better accounted for by another mental disorder (e.g., antisocial personality disorder, borderline personality disorder, a psychotic disorder, a manic episode, conduct disorder, or attention-deficit/hyperactivity disorder) and are not due to the direct physiological effects of a substance (e.g., a drug of abuse and a medication) or a general medical condition (e.g., head trauma and dementia of the Alzheimer's type).

Table 2 Research criteria for IED: IED-IR

- A. Recurrent incidents of aggression manifest as either:
 - A1. Verbal or physical aggression towards other people, animals, or property occurring twice weekly on average for one month.
or
 - A2. Three episodes involving physical assault against other people or destruction of property over a one year period.
- B. The degree of aggressiveness expressed is grossly out of proportion to the provocation or any precipitating psychosocial stressors.
- C. The aggressive behavior is generally not premeditated (e.g., is impulsive) and is not committed in order to achieve some tangible objective (e.g., money, power, intimidation, etc.).
- D. The aggressive behavior causes either marked distress in the individual or impairment in occupational or interpersonal functioning.
- E. The aggressive behavior is not better accounted for by another mental disorder (e.g., major depressive/manic/psychotic disorder; ADHD); general medical condition (e.g., head trauma, Alzheimer's Dx); or to the direct physiological effects of a substance.

criteria explicitly require the presence of subjective distress (e.g., in the individual) and/or social or occupational dysfunction in order to specifically link distress/dysfunction to aggressive behavior. (4) IED-IR criteria allow subjects with borderline and/or antisocial personality disorder (BPD/AsPD) to have a comorbid IED diagnosis (i.e., if they otherwise meet the IED-IR criteria, see below). This decision was based on the finding that IED subjects with or without BPD/AsPD are similarly aggressive, and much more aggressive, than non-IED subjects with or without BPD/AsPD. Accordingly, high levels of aggression have been found to be associated with the presence of IED but not the presence of BPD/AsPD. These research criteria for IED have been used in studies of IED in several sites in the United States. Moreover, several of the suggested changes made by 'Research criteria' have been adopted in the text revisions of the current DSM-IV text revision.

criteria for IED, and as many as 6 million or 10 million have met criteria in any 1 month or year, respectively.

Clinical Presentation

Aggressive outbursts in IED have a rapid onset, often without a recognizable prodromal period. Episodes are short-lived – typically less than 30 min – and involve verbal assault, destructive and nondestructive property assault, or physical assault. Aggressive outbursts most commonly occur in response to a minor provocation by a close intimate or associate, and IED subjects may have less severe episodes of verbal and nondestructive property assault in between more severe assaultive/destructive episodes. Episodes are associated with substantial distress, impairment in social functioning, occupational difficulty, and legal or financial problems. In a recent community sample study of more than 9200 individuals, subjects meeting current IED criteria (i.e., defined as three high-severity episodes in the current year) were found to engage in direct interpersonal aggression (67.8%), threatened interpersonal aggression (20.9%), and aggression against objects (11.4%). These subjects reported engaging in, on average, 28 high-severity aggressive acts during their worst year, with two to three lifetime aggressive outbursts requiring medical attention. Mean dollar value of property damage due to IED aggressive outbursts lifetime was approximately \$1600.

Clinical Picture and Course of Illness

Prevalence

Initially IED was described as rare. However, this designation was based on limited empirical research. Four recently published epidemiological studies report that approximately 4–6% of individuals meet lifetime criteria for IED, and 1-month and 1-year point prevalence estimates of IED have been reported to be in the 2–3% range. If so, approximately 16 million Americans have met lifetime

Clinical Example

Roger is a 28-year-old married man who works as a community outreach provider. He was self-referred for anger problems after he found his 4-year-old daughter crying in her room in the wake of a heated argument between Roger and his wife in which Roger punched a wall. Roger acknowledged always being hot tempered, providing examples of getting into shoving matches and two fistfights when playing sports, as well as frequent aggressive behavior (honking horn, screaming at drivers, flipping them off) when driving. His aggressive behavior worsens when he is intoxicated, and he has a history of alcohol abuse. He significantly reduced his alcohol use after the birth of his daughter; despite this he continues to have problems with aggressive behavior. Roger has had to replace his cell phone twice in the past year due to him throwing it in anger. Roger also continues to verbally snap and yell at his wife and occasionally his daughter, which has placed stress on an otherwise happy marriage. He understands that his behavior is excessive, and afterwards often feels guilty and remorseful, but he adds that his anger feels overwhelming at times and that he does not know how to control it.

Quality of Life

High levels of hostility and aggression negatively impact quality of life across several dimensions, including interpersonal relationships, sleep quality, job satisfaction, and health problems. Similarly, the limited data suggest that individuals with IED have more health problems, are more impaired in overall functioning, and are less happy than healthy volunteers or psychiatric controls. Furthermore, their quality of life improves after successful treatment. There are little data on the impact of IED on the quality of life for family members. However, multiple studies have linked witnessing and experiencing aggression in childhood with adverse adult consequences, including intergenerational transmission of aggression.

Age of Onset, Gender and SES

IED appears as early as childhood and peaks in mid-adolescence with a mean age of onset in three separate studies ranging from 13.5 to 18.3 years. In one study, the age of onset was found to occur at a significantly earlier time in males as compared to females. While IED may be more common in males, recent data suggest that IED may occur with a more equal prevalence among men and women. In a large epidemiological survey, sociodemographic variables (e.g., sex, age, race, education, marital, occupational status, and family income) did not differ as a function of IED status.

Comorbidity

Available data suggest that IED is a chronic disorder whose onset precedes other comorbid Axis I disorders. If so, it is unlikely that IED develops into another disorder. More likely, IED promotes the development of other disorders by leading to divorce, financial difficulties, and stressful life experiences that promote onset of other disorders later on in adulthood. In clinical samples, IED has been reported to be highly comorbid with multiple Axis I disorders, including mood disorders, anxiety disorders, and alcohol and other substance-use disorders. In community samples, however, the relationship between current IED and such disorders was only significant for generalized anxiety disorder, alcohol abuse, and any substance-use disorder. The vast majority of subjects reported that IED began at an earlier age than these comorbid conditions.

Familial Correlates

A family history study comparing first-degree relatives of 30 IED, and 20 control, probands found significantly elevated morbid risk for IED in relatives of IED, compared to control, probands (0.26 vs. 0.08, $p < 0.01$). Elevation in the morbid risk for IED was not caused by the presence or absence of comorbid conditions among the IED probands (e.g., history of suicide attempt, major depression, alcoholism, and drug use disorder) and was not due to increases in morbid risk of other non-IED disorders in the relatives (e.g., major depression, alcoholism, drug use disorders, anxiety disorder, any disorder). Accordingly, familial aggregation of IED is not due to an epiphenomenon of the liability of either the proband or the relative to having non-IED comorbid conditions and suggests a clear familial signal. This supports research showing that aggressive behavior is under a substantial degree of genetic influence.

Biology

While laboratory studies clearly show a biobehavioral relationship between aggression and selected brain chemicals (e.g., serotonin), studies in IED, specifically, have been conducted only over the past few years. To date, published data have reported IED subjects as having altered serotonin function compared with non-IED subjects or healthy control subjects. Other studies supporting the IED-serotonin link demonstrate a reduction in: (1) prolactin responses to d-fenfluramine challenge in IED subjects compared with non-IED or healthy control subjects and (2) numbers of platelet 5-HT transporters (via H^3 -paroxetine binding) in IED subjects compared with non-IED or healthy control subjects. These findings are supported by imaging studies. Two fluoro-deoxy-glucose

(FDG) positron emission tomography (PET) studies found low FDG utilization after d,l-fenfluramine challenge in frontal areas of the brain and low FDG utilization after *meta*-chlorophenylpiperazine (*m*-CPP) challenge in the anterior cingulate in IED subjects compared with healthy control participants. A third, ligand-binding study of the serotonin (5-HT) transporter also reports reduced low 5-HT transporter availability in the anterior cingulate in IED versus control subjects. Finally, a functional magnetic resonance imaging (fMRI) study demonstrated increased activation of amygdala, and reduced activation of orbital medial prefrontal cortex, to anger faces in IED subjects as compared to healthy control subjects.

Treatment of IED

Psychopharmacological treatment

Classes of agents shown to have anti-aggressive effects in double-blind, placebo-controlled trials of individuals with primary aggression (i.e., not secondary to psychosis, severe mood disorder, or organic brain syndromes) include mood stabilizers (e.g., lithium), 5-HT reuptake inhibitors (e.g., fluoxetine), and anticonvulsants (e.g., diphenhydantoin and carbamazepine). While noradrenergic (NE) beta-blockers (e.g., propanolol/nadolol) have also been shown to reduce aggression, these agents have exclusively been tested in patient populations with secondary aggression (e.g., mental retardation, organic brain syndromes, etc.). Classes of agents which may have pro-aggressive effects include tricyclic antidepressants (e.g., amitriptyline), benzodiazepines, and stimulant and hallucinatory drugs of abuse (e.g., amphetamines, cocaine, and phencyclidine). Double-blind, placebo-controlled, clinical trials suggest that anti-aggressive efficacy is specific to impulsive, rather than nonimpulsive, aggression.

A double-blind, placebo-controlled trial of fluoxetine on impulsive aggressive behavior in 100 subjects with IED (by research criteria) demonstrated anti-aggressive efficacy for fluoxetine over placebo. This study observed reduction in overt aggressive behavior as reported by subjects, subjective/objective anger/aggression, and a response rate of 70% (CGI scores of much improved or very much improved). Notably, fluoxetine was not associated with any increase in aggression compared with those randomized to placebo. In contrast, placebo was associated with a greater frequency of increased aggression, and increased magnitude of aggression, after randomization compared with fluoxetine treated subjects. While positive in result, only 29% of IED subjects displayed no aggression at end of trial. This indicates that while fluoxetine can reduce impulsive aggressive behavior, remission from IED symptoms may take more than the drug itself. Another placebo-controlled study of IED involving divalproex reported a favorable effect of this

agent on overt aggression but only in IED subjects with comorbid cluster B personality disorder.

Psychotherapeutic Treatments

The authors recently completed a psychotherapy outcome study comparing the efficacy of a 12-week multicomponent CBT treatment presented in either group or individual format to a wait-list control group in the treatment of IED ($N = 45$). The treatment was modeled after the Cognitive Restructuring, Relaxation and Coping Skills Training (CRCST) treatment developed to treat anger, but was modified to serve as a more appropriate treatment for aggressive individuals (e.g., extend treatment from 8 to 12 session, include a time-out technique, and increase the emphasis on the prevention of and relapse to aggression). Aggression, anger, and associated symptoms were assessed at baseline, mid-treatment, posttreatment, and 3-month follow-up. Relative to the wait-list condition, both group and individual CRCST improved anger control and reduced aggression, anger, hostile thinking, and depressive symptoms. Post-treatment effect sizes were large and were maintained at 3-month follow-up, providing initial support for the efficacy of CBT in the treatment of IED.

Other Issues Regarding Treatment of IED

There have been no published studies regarding length of treatment for IED. Our experience is that impulsive aggression is a trait that can be suppressed, but not eliminated, by medication. We have found that within about 1 month of discontinuing fluoxetine that patients with impulsive aggressive behavior often demonstrate a return of impulsive aggressive behavior to pretreatment levels. The one study that examined the effect of lithium on impulsive aggression in prison inmates found that impulsive aggressive behavior returned to pretreatment level within 1 month of being switched to placebo. This finding contrasts with our findings with CRCST. CRCST effects continue at least 3 months after active treatment has ended, probably because treatment components (relaxation training, cognitive restructuring, and coping skills training) have been incorporated into the individual's life and are still active. In contrast, once medication is no longer in the body, its effects on behavior typically end.

There have been no published studies regarding the effect of combining modalities of treatment. Examining our own data with fluoxetine and CRCST in IED subjects, we note that both modalities yield a similar magnitude of improvement in outcome measures (e.g., ~30% remission and ~15% partial remission from IED). Since these two modalities work through different mechanisms, we would hypothesize that together they would be more effective than either alone. Our clinical

experience is consistent with this idea but these data are anecdotal. Whether medication or CRCST should be first-line may depend, in part, on the patient since some prefer medication (some individuals perceive this as easier) and others prefer psychotherapeutic treatment (some individuals wish to avoid being placed on medication). Severity of aggression may also influence choice of modality and one can envision medication (and/or both medication and CRCST) as being first-line in cases of severe aggressive behavior. While an attractive strategy, there are no currently little empiric data to support either approach at this time.

Glossary

Antisocial personality disorder – A psychiatric condition characterized by persistent disregard and violation of the rights of others and what society considers right and wrong.

Escitalopram – A drug in the selective serotonin reuptake inhibitor (SSRI) class which is an isomer of citalopram and is used to treat depression and anxiety.

Opioid antagonist – A class of medications which bind to the opioid receptors in the brain, effectively blocking the effects of opiates (e.g., heroin and morphine). Examples of this class of medication include naloxone hydrochloride and naltrexone hydrochloride.

Serotonergic dysfunction – Problems in the neurotransmission of serotonin.

Ventromedial prefrontal cortex – A brain region that contributes to decision-making and risk-taking.

White matter – Brain tissue consisting of myelinated nerve fibers (e.g., axons).

include significant legal consequences, reduced quality of life, and impaired functioning. Suicide attempts are also common and have been reported in 25–30% of persons in treatment for kleptomania.

Estimates of more than \$13 billion of retail sales lost due to shoplifting have been documented by the National Association for Shoplifting Prevention in 2009. Recent data provided through the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) illustrate rates of lifetime shoplifting of 11.3% in the United States. Historically, the terms ‘shoplifting’ and ‘kleptomania’ have been used interchangeably but significant differences separate someone with kleptomania from one who shoplifts. Shoplifting is defined as stealing items from a store without a specific motivating factor. Kleptomania, on the other hand, is defined as a psychiatric diagnosis characterized by a diminished ability to resist recurrent impulses to steal objects that are not needed for their monetary or personal use. Although kleptomania has been documented for almost two centuries, it remains a poorly understood disorder with limited data regarding neurobiology or treatment. This article details what is currently known about the clinical characteristics, neurobiology, and treatment of kleptomania.

Introduction

Kleptomania is a psychiatric disorder characterized by persistent and recurrent patterns of stealing. The *Diagnostic and Statistical Manual* (Fourth Edition) defines kleptomania by the following criteria: (1) recurrent failure to resist impulses to steal objects that are not needed for personal use or for their monetary value; (2) increasing sense of tension immediately before committing the theft; (3) pleasure, gratification, or relief at the time of committing the theft; (4) the stealing is not committed to express anger or vengeance and is not in response to a delusion or a hallucination; and (5) the stealing is not better accounted for by conduct disorder, a manic episode, or antisocial personality disorder. Psychosocial problems are common among individuals with kleptomania and

History

Reports of uncontrolled, impulsive shoplifting behavior date back centuries and gained notoriety in the nineteenth century with the advent of the department store which made a variety of goods available in a concentrated area. Upper-middle-class women were caught stealing from these stores, creating a media-frenzy in the newspapers of both North America and Europe describing unbridled shoplifting behavior. It was at this time that the medical community began attempts to explain this behavior.

First coined in 1816 by the Swiss physician Andre Matthey, the term 'klopmannie' was derived from the Greek words 'kleptein' (to steal) and 'mania' (insanity) to describe a person who could not or did not control their stealing behavior. In 1838, Jean-Etienne Esquirol wrote the first detailed description of this seemingly nonvolitional and irresistible behavior. This article on kleptomania was important as it distinguished a person with this disorder from those who steal due to a lack of moral character.

Because of the extensive newspaper reports in the nineteenth century depicting women stealing, the medical community initially attributed this 'exclusively female' behavior to the female reproductive system, specifically uterine diseases and premenstrual tension. Following the dismissal of this explanation in the early twentieth century, partially due to the observation that more men were presenting with similar behavior, nearly all research pertaining to kleptomania ceased. The first *Diagnostic Manual of Mental Disorders* (DSM-I) in 1952 did not include kleptomania as a formal diagnostic illness but rather as a supplementary term. Kleptomania was not included in DSM-II. In 1980, DSM-III categorized kleptomania as an impulsecontrol disorder not elsewhere classified, the same clinical diagnostic category it currently holds in the DSM-IV-TR.

Epidemiology

Although kleptomania has been documented in case studies and newspaper articles for centuries, relatively little is known about its prevalence in the general population. In the only study assessing rates in a general community sample using DSM-IV criteria, researchers examined 791 college students and found that although 28.6% reported having stolen an item in his/her lifetime, only 0.4% met criteria for kleptomania.

Other studies have examined the rates of kleptomania in treatment samples. An adult psychiatric inpatient study ($n=204$) revealed lifetime rates of 9.3% ($n=19$) while 7.8% ($n=16$) had symptoms consistent with a current diagnosis of kleptomania. In a recent study of 102 adolescent psychiatric inpatients, researchers noted that 9 (8.8%) met diagnostic criteria for current kleptomania.

The prevalence of kleptomania in specific psychiatric populations has also been assessed. A study of 79 patients with alcohol dependence found that 3.8% ($n=3$) endorsed symptoms consistent with kleptomania while a study of 107 depressed patients found that 3.7% ($n=4$) suffered from kleptomania. In two studies of individuals with pathological gambling, rates of co-occurring kleptomania were 2.1% and 5%.

A Comparison of Kleptomania and Shoplifting

Individuals with kleptomania differ from 'ordinary' shoplifters in that they do not steal for personal gain, but rather for symptomatic relief. It is estimated that more than \$13 billion worth of goods are stolen from retailers each year, which translates into more than \$35 million per day. Vast majority of shoplifters are described as amateurs with sporadic activity and no known history of criminal activity who steal for their own consumption rather than for resale. Studies involving apprehended, legally referred shoplifters indicate that shoplifting may be more common in women (ranging from 52% to 100%) than in men. However as with kleptomania, these rates may be falsely elevated because women may be more likely to be referred for psychiatric evaluation or seek psychiatric treatment than are men. Male shoplifters are more likely to be apprehended during adolescence and early adulthood, whereas women shoplifters are more likely to be apprehended during puberty/early adulthood and around the age of menopause. Some of these same studies also revealed that shoplifting was not related to lower socio-economic level and that most stole for personal gain. Rates of kleptomania among people who are arrested for shoplifting have ranged from 0% to 8%. A study that compared individuals with kleptomania to shoplifters interviewed directly after apprehension found that 58% of the shoplifters were male compared to only 32.4% of kleptomania patients. The mean age among shoplifters was 27 years and among the kleptomaniacs, 41 years. Although none of the shoplifters met DSM criteria for kleptomania, approximately one-fifth had not stolen for personal use and had eventually discarded the object. The study also found that both groups reported the same degree of impulsivity and 'a feeling of not being oneself.' On the other hand, individuals with kleptomania reported a relatively greater number of previous thefts compared to shoplifters, a finding consistent with a compulsive aspect of kleptomania.

Childhood and Adolescent Stealing

Both typical shoplifting and kleptomania may start at a relatively early age. A young child generally has little, if any, concept of stealing – for him or her, desiring or wanting means possession of the object. By the age of 6 or 7, children begin to realize they are doing something wrong when they take something that does not belong to them. Children may steal because they are unhappy, lonesome, jealous, fearful, or craving attention. For older children and adolescents, stealing can be used to gain acceptance from a group, but is also a strong predictor

of future delinquency and a marker for families lacking in warmth and personal stimulation. A strong attachment to parents decreases involvement in shoplifting.

Overall, studies have shown that roughly 40% of apprehended shoplifters are adolescents. A study involving almost 1700 adolescents found that 37% reported shoplifting at least once in the prior 12 months. The percentage of subjects acknowledging shoplifting peaked around the 10th grade and then declined, consistent with official crime statistics. One hypothesis for adolescent theft involves multiple, non-mutually-exclusive factors involving a function of immaturity during a stressful transition to adulthood, an inability to purchase certain items, and an increased opportunity (the steepest gain of independence occurs around age 16 when most adolescents are allowed to drive and work). On the other hand, adolescents report that they shoplift because of the associated novelty and risk, for social reasons, and because they desire for the stolen items. Additionally, no relationship has been found between family occupational status and adolescent shoplifting. How many of these adolescent shoplifters currently suffer from, or will develop a problem with, kleptomania is not clear. Longitudinal studies of this nature, to help clinicians better assess who should receive treatment, are needed.

Clinical Characteristics of Kleptomania

Case Vignette

Jennifer, a 54-year-old married female, described a history of uncontrollable shoplifting beginning at about age 16 years of age. She started by stealing a scarf ‘in a dare’ from a friend but found the ‘high’ was intense and overwhelming. Over the course of about 1 year, she reports that she progressed from occasional theft to being unable to control herself when she entered a store. Although she has had periods of a year or two without any shoplifting, Jennifer reports that she currently shoplifts once or twice a week. She describes a ‘rush’ each time she steals. In fact, the ‘rush is short-lived’ and when she leaves the store she usually throws away the stolen item or leaves it outside the store. Although she usually steals clothing, she denies really wanting the items and she could easily afford to buy them. Jennifer also describes daily thoughts and urges to shoplift that interfere with her ability to concentrate at work. In addition, she has never told her husband about her behavior. The behavior and the lying cause significant depression and feelings of worthless. Jennifer tried to commit suicide on one occasion, never telling anyone the reason behind her suicide attempt. She also reports drinking in the evening to ‘deaden’ the pain and guilt over her shoplifting.

Kleptomania usually begins in adolescence or early adulthood, with males tending to start at an earlier age,

though kleptomania has been documented in patients as young as 4 years old and as old as 77 years old. Although prospective studies are largely lacking, kleptomania appears to follow a similar trajectory as substance dependence, with high rates in adolescent and young adult groups, lower rates in older adults, and periods of abstinence and relapse.

One study found that individuals with kleptomania stole, on average, twice or thrice a week. The places from which items are stolen and the value of those stolen items generally change over time for those with kleptomania. Although stealing from stores is the most common place of theft, stealing from friends, relatives, and work is not uncommon. The objects stolen by the individual are usually affordable and are typically discarded, hoarded, thrown away, discreetly returned to the store, or given away. Most individuals with kleptomania report that the value of a stolen item increases over time. Examples of commonly stolen objects include sweets, newspapers, food, books, and clothes. The excitement and rush associated with the act of committing the theft and getting away with it are typically immediately followed by feelings of shame and remorse.

Gender Differences

Clinical samples of patients have reported that two-thirds of patients with kleptomania are female. Women with kleptomania are more likely to be married, tend to have a later onset of shoplifting, are more likely to steal household items, and hoard the items stolen. They are also more likely to have a comorbid eating disorder. Men with kleptomania are more likely to steal electronic goods and more likely to have another co-occurring impulse control disorder (most commonly intermittent explosive disorder or compulsive sexual behavior).

Quality of Life Issues and Legal Consequences

Individuals with kleptomania endorse a significant amount of impairment in their daily lives. Independent of comorbidity, they report significantly poorer life satisfaction compared to a general, nonclinical adult sample. Perhaps because many individuals with kleptomania report significant amounts of shame and embarrassment, patients may not tell their significant other about the behavior or endorse kleptomania symptoms until after being arrested or after responding to treating for a co-occurring psychiatric condition.

Along with impairment in the social and occupational realms, legal repercussions are common for individuals with kleptomania. Among clinical samples of patients who meet criteria for kleptomania, a majority have been arrested. In fact, many individuals with kleptomania

have been apprehended multiple times. Because kleptomania often goes undiagnosed for years, it is important upon initial presentation to consider the involvement and education of psychiatric, psychological, and legal professionals.

Psychiatric Comorbidity

Comorbid Axis I psychiatric conditions are common in kleptomania. Substance use (15–50%), eating (9–25%), impulse control (20–47%), and mood (45–100%) disorders are frequently observed. Suicidal ideation among individuals with kleptomania is common.

Personality disorders also appear to be common in kleptomania. High frequencies of paranoid (17.9%), schizoid (10.7%), and borderline (10.3%) personalities have been reported in individuals with kleptomania.

Family History

Few family history and genetics studies of kleptomania have been performed. In the only study to use a control group, the first-degree relatives of subjects with kleptomania had a significantly higher frequency of alcoholism (15.1%) as compared to healthy controls (5.1%). Other studies have reported frequent depression, bipolar, and obsessive-compulsive disorder in the first-degree relatives of individuals with kleptomania.

Neurobiology

Although the etiology of kleptomania is unknown, serotonergic dysfunction in the ventromedial prefrontal cortex has been suggested as one contributing factor underlying the poor decision making seen in individuals with kleptomania. One study examining the platelet serotonin transporter in patients with kleptomania found that the number of platelet 5-HT transporters, evaluated by means of binding of ³H-paroxetine, was lower in kleptomania subjects compared to healthy controls, thereby suggesting some nonspecific serotonergic dysfunction.

Neurocognitive assessment of women with kleptomania revealed, as a group, no significant deficits in tests of frontal lobe functioning when compared to normative values. Those individuals with greater kleptomania symptom severity, however, had significantly below-average scores on at least one measure of executive functioning. Significantly higher rates of cognitive impulsivity were found in kleptomania subjects compared to a control group of psychiatric patients without kleptomania.

Damage to the orbitofrontal–subcortical circuits of the brain has been reported to result in kleptomania. Neuroimaging techniques have demonstrated decreased white matter microstructural integrity in the ventral-medial frontal brain regions of individuals with kleptomania compared to controls. These findings are consistent with reports of increased impulsivity in individuals with kleptomania. These studies also support the hypothesis that specific brain-based differences contribute to some individuals with kleptomania demonstrating a diminished ability to control their impulses to steal.

Treatment

There are limited data regarding effective treatments for kleptomania. Most available data are confined to case reports and case series with small samples of subjects. Although there are no medications approved by the Food and Drug Administration in the United States to treat kleptomania, pharmacotherapy and psychotherapy have shown some early promise in treating this disorder.

Pharmacotherapy

Case series and case reports have suggested a benefit of mono- or combination pharmacotherapy in the treatment of kleptomania. In the case of monotherapy, the following medications have shown preliminary benefit: topiramate, naltrexone, escitalopram, paroxetine, fluoxetine, valproic acid, and fluvoxamine.

In terms of combination therapy the following have been preliminarily reported as successful in treating kleptomania: paroxetine plus valproic acid plus naltrexone; topiramate plus paroxetine; naltrexone plus venlafaxine; lithium plus fluoxetine; trazodone plus tranylcypromine; sertraline plus methylphenidate; and imipramine plus fluoxetine.

To date, there are only two published trials of pharmacotherapy for the treatment of kleptomania. In the first of these trials, 24 subjects received open-label escitalopram. After 7 weeks of treatment, escitalopram was shown to reduce shoplifting urges in 19 (79%) of the participants. Responders were then randomized to a double-blind discontinuation phase where patients either received active medication or placebo. At the end of this portion of the study, no significant differences were seen between active medication and placebo as 50% of those on placebo and 43% on active medication maintained their improvement from the open-label portion of the study.

The other open-label study involved the use of the opioid antagonist naltrexone in the treatment of kleptomania. After 12 weeks, at a mean dose of 145 mg/day, 20% of subjects reported full remission of symptoms and 80% overall had significant improvement in their shoplifting urges and behavior.

A naturalistic study of naltrexone produced similar results. Seventeen subjects were followed over a 3-year period while being treated with naltrexone (mean dose of 135.3 mg/day). The study showed that 41% of subjects reported complete abstinence from stealing and 76% of subjects reported significant reductions in their urges to steal.

Pharmacotherapy and Combination Treatments

Although there have been no studies evaluating the efficacy of psychotherapy for kleptomania, case reports have illustrated the benefit of combining medication with cognitive-behavioral therapy (CBT). Aversion therapy, covert sensitization, and systematic desensitization are CBT techniques shown in case reports to benefit patients with kleptomania. In addition, techniques such as a self-imposed ban on shopping appear to be the most common intervention which allows the patient to treat the behavior without seeking help from a medical professional.

Promising examples of combined psychotherapy and pharmacology for the treatment of kleptomania include: fluoxetine 40 mg/day combined with supportive psychotherapy; fluoxetine 40 mg/day combined with problem-oriented psychotherapy; fluoxetine 20 mg/day plus cognitive therapy; combination of CBT, sertraline 50 mg/day, and a self-imposed shopping ban; and a combination of CBT and citalopram 40 mg/day.

Conclusions

Kleptomania, a disorder currently receiving scant attention from the psychiatric community, may present as a chronic illness for many individuals and cause significant psychological, social, and legal repercussions. Since presentation specifically for kleptomania is rare, it is important that clinicians recognize the disorder and screen patients appropriately. Various treatments have been helpful in case studies and small treatment studies but more research examining etiology and treatment is needed.

Glossary

Body mass index (BMI) – A ratio derived by dividing weight in kilograms by height in meters-squared; useful in the determination of overweight and obesity.

Bulimia nervosa – An eating disorder characterized by bingeing and purging of food.

Cannabinoid – Relating to cannabis. For example, cannabinoid receptors bind cannabis when the drug is introduced in the body. Cannabinoid receptors have been implicated in regulating hunger and this feature may explain patterns of eating behavior (e.g., having the munchies) when smoking cannabis.

Cardiac valvulopathy – A disease involving the valves of the heart.

Diagnostic and statistical manual – A book widely used in psychiatry that categorizes and defines mental health disorders.

FDA – Food and Drug Administration, the US federal agency that regulates drugs and related products, including approving drugs for specific therapeutic indications.

Lipase – An enzyme that breaks down lipids or fats.

Obesity – The condition defined by a BMI ratio above 30; often marked by a co-occurrence of such health complications as hypertension, cardiovascular disease, and type II diabetes.

Overweight – The condition defined by a BMI ratio between 25 and 30; often associated with adverse health measures, albeit to a lesser extent than with obesity.

Type II diabetes – The form of diabetes that typically has its onset in adulthood and is associated with obesity. Type II contrasts with type I diabetes that typically has a childhood onset and is typically not associated with obesity as it has a different pathophysiology.

Introduction

Obesity represents a major public health concern. Although questions remain regarding optimal prevention and treatment approaches, research has illuminated many characteristics of obesity. Binge eating disorder (BED) is characterized by seemingly impulsive or excessive bouts of eating, and BED typically co-occurs with obesity. Both obesity and BED are addressed in the following sections.

Epidemiology of Obesity

Several calculated ratios are used to define overweight states and obesity. The body mass index (BMI) – which is derived by dividing weight in kilograms by height in meters-squared – is the most widely accepted and used measure for the determination and classification of obesity and overweight. Using this system, a BMI value in the 19–25 range generally indicates a healthy, normal weight, while a ratio of 25–30 defines overweight, and a calculation over 30 classifies obesity. Obesity has been subclassified into three types according to BMI: type I (30–34.9); type II (35–39.9), and type III or extreme (≥ 40). However, BMI might not accurately reflect obesity status in some cases; certain athletes, for example, may have high BMIs related to increased muscle mass. The waist-to-hip ratio serves as another useful tool in the diagnosis of overweight and obese states, with measures over 88 cm in women and greater than 102 cm in men indicating abdominal obesity.

According to the World Health Organization (WHO), the global rate of obesity continues to increase at an alarming rate. Over 60% of the US adult population is now classified as overweight. Similar findings are indicated in Europe, Canada, and growing numbers of South American countries. Such startling obesity rates are not

localized to Western, industrialized nations. Rather, a growing tendency toward obesity has also been seen in several African nations – despite strained regional demands on limited food supplies – particularly among black African women in areas that have recently experienced socioeconomic growth and increased urbanization. Many Asian countries, also, have demonstrated similar statistics. By WHO estimates, almost 10% of the global population meets the criteria for obesity.

Clinical Characteristics and Co-Occurring Disorders

The increasing prevalence of obesity has been linked with a rise in illness and death from obesity-related health complications. Over a quarter of a million annual obesity-related deaths occur in the United States alone. Being overweight or obese has been linked to multiple health complications including hypertension, cardiovascular disease, stroke, heart attack, congestive heart failure, hypercholesterolemia, type II diabetes, osteoarthritis, obstructive sleep apnea, and certain cancers.

In addition to lowering life expectancy, the relationship of obesity to disease may negatively impact quality of life. Overweight or obese individuals experience higher levels of stigmatization and social discrimination than those falling within healthy-weight ranges, perhaps accounting for the markedly increased prevalence of anxiety and affective disorders, especially depression, in overweight individuals as compared to their healthy-weight counterparts.

Binge Eating Disorder

BED is characterized by episodes of extreme or out-of-control eating. Majority of individuals with BED are either overweight or obese. BED has been proposed as a separate diagnostic category distinct from obesity and bulimia nervosa. Currently, BED is recognized as a provisional diagnosis in need of further study in the *Diagnostic and Statistical Manual of Mental Disorder*, Edition 4, Text Revision (DSM-IV-TR) and is defined in Appendix B by the following criteria:

- recurrent episodes of binge eating in which an individual consumes an abnormally large quantity in a short time; these episodes are typically associated with eating more rapidly than normal, eating until feeling uncomfortably full, eating in the absence of physical hunger, or eating alone due to embarrassment;
- subjective experience of loss of control over eating behaviors during binge-eating;

- distress regarding eating behavior, often marked by feelings of guilt, disgust, or depression after overeating, as well as concern over weight and shape.

Importantly, the occurrence of such behaviors is not seen in conjunction with regular compensatory measures in response to binge episodes, such as purging, laxative abuse, or excessive exercise, thereby distinguishing BED from bulimia nervosa.

Although BED is associated with obesity, findings have indicated differences between overweight/obese individuals with and without BED. Individuals with BED more frequently demonstrate co-occurring Axis I and Axis II psychiatric conditions than do overweight/obese individuals without BED, particularly with respect to major depression and borderline personality disorder. The association between binge eating and depression seems to operate bidirectionally: while the onset of binge eating may follow periods of depression in many individuals, affective disorders often have their onset prior to BED. Other diagnoses frequently seen in people with BED include other mood disorders, obsessive-compulsive personality disorder, and avoidant personality disorder. Body image disturbances and weight and shape concerns also seem more prominent in obese individuals with BED as compared to those without BED.

Although methodological constraints in the identification of BED (such as the inconsistent and varied use of assessment techniques across different studies) have hindered the precise determination of BED prevalence in the general population, it is estimated that approximately 3% of all adults in the United States, and roughly 8% of all obese adults, suffer from BED. The disorder is seen across ethnic and racial groups, with BED having a slightly higher, although not statistically significant, prevalence in women than in men. Such gender-related differences, however, should be considered preliminary as much of the existing BED research has thus far been limited to exclusively female samples.

As few longitudinal studies have been performed, the natural history of BED is poorly understood. Among clinical samples, many individuals with BED report a long history of the disorder, with a fluctuating course defined by intermittent remission and recurrence.

Etiology of Obesity and Binge Eating Disorder

Although many questions exist regarding the etiologies of obesity and BED, genetic, neurobiological, and behavioral features that may influence the course of these disorders have been identified. From a physiological perspective, obesity may be described as a homeostatic energy

imbalance in which energy intake significantly exceeds energy expenditure. This imbalance, in turn, is modulated by a complex interaction of factors regulating hunger, satiety, and metabolic rate. Specific genetic factors, when combined with certain environmental factors (such as high-caloric diets, low physical activity, or certain *in utero* factors) may significantly increase the likelihood of developing obesity and BED.

Genetics

Twin and family studies investigating the heritability of obesity and BED suggest significant genetic contributions. Obesity was found to occur twice as frequently among individuals with at least one relative who was overweight or obese. These findings varied with severity of obesity: individuals whose relatives fell within the top 1% of BMI distributions were up to 5 times as likely to be overweight or obese as individuals in the general population.

Similar studies suggest a heritability component of approximately 50% in BED. However, only a limited number of studies have thus far explored the genetic transmission of BED, and methodological concerns – such as the heterogeneity of criteria used for defining BED across investigations – leave precise heritability estimates in question.

Molecular investigations have identified associations between extreme obesity and specific genetic factors. A variant of the gene encoding the melanocortin-4 receptor (Mc4r) has been identified in approximately 3–5% of all morbidly obese individuals. However, not all individuals demonstrating this genetic variation are found to be obese, suggesting that environmental factors and/or multiple genes – such as those contributing toward metabolic regulation, energy conversion, and fat storage – may contribute to determining an individual's propensity to obesity. For example, individuals with overweight or obese spouses or cohabitating partners are frequently overweight or obese themselves; thus, existing data suggest a complex interaction between genetic and environmental factors.

Neuroanatomical and Neurochemical Features

Factors governing hunger, food intake, and body weight play important roles in the etiology of obesity. Multiple appetite-related hormones and signaling factors act on receptors in the hypothalamus to trigger hunger responses and indicate satiety upon sufficient food absorption. These signaling factors include leptin, ghrelin, serotonin, dopamine, norepinephrine (NE), corticotropin-releasing factor, neuropeptide Y, gonadotropin-releasing hormone, and thyroid-stimulating hormone. Dysfunction involving any of these factors or the excitatory or inhibitory pathways they influence may potentially impact upon food-intake regulation and contribute to the development of obesity.

Other potential neurochemical elements implicated in the etiology of obesity include dopamine and related systems that influence motivational and emotional states, responses to reward, and reinforcement of behaviors. Prenatal environmental factors may also influence metabolic functioning, with extreme caloric deprivation *in utero*, for example, showing an association with high BMI in childhood.

While no specific neurochemical or structural anomalies have as yet been definitively identified in BED, it has been hypothesized that dysregulation of serotonin pathways regulating mood, appetite, and impulse control may contribute to the disorder. Although few imaging studies have been conducted thus far in BED, early functional imaging data suggest reduced serotonin transporter binding in obese individuals with BED. When exposed to food cues, individuals with BED report a greater subjective desire to eat and demonstrate greater regional cerebral blood flow in the left as compared to the right hemisphere, particularly in frontal brain regions, perhaps suggesting increased reinforcement sensitivity to food-based reward cues in BED. Notably, these findings also seem to indicate that activation patterns in individuals suffering from BED also differ significantly from those seen in subjects diagnosed with bulimia nervosa. Although further imaging work in BED remains to be done, such differential responses to visual food cues between BED and bulimia nervosa subjects seem to highlight the distinctiveness of BED as a condition independent of BN.

Neurocognitive and Behavioral Features

While multiple influences impact disease etiology, environmental factors and lifestyle choices (governed by motivational behavioral decision-making) seem particularly important in the development of obesity. Among these behavioral elements, dietary habits, eating patterns, and physical activity seem particularly relevant.

Obesity co-occurs frequently with mental health disorders, and this relationship seems especially salient for women. In particular, depression and anxiety are reported at higher rates among individuals who are overweight or obese, and the extent to which this relationship reflects genetic influences, environmental contributions such as those related to stigmatization and social discrimination, or an interaction between genetic and environmental factors remains to be determined.

While an imbalance between energy intake and expenditure may summarize obesity's etiology, caloric intake does not in, and of, itself predict obesity. Rather, the nutritional nature of food eaten seems particularly important, with BMI correlating with dietary fat consumption.

Decreased physical activity is also associated with obesity. Lifestyle changes over the past few decades include substantially decreased levels of average daily physical activity. Frequent usage of motorized

transportation, for example, has drastically reduced the reliance on more active methods of travel such as walking or cycling. Daily television viewing hours have significantly increased in many industrialized nations. These factors may contribute to the rapidly increasing rates of childhood obesity.

Factors associated with BED include adverse childhood experiences, including physical or sexual abuse, family problems, bullying, and teasing or negative criticism about weight, shape, or eating. These findings suggest that binge eating may function as a type of maladaptive emotional coping mechanism.

Treatment of Obesity and BED

Today, the three most widely accepted strategies for the treatment of obesity and BED are behavioral therapies such as cognitive behavioral restructuring (often employed in conjunction with training for healthier diet and increased physical activity), pharmacotherapy, and, in extreme cases of obesity, surgery.

Cognitive Behavioral Treatment of Obesity

A goal-oriented treatment strategy focusing on the direct modification of dietary and exercise habits, cognitive behavioral therapy (CBT) is widely used in the treatment of obesity. With a clearly defined objective of behavioral change, this approach centers on building new skill sets and advocates steady, reasonable progress to change, rather than sudden, drastic (and typically short-lived) behavioral modification. Cognitive behavioral approaches for obesity often include a nutritional education component and strategies for increasing physical activity.

Cognitive restructuring is also typically incorporated within a CBT program to minimize self-defeating thoughts or unrealistic goals which, when not met, may deflate self-confidence and hinder treatment efficacy. The strengthening of skill sets such as communication and self-control in situations which have previously led to overeating is also addressed. Special attention is often given to teaching self-monitoring, or the thoughtful observation of one's behavior, especially with respect to food selection and intake, physical activity, and environmental and emotional cues associated with periods of overeating. By focusing on the development of such skills, CBT in the treatment of obesity aims to help individuals understand circumstances and motivations which may lead to overeating and learn to use a variety of different problem-solving strategies to recognize and avoid such lapses in the future, thereby helping patients gain improved control over eating behaviors.

Behavioral modifications of diet and exercise are presented to help individuals reach a reasonable weight loss

goal. Through the course of treatment, individuals learn the importance of well-balanced diets and are encouraged to gradually modify eating patterns to establish healthier, more nutritious eating habits. An integrated exercise component is perhaps one of the most critical aspects of a CBT program for obesity, as sustained increased physical activity seems to be a strong predictor of long-term weight control. Lifestyle changes which may directly lead to increased activity, such as encouraging using the stairs instead of an elevator or walking to a nearby destination instead of riding in the car, are generally advocated over the sudden introduction of more high-intensity exercise approaches. Such small behavioral changes leading to increased energy expenditure have proven more successful in encouraging a long-term commitment to habitual activity.

CBT has shown short-term efficiency in terms of weight loss, with many individuals losing an average of 10% of their initial weight in the short term, although further research remains necessary to examine the long-term success of such treatment strategies. Preliminary findings suggest a typical weight regain of approximately one-third of initial loss in the first year following treatment. Furthermore, almost 50% of patients completing a CBT program for obesity return to baseline weight within 5 years. While studies suggest that follow-up weight-maintenance programs may help individuals continue to utilize weight control skills by emphasizing positive coping with slips and relapses, such courses seem to delay, not prevent, weight regain in the future. To this end, the incorporation of a therapeutic pharmacological component may prove useful in the continued treatment of obesity.

CBT Treatment of BED

Arguably even more so than in obesity, CBT appears helpful for individuals with BED. Because BED shares features with bulimia nervosa, some treatment approaches for BED have been modeled after those for bulimia nervosa.

While focusing primarily on the reduction and control of binge eating episodes, CBT in BED aims to improve an individual's body image and simultaneously address co-occurring psychological disorders. Toward these ends, structured patterns of food intake may be emphasized with the specific goal of reducing instances of binge eating. Concurrently, cognitive restructuring techniques may be employed to help reshape an individual's often negative attitudes toward weight, shape, body image, and food in general. Like with CBT in obesity, other elements may include the teaching of self-monitoring skills, nutritional education, and useful techniques for relapse prevention.

Weight loss, while also important in CBT for BED, is often postponed until an effort has been made toward controlling binge eating behavior. Thus, in addition to nutritional education and an emphasis on regular, structured eating habits, CBT in BED may encourage exercise and increased physical activity. CBT has shown positive results in the treatment of BED, although, as with the treatment of obesity, there may exist limited long-term success in maintaining weight loss and controlling binge eating in obese individuals with BED.

In addition to CBT, other psychotherapy strategies, including interpersonal and dialectical behavior therapy (DBT), have shown promise in the treatment of BED. Modeled after therapeutic treatment programs for depression, interpersonal therapy (IPT) aims to address negative mood and interpersonal conflict arising from repeated episodes of binge eating. DBT, in turn, is structured on the basis of an affect regulation model of binge eating. Under this paradigm, binge episodes are viewed as maladaptive strategies for coping with unpleasant affect. Therefore, DBT aims to help individuals learn to regulate emotion by using healthier coping mechanisms. While both techniques have shown some efficacy in reducing the frequency of binge eating, further investigation is necessary to optimize treatment strategies for BED.

Pharmacological Treatment of Obesity

Pharmacotherapies for obesity might be broadly categorized into two groups: drugs that produce weight loss by interfering with intestinal digestion of fat and those that lead to weight reduction through appetite suppression or other central, brain-based mechanisms.

Of the lipase-inhibiting drugs, orlistat is currently the most widely prescribed. Treatment programs incorporating orlistat have shown modest weight reductions in obese patients and may help reduce the risk of type II diabetes. Due to its mechanism of action, orlistat is not recommended for individuals whose dietary intake is composed of less than 30% fat, as little weight loss is typically seen when these subjects are treated with the drug. Adverse events seen with the use of orlistat may include a decrease in absorption of fat-soluble vitamins presumably related to the drug's inhibition of intestinal triglyceride digestion.

The appetite-suppressing class of drugs, in contrast, reduces weight in obesity by decreasing food intake through several different paths of action. Benzphetamine, phendimetrazine, and diethylpropion stimulate the release of NE and have only been approved by Food and Drug Administration (FDA) for short-term use. Rimonabant, a cannabinoid antagonist which binds CB1a receptors, is indicated for use as an anti-obesity agent. Mazindol acts by blocking NE reuptake, and sibutramine – which has approval for long-term, maintenance

treatment of obesity – operates by blocking both NE and serotonin (5-HT) reuptake. Adverse effects related to appetite-suppressing drugs vary and may include dry mouth, constipation, and insomnia. Sibutramine may also produce a small but medically significant increase in pulse and blood pressure, therefore warranting careful observation and contraindicating the drug's use in some individuals with hypertension and heart disease.

In addition to the lipase inhibitors and appetite suppressants currently in use for the treatment of obesity, several other drugs are actively being explored for their potential efficacy. Not currently approved for weight loss, bupropion has been associated with weight loss in the treatment of depression, perhaps related to the drug's noradrenergic properties. Topiramate, a carbonic anhydrase inhibitor used in the treatment of epilepsy and bipolar disorder, has also been associated with weight loss. Antagonists to the melanin-concentrating hormone peptide receptor – which are found primarily in the lateral hypothalamus and regulate food intake – also present a potential future course in the treatment of obesity.

While current and developing pharmacotherapy approaches offer encouraging prospects, drug therapy courses are not without complications and undesirable consequences. For example, fenfluramine, dexfenfluramine, and phentermine have been associated with instances of cardiac valvulopathy and withdrawn from the market. The prescription of other drugs, especially amphetamines and methamphetamines which decrease body weight by stimulating thermogenesis and reducing appetite, should be carefully considered given their addictive potential.

Although pharmacotherapy has shown efficacy in the treatment of obesity, the most effective strategy for the treatment of obesity may involve the combination of medication and behavioral interventions, like CBT, that integrate elements of dietary modification and increased physical activity.

Pharmacological Treatment of BED

While psychotherapeutic approaches such as CBT, IPT, and DBT have shown efficacy in reducing binge frequency, they have demonstrated little success in long-term maintenance of weight loss in BED. To this end, the pursuit of pharmacological approaches to treating BED has been examined.

Although no definitive pharmacological treatment has yet been established for the treatment of BED, at least three different classes are being investigated: serotonergic and noradrenergic drugs used in the treatment of depression, appetite suppressants currently used in the treatment of obesity, and anticonvulsants which have shown efficacy in the treatment of bipolar disorder.

Selective serotonin reuptake inhibitor (SSRI) antidepressant medications, including fluoxetine, fluvoxamine, sertraline, and citalopram, have been found to reduce the frequency of bingeing episodes and contribute toward a decrease in body weight. Tricyclic antidepressants, such as desipramine and imipramine, which block the reuptake of NE, have also shown some efficacy in the treatment of BED.

In addition to antidepressant medications, centrally acting appetite suppressants that have serotonergic and noradrenergic mechanisms of action, such as sibutramine, have shown some preliminary success in the treatment of BED. Furthermore, anticonvulsants have been associated with modest reductions in both weight and frequency of binge episodes in preliminary investigations. Zonisamide, for example, has shown peripheral weight loss in its use as an antiepileptic and has been found to reduce episodes of binge eating, although further clinical investigations are necessary to explore the efficacy of this drug in the treatment of BED. While these initial findings are encouraging, further research is needed to demonstrate the short- and long-term effectiveness of pharmacotherapies in the treatment of BED and to identify who might respond best to which treatments.

Surgical Approaches to the Treatment of Extreme Obesity

In cases of extreme obesity (BMI greater than 40 or greater than 35 with some comorbid disorders such as type II diabetes, hypertension, heart disease, and significant arthritis in weight-bearing joints) where repeated dietary and exercise modification efforts have been ineffective, surgical techniques may offer a promising treatment alternative. There are three central classes of surgical techniques in practice today for the treatment of extreme obesity: restrictive surgery, malabsorptive procedures, and mixed procedures such as gastric bypass which combine elements of both restrictive and malabsorptive interventions. While all three types of surgeries aim to reduce weight, each has differences with respect to efficacy and adverse effect profiles.

In restrictive procedures – which limit food intake to induce weight loss – surgical techniques are used to reduce stomach size. On average, patients who undergo the procedure lose between 40% and 60% of excess weight within the first 2 years postsurgery. While such surgeries have shown success in treating extreme obesity, they are not encouraged in the treatment of overweight individuals who also suffer from BED, nor in patients whose BMI exceeds 50, in part related to surgical risks. Unfortunately, individuals with extreme obesity who undergo restrictive operations may experience subsequent weight gain and complications, including band

slippages or erosions and pouch dilations which may necessitate further corrective surgery.

Malabsorptive procedures, in contrast, reduce nutritional absorption by diminishing the amount of mucosal surface encountered in the process of digestion through a bypass of certain areas of the intestinal tract, thereby resulting in weight loss. Strictly, malabsorptive procedures are now implemented more rarely as they may be associated with malnutrition problems.

Mixed procedures describe an array of surgical techniques which combine elements of both restrictive and malabsorptive surgical strategies. Of these, gastric bypass is the most common operation in use today. In this procedure, a reduced stomach capacity decreases food intake, while an intestinal shortening and bypass incorporates the advantages of malabsorptive procedures. While leading to weight loss, gastric bypass procedures may improve symptoms of diabetes as well. Data suggest that gastric bypass procedures may be superior to restrictive procedures alone in weight loss and in reduction of obesity-related health problems.

Although surgical interventions in the treatment of obesity have been used for several decades, there remains little standardization, and criteria for choosing one intervention over another remain to be established. Toward this end, further research directly comparing the efficacies of various surgical approaches is needed. Such procedures, however, represent a promising development in the treatment of individuals with extreme obesity that fails to respond to other therapeutic strategies.

Obesity in Children and Adolescents

In recent years, the prevalence rates of obesity in children and adolescents have increased at an alarming rate. Today, BMI represents the most effective tool for assessing obesity in children and adolescents, where age- and gender-specific BMI ranges are used to categorize underweight, normal weight, overweight, and obese individuals. One approach uses percentile values along an estimated normal distribution curve of BMI values for each respective age and gender group, with values falling between the projected 85th and 95th percentiles of BMI indicating overweight, and BMI ratings above the 95th percentile describing obesity.

However, current estimates suggest that a much larger percentage of children have BMI ratings falling above the projected 85th percentile mark than would be expected under a pattern of normal distribution. By this classification standard, approximately one-third of all American children are overweight, as are roughly 14–22% of their European counterparts, with about 9–13% of all children falling within the classification ranges for obesity.

Childhood obesity has been associated with multiple negative health measures, including hypertension, glucose intolerance and insulin resistance (both conditions often seen as a precursor to type II diabetes), and respiratory abnormalities. Childhood obesity is linked with both obesity and obesity-related health complications in adulthood. Overweight and obese children may experience stigmatization which may hinder development of social skills in adolescence and negatively impact self-esteem. Emotional and behavioral problems are also often seen in overweight children.

Since being overweight as a child appears to predict adult obesity, early implementation of preventative strategies is important. Behaviorally oriented programs may teach children regarding the importance of proper nutrition and healthy diets while also encouraging physical activity over pastimes such as watching television and playing video games. Therapeutic approaches, such as those based on CBT approaches used in the treatment of adults with obesity, have shown some success when implemented with overweight and obese children. Such programs may be particularly helpful with the involvement of parents (and other family members), who are encouraged to help their children continue at home the techniques learned in treatment sessions.

Binge Eating in Children and Adolescents

While patterns of binge eating may be seen early in life, it remains difficult to assess the prevalence of BED in this population, principally because diagnostic criteria for identifying BED have not been adequately established or validated in children and adolescents. Findings suggest a 7–28% occurrence rate of binge eating episodes in children and adolescent (the broadness of this range is perhaps accounted for by the use of different definitions of binge eating across different investigations). BED as defined in the DSM-IV-TR may be seen in roughly 1–3% of children and adolescents. The relationship between childhood binge eating and adult BED requires further research.

Case Example

The following account of a BED patient's history illustrates one possible course of the illness. Amy, a 29-year-old single female, describes frequent episodes of extreme eating in which she often feels out of control over the quantity of food she consumes, eats more rapidly than normal, and habitually eats when not physically hungry or until she feels uncomfortably full. She does not report ever engaging in any sort of compensatory behaviors

(such as purging or excessive exercise) following binge episodes, although she does endorse feelings of guilt, embarrassment, and/or depression after excessive eating. Her medical history reveals that she has experienced at least one major depressive episode in the past 3 years and has previously sought treatment for anxiety. The patient has a BMI of 31 and is being treated for hypertension. Treatment approaches in this case could include cognitive behavioral restructuring coupled with SSRI-based pharmacotherapy to jointly target the reduction of binge episodes. While the primary goal of CBT would be to manage the frequency binge eating, a secondary objective of weight loss through training for healthier diet and increased physical activity would also be pursued once the occurrence of binge episodes has been controlled. The patient's body image and co-occurring psychological disorders would also be addressed.

Conclusion

Although recent research has contributed to an improved understanding of obesity and BED and their symptoms, related features, underlying causes, and potential treatments, many questions still remain. With continued research in this field, however, the development in the near future of new and effective approaches to the prevention and treatment of these conditions seems promising.

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Appetitive – Driven by a hedonic or pleasurable feeling or motivation.

Diagnostic and Statistical Manual – A book widely used in psychiatry that categorizes and defines mental health disorders.

Ego-dystonic – In opposition with the ego, or unpleasurable.

Ego-syntonic – In conjunction with the ego, or pleasurable.

Gambling – Placing something of value at risk in the hope of gaining something of greater value.

Microdialysis – A method for measuring levels of chemicals within the brain.

Pathological gambling – A mental health disorder characterized by excessive and interfering patterns of gambling.

Polymorphism – In genetics, a term used to describe a variant form of a gene, gene segment, or other segments of DNA.

knowledge that there is a high probability of severe social and economic consequences. This may be particularly true when aspects of tolerance develop, akin to and suggestive of drug tolerance in drug dependence.

One conceptual framework has been proposed in which impulsive features of PG are considered along an impulsive-compulsive spectrum similar to obsessive-compulsive disorder (OCD). In this framework, affected individuals are purported to experience an intense unpleasantness resulting in attendant neurophysiological compensation, and these processes, in turn, may promote an intense drive to perform the specific behavior, namely gambling. A key characteristic hypothesized to distinguish these obsessive-compulsive spectrum disorders is the degree to which an ego-syntonic component of PG is related to an underestimation of risk. By contrast, ego-dystonic feelings in OCD may lead to an overestimation of harm, risk aversion, and anticipatory anxiety. Alternate models consider the relationship between PG and mood regulation. Given the frequent co-occurrence of PG and depression and suicidal ideation and impaired judgment, as is also seen in bipolar disorder, PG has been conceptualized as an affective spectrum disorder. A third conceptual model posits PG as a non-substance-related addiction, consistent with its frequent co-occurrence with substance use disorders (SUDs).

Although the term addiction was not initially linked to excessive patterns of substance use, it has been specifically used to define ‘impaired control over substance use behaviors.’ However, recent arguments bolstered by biological data have been forwarded to consider non-substance-use illnesses such as PG as addictive disorders. One element proposed as a common characteristic has been loss of control or impaired control over a particular problem behavior with the attendant adverse consequences.

Case Example

James is a 43-year-old, married African-American man who suffers from compulsive thoughts of gambling, an inability to resist the urge to gamble, alcohol dependence, and high blood pressure. James began gambling and experimenting with drugs at age 16. Despite being a talented student-athlete, he frequently smoked pot on the weekends and drank beer with his friends, who would gamble and get involved in petty criminal mischief. When James went to college, his academic performance began to decline as he frequented a popular

Phenomenology

Of the formal group of impulse control disorders (ICDs) not elsewhere classified, which also includes intermittent explosive disorder, kleptomania, pyromania, trichotillomania, and ICDs not otherwise specified, pathological gambling (PG) arguably represents the disorder studied in greatest detail. ICDs have been characterized as obsessive-compulsive spectrum disorders and behavioral addictions, and diagnostically they are grouped in the *Diagnostic and Statistical Manual of Mental Disorders – Fourth Edition (DSM-IV)* as a heterogeneous cluster of disorders linked by failure-to-resist impulses to engage in harmful, disturbing, or distressing behaviors. Thus, a core set of clinical features characterize these disorders: (1) compulsive and repetitive performance of the problematic behavior despite adverse consequences; (2) diminished control over the behavior; (3) craving or appetitive urge states that precede the performance of the behavior; and (4) pleasure or release of tension derived from the behavior. These features are exhibited by individuals with PG who continue to gamble until financial resources are exhausted, and who do so with the

athlete-oriented, off-campus nightclub. He spent the majority of his time socializing, getting high, and skimping on his studies. After college, he married. Thereafter, his doctor sternly advised him to lose weight and cut down on alcohol intake, because of his positive family history of coronary artery disease and borderline hypertensive readings. Eventually, James resolved to get back into shape and was able to reduce his alcohol consumption and avoid gambling.

However, over the past 2 years, he has steadily become more engaged in high-stakes gambling activities, is preoccupied with gambling, always planning his next gambling excursion, and seeking ways to obtain money for gambling. He has begun to drink more heavily as the frequency of his gambling has escalated. His tolerance to alcohol has increased and he drinks daily to control symptoms of withdrawal, such as late-afternoon tremors.

James' drinking and gambling forays have left the family's finances in ruins and have had an impact on his job performance. Often, he arrives late for work and is exhausted due to gambling. He and his boss have clashed over the poor quality of his work. At home, he and his wife bicker constantly over their finances and the increasingly large cash withdrawals he makes before the weekend. At the time of his evaluation, James reported gambling about 3 times during the workweek and the entire weekend. When not gambling, he reports intense urges to gamble. When he is gambling, he reports alcohol cravings and a feeling of relief that comes over him when he has his first drink of the day, usually immediately after work at his favorite watering hole. When he goes to the casinos, he is mesmerized by the atmosphere and gambles up to 8 h continuously.

Over the past several months, his wife has become more resentful because of his worsening gambling and alcohol addiction, his lack of attention to his family, and his refusal to get help. This has left him feeling hopeless,

guilty, anxious, and depressed. He fights these feelings by drinking more heavily, and resolving to hit it big the next time. He has borrowed money from his family, and as it became obvious that he had a gambling addiction, they refused additional loans. He insists that his behavior is not problematic but has become desperate, resorting to illegal activity, including placing bets with a local bookie. Recently, he started having an affair and justifies this behavior by stating that his wife is distant because "she is hung up on material possessions."

Diagnosis and Assessment

In 1980, PG was introduced into the *DSM*. Having undergone several revisions since its inception, a current listing of diagnostic criteria is included in **Table 1**. As the above case vignette illustrates, current diagnostic criteria for PG share similar features with substance dependence, including interference in major areas of life functioning, tolerance, withdrawal, and repeated unsuccessful attempts to cut back or quit. It is characterized by persistent and recurrent maladaptive patterns of gambling. Screening instruments include the South Oaks Gambling Screen (SOGS) and symptom severity instruments include the Yale Brown Obsessive–Compulsive Scale for Pathological Gambling (PG-YBOCS) and Gambling-Symptom Assessment Scale (G-SAS).

Epidemiology

In surveys conducted throughout the United States and Canada, prevalence rates of PG ranged between 0.4% and 2.0%; in Australia, New Zealand, and Europe, 0.2–2.1%; and in Asian countries, 1–2%. A meta-analysis of prevalence studies performed in North America over several decades estimated the lifetime prevalence rates of problem gambling and PG at 3.9% and 1.6%, respectively.

Table 1 Diagnostic criteria for Pathological Gambling

- A. Persistent and recurrent maladaptive gambling behavior as indicated by five (or more) of the following:
 - 1. is preoccupied with gambling (e.g., preoccupied with reliving past gambling experiences, handicapping or planning the next venture, or thinking of ways to get money with which to gamble)
 - 2. needs to gamble with increasing amounts of money in order to achieve the desired excitement
 - 3. has repeated unsuccessful efforts to control, cut back, or stop gambling
 - 4. is restless or irritable when attempting to cut down or stop gambling
 - 5. gambles as a way of escaping from problems or of relieving a dysphoric mood (e.g., feelings of helplessness, guilt, anxiety, depression)
 - 6. after losing money gambling, often returns another day to get even (chasing one's losses)
 - 7. lies to family members, therapist, or others to conceal the extent of involvement with gambling
 - 8. has committed illegal acts such as forgery, fraud, theft, or embezzlement to finance gambling
 - 9. has jeopardized or lost significant relationship, job, or educational or career opportunity because of gambling
 - 10. relies on others to provide money to relieve a desperate financial situation caused by gambling
- B. The gambling behavior is not better accounted for by a Manic Episode.

Hence, while a majority of people (86%) are thought to have engaged in some form of gambling activity, only a relatively small fraction develops gambling problems. In adolescents and young adults, higher lifetime prevalence rates of problem gambling and PG have been reported, 9.45% and 3.88%, respectively. Males may represent a high-risk group, with most studies reporting a male-to-female ratio of approximately 2:1. However, the recently increased accessibility to legalized gambling, particularly, forms that appear more problematic for women such as slot machines, presages a decline in this ratio. Some studies have suggested that minority groups, particularly African-Americans, represent a high-risk group for PG. For example, African-Americans comprised 31% of problem gamblers as compared with 15% of recreational and 21% of nongamblers in the St. Louis Epidemiologic Catchment Study. The limited data on Hispanic, Asian-American, and Native American groups suggest that they may be at heightened risk for developing problem gambling or PG.

Psychiatric Comorbidity

An important factor in establishing effective treatment regimes is having reliable data on comorbidity of PG and other psychiatric disorders. In a placebo-controlled, double-blinded, randomized, parallel-arm trial, lithium was superior to placebo in reducing symptoms of gambling and mania in individuals with PG and co-occurring bipolar spectrum symptomatology. Furthermore, in an independent trial in individuals with PG and co-occurring anxiety disorders using open-label escitalopram, followed by double-blind discontinuation, reductions in gambling and anxiety occurred during the open-label phase that persisted after double-blind discontinuation in the active condition but not the placebo one.

Individuals with SUDs have been reported to have 4- to 10-fold higher rates of PG (rates of 5–15% depending on the substance and the study). Studies have also found high rates of SUDs in PG cohorts, with rates as high as 45–55%, and nicotine dependence in the range of 70%. Some data suggest that PG and certain SUDs result from shared genetic factors representing a common etiologic basis. The presence of a co-occurring SUD may have a significant impact on clinical outcome. A study of individuals with alcohol dependence and a co-occurring nongambling disorder found that the presence of PG symptomatology was associated with a poorer treatment outcome. Therefore, it is important that concurrent treatment of gambling and comorbid disorders be tested further such that more precise treatment algorithms can be developed and validated.

Clinical Course, Pathophysiology, and Classification of Pathological Gambling

PG has been associated with impaired social functioning, bankruptcy, divorce, and incarceration. PG often begins early in the teen and young adult years, particularly among males. The progression of PG appears similar to that seen in SUDs, with high rates among youth, low rates among older adults, and periods of gambling interspersed with periods of abstinence. A ‘telescoping’ pattern, defined as a foreshortened time-period between initiation and problematic levels of behavioral engagement seen in women as compared to men, is observed in both PG and SUDs.

PG and other ICDs may go unrecognized in clinical settings. In one study that actively screened for ICDs following admission, over 30% of patients hospitalized for psychiatric care were found to have a current ICD, and this percentage contrasted with the less than 2% who were diagnosed with an ICD at the time of their hospitalization. Improved identification of ICDs with brief screening instruments may thus help to identify patients who could benefit from treatment of ICDs including PG.

Proposed Models of Addiction, Impulsivity, and Pathological Gambling

The core clinical features of addiction overlap with those for impulsivity. Impulsivity has been defined as “a predisposition toward rapid, unplanned reactions to internal or external stimuli with diminished regard to the negative consequences of these reactions to the individual or others.” Thus, PG has been described as a “behavioral addiction” or an “addiction without the drug” because of shared similar features with substance dependence. Blum and colleagues have conceptualized a mechanism underlying impulsivity and addiction, using the term ‘reward deficiency syndrome.’ They hypothesize that diminished dopamine (DA) function in mesolimbic reward pathways renders affected individuals sensitive, potentially placing them at elevated risk for addictive, impulsive, and compulsive behaviors. Alternatively, the “impaired response inhibition and salience attribution” model of addiction and the allostatic addiction model proposed by Koob and Le Moal suggest that, among other aspects, there exist alterations in the DA reward pathways in people who are vulnerable to addiction. Each model incorporates important environmental and genetic contributions to the development of addictions.

Neurobiology

The DA neurotransmitter system represents an important component of the brain reward and reinforcement processes, particularly as related to drug addiction. DA neurons project from the ventral tegmental area (VTA) to the nucleus accumbens (NAcc). These neurons are important for reward reinforcement because interruptions in DA impulse trafficking along axonal routes or at the receptor level decrease the rewarding influences of VTA-related DA stimulation. This system may be perturbed in addictions wherein pleasurable sensation may be associated with DA release, and altered dopaminergic pathways may stimulate reward-seeking behavior. For example, acute ingestion of cocaine increases DA transmission in the basal ganglia, which may enhance the behavioral reinforcement and learned associations encoding the addictive behavior.

In addition to the DA system, other monoamine systems have been implicated in addictions. Serotonin (5-HT) has been proposed to be particularly relevant to the initiation and cessation of the problematic behavior, and norepinephrine (NE) appears particularly relevant to arousal and excitement. Abnormalities in DA, 5-HT, and NE neurotransmitter systems have been reported in PG. Hypotheses that drive the investigation of medications in the treatment of PG are typically based on the neurobiology of PG. Effective pharmacological treatments may also provide insights into the pathophysiology of PG.

Animal Models of Impulsivity and Neuronal Activation

Animal models have been used to assess impulse control. Preferred-choice paradigms of impulsivity may involve simultaneous measurements of real-time neurophysiological and neurochemical data. Such models suggest that ventral and dorsal prefrontal regions represent distinct neuroanatomical substrates of impulsive behavior related to specific aspects of monoamine neurotransmission. The discrete ventral and dorsal areas of frontal cortex implicated in impulse control have been further divided into functionally dissociable areas. DA, 5-HT, and their metabolite concentrations in rat medial prefrontal cortex (mPFC) and orbitofrontal cortex (OFC) were measured using *in vivo* microdialysis during a model of impulsive choice, with mPFC-related 5-HT efflux specifically implicated. By contrast, increased 3,4-di-hydroxyphenylacetic acid (DOPAC, a DA metabolite) levels were observed in OFC, suggesting a double-dissociation, implicating frontocortical 5-HT and DA neuromodulation during impulsive decision making. In a similar experiment designed to measure DA release in PFC, Listar-hooded rats were tested on a visual attention task based on a behavioral disinhibition

model of impulsivity. Compared to their pretask levels, DA and DOPAC efflux increased significantly (~100%) during performance runs. The increase in DA release observed in the PFC was associated with performance measures. Those animals demonstrating a greater tendency for impulsive behavior were noted to demonstrate a similar magnitude of DA response. Primate studies of impulsive decision making have also implicated medial PFC function. Together, these animal data complement those from human studies suggesting an important role for ventral and medial prefrontal cortical function in impulsive behaviors.

Brain Imaging

Relatively few brain-imaging studies have investigated the ways in which brain function in individuals with PG differs from that in those without PG. One early functional magnetic resonance imaging (fMRI) study found that during exposure to gambling videotapes, men with PG, as compared with control comparison men, show relatively diminished activation of cortical, basal ganglia, and thalamic brain regions. These findings contrast with cue provocation studies in OCD in which relatively increased activation of these regions was reported. During the period of most intense gambling stimulus presentation, subjects with PG were distinguished from those without by showing diminished activation of the ventromedial prefrontal cortex (vmPFC), a brain region implicated in emotional regulation and decision making. A separate study of cognitive control used the Stroop color-word interference task and found that subjects with PG were distinguished most from those without by showing less activation of vmPFC. Subsequent fMRI studies investigating simulated gambling and decision making have found that individuals with PG (with or without SUDs) show less activation of the vmPFC when compared with nonaffected control subjects. Thus, these studies indicate that PG subjects show less activation of the vmPFC during performance of multiple cognitive and behavioral processes. These findings extend data from stroke patients with vmPFC lesions, who demonstrated disadvantageous decision making. Another brain region implicated in PG is the ventral striatum, a region including the NAcc, wherein less activation was seen during a simulated gambling task. Taken together, these studies suggest an important role for ventral cortico-striatal function in the pathophysiology of PG.

Genetics

PG is heritable, with twin studies suggesting that over 50% of the variance for PG is related to genetic contributions. These findings are similar to those for drug addictions in which 30–60% of the contributing variance is estimated to be genetic in nature. There is also overlap

in genetic and environmental contributions between PG and other comorbid disorders such as alcohol dependence and antisocial personality disorder. In comparison, a similar study found that the overlap between PG and major depression was accounted for predominantly by shared genetic factors.

Candidate genes have been proposed for PG and impulsivity in general. Genetic variations in the gene encoding the DA D4 receptor (DRD4) have been associated with novelty seeking and PG, and variations in the DRD2 allele have been associated with PG and drug addiction, albeit inconsistently. Preliminary data investigating influences of allelic variants of the DRD2 on reward processing have suggested differences in medial OFC, amygdala, hippocampus, and NAcc function. The extent to which such findings are observed in PG subjects requires further investigation.

While these results are intriguing, findings from genetic association studies should be viewed with caution. This is particularly true since there have been significant methodological limitations, such as the lack of definitive diagnoses or stratification by racial/ethnic identity. Perhaps given the preliminary nature and methodological limitations of early studies, some initial findings (e.g., an association between PG and DRD2 variation) have not been replicated in subsequent, controlled studies. Larger population-based studies using accurate diagnostic assessments and genome-wide interrogation should provide a framework for a more precise understanding of the genetic influences contributing to PG.

Treatment

Over the past decade, multiple pharmacotherapies have been tested in the treatment of PG. Placebo-controlled trials indicate frequent placebo responses so the findings from open-label trials should be interpreted cautiously. Serotonin reuptake inhibitors such as paroxetine and fluvoxamine have shown mixed findings, with some placebo-controlled trials observing superiority of active drug over placebo and others not. Preliminary data suggest that serotonin reuptake inhibitors may be particularly helpful for individuals with PG and co-occurring internalizing disorders (e.g., anxiety disorders). Mood-stabilizing drugs have been found to be helpful for some individuals. In one trial, lithium was found to be superior to placebo in diminishing gambling and manic symptoms in individuals with PG and co-occurring bipolar spectrum disorders (e.g., bipolar II disorder). Arguably, the most consistent findings have emerged from studies of opioid antagonists. In three separate placebo-controlled trials, the opioid antagonists nalmefene and naltrexone have been reported to be superior to placebo in the treatment of PG. Individuals with strong gambling urges at treatment

onset or a family history of alcoholism appear to respond particularly well to opioid antagonists. The glutamatergic neutriceutical *n*-acetyl cysteine has been found to be superior to placebo in one controlled trial. Although encouraging, the majority of pharmacotherapy studies have limitations with respect to short-term durations, small sample sizes, and exclusion of subjects with co-occurring disorders. As such, more study is needed to identify treatments with long-term benefits and to understand who might respond best to specific treatments.

As with SUDs, behavioral therapies are currently a cornerstone of treatment for PG. Self-help approaches like Gambler's Anonymous have been associated with improved outcomes. Among formal therapies, imaginal desensitization, motivational approaches, cognitive behavioral therapy, and brief interventions have support in controlled studies. However, in some instances, long-term follow-up data have not been as encouraging as short-term data. More research is needed to investigate the possible predictors of treatment outcome and evaluate combinations of behavioral and pharmacological therapies.

Conclusions

PG and SUDs share features including tolerance, withdrawal, repeated attempts to quit or cut back, and impairments in life functioning. Phenomenological similarities exist, including age-related prevalence estimates and telescoping patterns in women. Multiple neurotransmitter systems (e.g., 5-HT, NE, DA, and opioids) appear to contribute to PG. Treatments targeting these neurotransmitter systems have demonstrated varying degrees of promise. Ventral cortico-striatal brain pathways appear particularly relevant to impulsive decision making and PG. The relationships between PG and SUDs, as well as those between PG and other psychiatric disorders, may be important considerations in the development of improved prevention and treatment strategies.

Glossary

Impulse-control disorders – As defined in the fourth-edition text revision of the *Diagnostic and Statistical Manual* (DSM-IV-TR), these are disorders of impulse control that are not categorized in groupings of other major psychiatric disorders. The essential feature of impulse-control disorders is the failure to resist an impulse, drive, or temptation to perform an act that is harmful to the person or to others. The individual with the disorder typically feels an increasing sense of tension or arousal before committing the act and then experiences pleasure, gratification, or relief at the time of committing the act.

Impulsivity – Impulsivity has been defined as a predisposition toward rapid, unplanned reactions to internal or external stimuli with diminished regard to the negative consequences of these reactions to the impulsive individual or to others.

Intermediary phenotype – A measurable characteristic, one that may not be immediately obvious (e.g., impulsivity), that may be closer to biological phenomena than other phenotypes (e.g., diagnostic categories used in mental healthcare settings). Intermediary phenotypes may facilitate the identification of clinically relevant genes and the elucidation of their functions. An intermediary phenotype can involve a simpler behavior or an underlying endocrine or neural mechanism.

Internet-enabled sexual behavior (IESB) – Alternatively termed Internet sex and cybersex, it encompasses a wide range of sexual behaviors expressed on the Internet, including Internet pornography (solitary), on-line sexually charged relationships (bidirectional), and their variants such as webcam strip-shows and role-playing sex games.

Massively multiplayer on-line games (MMOGs) – These encompass a genre of computer games in which hundreds or thousands of players can cooperate and compete with one another in the same game in real time. They typically feature at least one persistent virtual world, and typically require players to invest large amounts of time.

Problematic Internet use – Also termed Internet addiction, pathological Internet use, and compulsive-impulsive Internet-use disorder, this term describes poorly controlled or excessive use of the Internet that is associated with significant psychosocial and functional impairments.

Time distortion – It describes an individual's experience that time seems to pass slower or faster than it actually does. It is revealed by the discrepancy between the perceived length of time and the measured amount of time spent on a certain activity. It is often associated with computer and Internet uses, and with other pleasurable activities as well.

Introduction

The Electrical Numerical Integrator and Calculator (ENIAC), constructed in the United States (US) in 1946 by John Mauchly and John Presper Eckert, is widely regarded as the first functionally useful electrical computer. It weighed almost 30 tons and covered 1800 square feet of floor space. The invention of the microprocessor in the 1970s made the development of consumer computers possible. By the 1990s, the computer became a common household appliance. It is estimated that at present over 70% of Americans own a personal computer. While computers may have been originally invented to be calculating machines, with the advent of the Internet the modern computer can now perform virtually unlimited varieties of functions and provide an unparalleled interactive experience. The significance of the computer and the Internet in human life has also assumed different dimensions. To many, the Internet enlivens the computer to much more than an inanimate device. The ways in which some individuals seem attached to or enslaved by computer activities, in particular Internet-based functions, led to the hypothesis of the addictive potential of such activities.

Internet addiction or problematic Internet use are two of the most commonly used terms for this behavioral syndrome. Both terms appear, in this article, to adhere to the terms used by different authors in describing their findings. Addiction is not a term used or defined in the current *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR). Although the term problematic Internet use is widely used to characterize a variety of Internet-related behaviors, there exists no unified definition for the disorder. In this article, a descriptive approach is employed and the term problematic Internet use is used to describe poorly controlled or

excessive use of the Internet that is associated with significant psychosocial and functional impairments. Computer activities are of a large variety and can be on- or off-line. Problematic patterns of computer use had been observed even before the Internet became widely available. However, since the advent of the Internet, it has been observed that the activities most typically associated with problematic use are Internet-based (e.g., Internet gambling, Internet-enabled sexual behavior (IESB), on-line gaming), and most existing research addresses problematic and compulsive use of the Internet.

Epidemiology

The true prevalence of problematic Internet use is not known. This is largely due to the lack of unified diagnostic criteria and assessment instruments, and the scarcity of epidemiological studies. One concern with regard to assessment instruments is that it is unclear how well they differentiate between normal and problematic uses, and their thresholds may greatly influence the prevalence estimates. Another problem is that most existing studies focus on children, adolescents, and college students based on the presumption that problematic Internet use is primarily a phenomenon of the younger population, although epidemiological evidence in support of this premise is largely lacking. Given the reports of problematic Internet use in people of different ages and professions, such as home-makers and working professionals, further study of the prevalence in the general population is needed.

The telephone survey conducted by Aboujaoude *et al.* in 2004 is probably the most methodological rigorous prevalence-estimate study to date. They conducted a nationwide, random-sample telephone survey of over 2500 US adults (≥ 18 years) utilizing a structured interview that elicited responses to eight suggested measures of problematic Internet use, which were extrapolations from established diagnostic criteria for impulse-control disorders, obsessive-compulsive disorder, and substance abuse. Four sets of possible diagnostic criteria were generated, and the least restrictive one required that Internet use interferes with relationships; the respondent be preoccupied with the Internet when off-line; and, has either tried unsuccessfully to cut down on Internet use, or often stayed on-line longer than intended. Merely 0.7% of respondents endorsed all of these four criteria. However, considerably larger proportions (3.7–13.7%) endorsed one or more of the suggested measures. The study did not include people younger than 18 years of age and had a relatively small proportion of younger adults. As such, the study design might have biased the prevalence estimates downward. Nevertheless, the results suggest that potential markers of problematic Internet use are present in a sizeable proportion of the population.

Multiple observations can be made from the existing epidemiological studies of problematic Internet use. Studies have been performed in multiple geographical regions and significant prevalence rates have been reported in countries across multiple continents and countries (e.g., the United States, Korea, China, Norway, and Italy) indicating that the phenomenon is recognized worldwide. The disorder may be more prevalent among children, adolescents, and college students, with prevalence estimates from off-line studies of younger populations ranging approximately from 2% to 8%, higher than the <1% in adults reported by Aboujaoude *et al.* Problematic Internet use also appears to have a male preponderance, with most, but not all, off-line studies reporting higher prevalence rates and heavier computer use in male subjects. One possible explanation is that men are more likely to engage in computer activities that are associated with a strong emotional-motivational state that contributes to addictive behaviors, such as computer games, Internet pornography, and gambling. Given that multiple gender differences have been reported in other behavioral addictions such as pathological gambling, differences in computer-use patterns between the sexes are likely to be complex. In a sample of about 700 young people in Hong Kong, being a young female student, endorsement of being emotionally open on-line, and using Internet chat function heavily were all associated with problematic Internet use. Men and women may be attracted to, and experience problems with, different computer activities. The above-mentioned observations require replication in future studies of large, representative samples with the use of standardized criteria and assessment instruments and structured interviews.

Clinical Characteristics

Subjective Experiences and Behavioral Patterns

Individuals with problematic Internet use typically spend large amounts of time on Internet-related activities, in some cases objectively measured to be over 35 h a week. Time spent on the Internet is frequently longer than originally intended. Individuals may excessively participate solely in specific Internet activities, and may have made unsuccessful efforts to control or stop Internet use. Lying to family members or therapists to conceal the extent of Internet use is commonly reported – a behavior also seen in pathological gambling.

The above-mentioned study by Aboujaoude *et al.* found that the subjective experience of feeling preoccupied with the Internet when off-line was most highly associated with other suggested clinical markers for problematic Internet use. Consistent with the description of impulse-control disorders, individuals may report difficulty resisting an impulse to use the Internet, an increased

tension prior to the desired activity, a release of the tension after the activity starts, and feeling stimulated and euphoric while engaging in the activity. Analogous to the phenomena of tolerance to and withdrawal from a chemical substance, individuals often report needing to use the Internet for increasing amounts of time in order to feel satisfied, and feeling restless, depressed, or irritable when Internet use is being cut down. Time distortion is also a common subjective experience, as documented by discrepancies between self-reported and measured amounts of time spent on the Internet. Subjects often report finding relief from dysphoric, unpleasant states through Internet activities, and thus may choose them as a way of coping or escaping.

Many of the above-mentioned clinical features are captured in proposed sets of Internet-addiction diagnostic criteria, and a commonly cited set was proposed by Young and modeled on the DSM-IV criteria for pathological gambling. The specificity and sensitivity of various symptoms and combinations of symptoms in differentiating normal versus problematic Internet use in the general population are yet to be established.

Physical Health Consequences

Problematic Internet use could potentially cause health problems secondary to the individual's general disregard of his or her health and reduction in physical activities. Poor personal hygiene, irregular eating and digestive system symptoms, declines in cardiovascular fitness, and sleep deprivation may occur in association with problematic Internet use. Other physical complaints related to excessive computer use may include musculoskeletal pain of the back and the wrist, eyestrain, and headache.

Psychosocial Impairments

Individuals with problematic Internet use may neglect family and friends outside the Internet world and thus may jeopardize significant relationships and work and educational opportunities. Individuals with problematic Internet use may be disciplined at work for nonproductive use of the Internet, and this may result in job loss. Other serious psychosocial problems, such as incurring debts and bankruptcy, academic failures, marital discord, and divorce, have also been associated with problematic Internet use.

Co-Occurring Disorders

As is the case in substance-dependence and impulse-control disorders such as pathological gambling, psychiatric disorders frequently co-occur with problematic Internet use. Common co-occurring psychiatric disorders

appear to include mood disorders, attention deficit and hyperactivity disorder (ADHD), other impulse-control disorders, social phobia, and substance-use disorders. Comorbid psychotic disorders appear less common. Comorbidity might indicate causal relationships among two or more disorders – that they share common etiological factors, or some other relationship. The study of comorbidities in problematic Internet use may shed light on the underlying mechanisms and further inform prevention and treatment efforts.

Mood Disorders

The association between depressive disorders and problematic Internet use appears to be robust and has been observed in adolescents, college students, and adults. Approximately 10–25% of individuals with problematic Internet use have been reported to be depressed, but larger epidemiological studies are needed to determine the precise rate. Excessive Internet use could lead to stressful social circumstances, such as academic failures and marital discord, which could contribute to depression. Moreover, increased time devoted to the Internet means decreased time available for social engagement, which may lead to isolation and depression, as suggested by a longitudinal study by Kraut *et al.*, which gave randomly selected families Internet access and found higher levels of depression and loneliness in respondents who used the Internet as little as a few hours a week after a 2-year follow-up. On the other hand, depressed people may be drawn to computer games and the Internet for consolation. Precisely how the use of the Internet as a coping strategy may progress to become compulsive or excessive is not well understood. Irrespective of the nature of the relationship, it is important to effectively evaluate and treat depressive disorders in individuals with problematic Internet use.

With regard to the potential role of hypomania and mania, the case series by Shapira *et al.*, in 2000, found that 70% of subjects with Internet addiction had a lifetime diagnosis of bipolar affective disorder I or II, but all had a current or recent depressive or mixed episode, and none had current or recent mania. Poorly controlled Internet use could be a manifestation of hypomania or mania, but this does not seem to be the case in the majority of subjects encountered clinically.

Attention Deficit and Hyperactivity Disorder (ADHD)

ADHD has been associated with problematic Internet use in children and in adults. In a sample of over 500 Korean elementary-school students, over 20% of those identified as problematic Internet users had co-occurring ADHD. The majority of those children used the computer to play

on-line games. Those with ADHD and problematic Internet use had more severe ADHD symptoms in that study, as reflected by reports by parents, teachers, and children. Further, in a college-student study with subjects older than 18 years of age, adult ADHD – as ascertained via diagnostic interviews – was the most significantly associated factor with Internet addiction in a logistic regression analysis. Since ADHD predated Internet use, Internet addiction may be a manifestation of ADHD or the two conditions may share common intermediary phenotypes such as a shortened delay gradient. This feature, which has been termed delay discounting and is related to impulsivity, manifests as the tendency to select an immediate reward over a larger but delayed reward. Immediate gratification is often a central experience of using the Internet, where objects of desire are just one-click away. ADHD patients may also have impaired impulse control and hence face difficulties restraining the urge to engage in activities like on-line games.

Obsessive-Compulsive Disorder (OCD) and Impulse-Control Disorders

Problematic Internet use has phenomenological similarities to OCD and impulse-control disorders, in particular pathological gambling. Impulse-control disorders and OCD have been proposed to lie along ends of an impulsive/compulsive spectrum. While obsessive-compulsive symptoms and the trait of harm-avoidance have been associated with excessive Internet use in some cases, patients typically report Internet use as more impulsive and ego-syntonic rather than ego-dystonic (as in OCD), and the remorse from losses secondary to problematic Internet use appears different from the irrational fears often present in OCD. In small case series in which clinical diagnoses were made, the frequencies of co-occurrence of OCD with problematic Internet use varied substantially (0–15%), but were low when compared to those of any non-computer-related impulse-control disorder (up to 50%). Multiple impulse-control disorders have been identified in association with problematic Internet use, and these include intermittent explosive disorder, kleptomania, pathological gambling, pyromania, compulsive buying, compulsive sexual behavior, and compulsive exercising.

Social Phobia

Shyness has been associated with heavy Internet use in college students. It has been contended that the anonymity of the Internet may draw socially fearful individuals to participate in low-risk social interactions via the web. In the case series of 20 patients reported by Shapira and colleagues (2000), concurrent social phobia was found in 40% of subjects, and social phobia was the most common

anxiety disorder in the series. However, social phobia did not predict problematic Internet use in a large epidemiological study in Taiwan, nor in a sample of college students after depression and ADHD were controlled. It appears that social phobia, although it may contribute to heavier Internet use, may not fully explain or account for problematic Internet use.

Substance-Use Disorders

Given the phenomenological similarities between substance dependence and problematic Internet use, the co-occurrence of the two conditions might be anticipated. Moreover, pathological gambling, to which problematic Internet use has been likened, is commonly comorbid with substance-use disorders. However, epidemiological data are almost nonexistent in this regard, with one adolescent survey finding no association between Internet addiction and alcohol and nicotine dependence. On the other hand, small case series have found that up to 50% of subjects with Internet addiction have a lifetime diagnosis of substance abuse. Further epidemiological research is needed.

Internet Gambling, IESB, and On-Line Gaming

Internet gambling, IESB, and on-line gaming are behaviors most frequently associated with problematic patterns of use, although other computer-based behaviors such as on-line chatting and e-mailing may also become problematic. These forms of Internet use appear to share the propensity to alter mood states, a feature which has been proposed to contribute to addictive behaviors. Gambling, sexual behavior, and computer-gaming are not Internet-specific activities. However, certain distinctive properties of the Internet, including interactivity, accessibility, affordability, and anonymity, may potentially exacerbate or promote excessive involvement in specific individuals, although more research is needed to examine these possibilities. From the limited epidemiological data available, problematic forms of these behaviors appear to be more common in males than in females.

Internet Gambling

The majority of adults in the US have gambled within the past-year, and epidemiological studies suggest that problem and pathological gambling occur in a small proportion of the population, probably up to 4.0%. The hypothesis that Internet gambling exacerbates the problem of pathological gambling because of the above-mentioned properties has not been confirmed by

empirical studies. Two large-scale Internet gambling studies which recorded Internet betting activities from more than 4000 subscribers to an Internet gambling website over a 2-year period found that gambling behaviors were moderate at the population level, with 1–5% of subjects exhibiting behaviors that deviated markedly from the norm. However, Internet gambling may be a larger problem in subsets of the population such as college students. In one study, almost 25% of college subjects reported having wagered on the Internet at least once in their lives. The study also found that markedly more regular Internet gamblers than off-line gamblers were pathological gamblers (61.6% vs. 5.0%), and Internet gambling was associated with poorer mental health ratings. The question remains whether Internet gambling leads to problematic gambling behaviors, problem gamblers are drawn to Internet gambling, or some other relationship exists.

Internet-Enabled Sexual Behavior

Sex addiction, or nonparaphilic compulsive sexual behavior, is one of the proposed conditions currently subsumed under the DSM-IV-TR category of impulse-control disorder not otherwise specified. IESBs include pornography viewing, on-line sexual relationships, and their variants. It has been estimated that the Internet pornography industry is worth well over \$1 billion, and most of the top word searches are related to Internet sex. Hence, IESBs appear to be very prevalent at the societal level. Internet sex replaces real-life intimacy in many cases, and has been related to reprimands at work, serious relationship problems, and divorce. However, given the secretive nature of the condition for the majority of individuals, the prevalence and extent of compulsive or problematic IESBs are difficult to determine. In a small outcome study of treatment for men involved in problematic IESBs, subjects with different co-occurring disorders responded differently to integrated group therapy – those with anxiety disorders responded best; those with depression showed a moderate response; and those with ADHD appeared to be most resistant to treatment, illustrating the heterogeneity of subjects with problematic IESBs.

On-Line Gaming

Computer gaming can be conducted on-line or off-line, but heavy or excessive playing is more frequently associated with on-line gaming modalities. Another observation repeatedly reported in multiple studies is that players and problematic players are predominantly males. Both quantitative and qualitative studies have shown that to socialize and interact with others is an important motivational factor in on-line gaming. This is

consistent with the observation that excessive playing is most often associated with massively multiplayer on-line games (MMOGs). The design of MMOGs inherently promotes heavy gaming, since the competition runs continuously in real time, making devotion to gaming mandatory. A study of Korean adolescents found that role-playing game users had significantly higher Internet-addiction ratings than players of other genres, such as sports games. Although computer games are traditionally regarded as a leisure activity of children and adolescents, an on-line study of players of the popular on-line game Everquest found that almost 60% of players were between the ages of 18 and 31, indicating that on-line gaming may be gaining a wider audience. Whether the prevalence of compulsive gaming is increasing in the older age group is not known. In clinical practice, it is still most commonly encountered in children and adolescents, and underlying ADHD is implicated in some cases.

Neurobiological Features

Knowledge about the neurobiology of problematic Internet use is currently very limited. The theoretical models of substance-addiction and impulse-control disorders, to which problematic Internet use has been likened, are not mutually exclusive, and studies have shown multiple neurobiological and genetic similarities between the two groups of disorders. Pathophysiological mechanisms implicated in substance-addiction and impulse-control disorders may also contribute to problematic Internet use, but direct evidence is lacking.

Dopaminergic projections from the ventral tegmental area to the nucleus accumbens are considered to be important in the expression of goal-directed behaviors, and this pathway has long been implicated in drug addiction. A current hypothesis posits that low dopamine D2-receptor availability may mediate vulnerability to addiction. Multiple clinical observations suggest that the mechanism might also underlie problematic Internet use. The phenomenon of *punding* – characterized by an intense fascination with repetitive handling of technical equipments seen in relation to the use of psychostimulants (e.g., amphetamine and cocaine) and dopaminergic anti-Parkinsonian medications – has also involved compulsive use of the computer in some patients. Computer-use behaviors in punding and problematic Internet use in subjects not under the influence of dopaminergic medications share phenomenological features. A case report documented the successful treatment of compulsive IESB with naltrexone, the hypothesis being that a non-chemical stimulus such as Internet pornography causes the release of endogenous opiates which enhances dopamine release, and naltrexone works via blocking opioid receptors. As mentioned, further research with direct

examination of the roles of dopaminergic and opioidergic systems in problematic Internet use is needed to examine these hypotheses.

A preliminary electroencephalographic study reported that as compared to nonaddicted computer-game players, addicted ones showed higher emotional arousal and stronger cortical reactivity in response to computer-game-related visual cues. In addicted computer-game players, game-related cues induced late positive complexes of significantly larger amplitudes. The findings are consistent with previous reports that individuals with Internet addiction may have a different Internet-use experience than do nonaddicted individuals, being more emotionally engaged with the Internet. Similar cue-induced responses had been described in alcohol- and drug-dependent subjects, as well as pathological gamblers confronted with related cues. Thus, problematic Internet use may share common pathophysiological processes with these other disorders.

Genetics

No genetic study has been published examining problematic Internet use. Genetic studies of pathological gambling showed that genetic factors contribute significantly, and pathological gambling shares genetic risk with alcohol dependence and antisocial behavior. All these conditions may be linked via common underlying pathways such as impulsivity. Hence, genetic study of problematic Internet use may help clarify its relationships with other impulse-control disorders and substance addictions.

Treatments

Given the recent recognition of problematic Internet use as a psychiatric problem, not much research has evaluated the efficacy of treatments for the disorder. No double-blind, controlled trials of pharmacotherapies or psychotherapies have been published. However, many patients seek help and the resulting treatment infrastructure is expanding. Multiple treatment centers and groups have emerged over time, both on- and off-line. For example, specialized outpatient treatment service is available at the Computer Addiction Study Center at McLean Hospital of Harvard Medical School. In some instances, patients have been admitted for inpatient rehabilitation. In China, a halfway house was recently opened for adolescents with problematic Internet use.

Since the Internet is an integral part of life for many, total abstinence may not be practical. Hence, many contend that moderated and controlled use is the most appropriate treatment goal. With regard to children and

adolescents, the input of parents is essential. It has been found that although most parents appear open to buying computers because of perceived positive features, few may discuss with their children their appropriate use in detail or carefully supervise their use, unless or until the use becomes problematic.

Psychopharmacological Treatments

Selective serotonin-reuptake inhibitors (SSRIs) are effective in the treatment of OCD. Studies of the use of SSRIs in impulse-control disorders have shown mixed results. Problematic Internet use appears to have compulsive and impulsive qualities, and treatment with escitalopram, an SSRI, has been studied. An open-label study in 19 subjects by Dell'Osso, in 2006, showed that 10 weeks of escitalopram treatment (20 mg per day) was associated with significant decreases in weekly hours spent on-line (from a mean of 36.8 to 16.5 h) and in measures of impulsivity and compulsion, as well as improvement in global functioning. After 10 weeks, subjects were blindly randomized to continue treatment with escitalopram or placebo. Following another 9 weeks of treatment, therapeutic gains achieved at week 10 were maintained in both treatment groups and no further gain was shown for either group. The medication was well tolerated. The most frequently reported side effects were drowsiness and nausea, which were modest and self-limited. In a case report, escitalopram successfully treated a depressed adult patient with compulsive on-line gaming. Another case study reported the successful use of an atypical antipsychotic (quetiapine) as augmentation for citalopram in the treatment of a subject with compulsive Internet use. This augmentation strategy has also been successfully used in treating OCD. Naltrexone has also been used with the reasoning that it may antagonize endogenous opiates that are induced by pleasurable stimuli, perhaps through modulation of dopamine pathways underlying motivated behaviors. A case report documented the successful use of naltrexone in the treatment of compulsive IESB. The patient's depressed mood initially responded to sertraline, but his urge to view Internet pornography was still uncontrolled until naltrexone was started. He reported complete control of his impulse at the dose of naltrexone 150 mg daily. Further clinical trials are needed to establish the efficacy and effectiveness of medication monotherapy and augmentation strategies.

Psychological Treatments

Cognitive behavioral therapy

Cognitive therapy is based on the underlying theoretical rationale that an individual's affective states and behaviors are largely determined by the way in which he or she structures the world on the basis of cognitions and

assumptions. Recognition, examination, and correction of faulty cognitions and assumptions may then lead to changes in regulating affective states and controlling behaviors. Principles of cognitive therapy have been applied to the treatment of problematic Internet use. Studies suggest that compulsive Internet users may be more likely to expect positive outcomes and relief from negative affective states from Internet use, which may not be true given the psychosocial impairments they suffer from excessive use of the Internet. They may presume that the Internet is the most effective way to alleviate depressive feelings and meet truthful friends ("unlike my dishonest husband..."). Such expectations represent potential targets for cognitive restructuring, as are other dysfunctional thoughts such as "Just a few more minutes won't hurt" which may maintain the pattern of Internet use.

Cognitive therapy is typically combined with a behavioral component in the initial phase. Such therapies may initially start with a daily log to evaluate Internet-use behaviors and a focus on establishing and achieving reasonable goals such as decreasing the amount of time of use, abstaining from problematic applications, and developing alternative activities and coping skills. Such therapies may be combined with the use of software to restrict Internet access.

The outcome of CBT in the form of on-line counseling for problematic Internet use has been evaluated in a study conducted by Young. Overall, subjects reported incremental or continuous improvements in symptoms and functioning throughout the course of therapy of 12 sessions, and maintenance of benefits at 6-month follow-up. The moderate sample size (114 treatment-seeking subjects) and its highly educated composition may limit the generalizability of the results.

Motivational interviewing and stages of change

A transtheoretical model of behavioral change was proposed and developed by Prochaska and DiClemente. Based on this model, motivational interviewing has been successful in the treatment of substance addictions. The model has been adopted in the psychotherapy of problematic Internet use. The principle states that behavioral change goes through successive stages of pre-contemplation, contemplation, preparation, action, maintenance, and termination, and individuals at different stages have different needs and levels of readiness. A therapist should be sensitive to the motivational stage of the patient and respond to his or her needs accordingly. If the patient does not recognize any problem with his or her Internet use, it would not be therapeutic for the therapist to propose an action plan. The goal at this precontemplation stage is to help the patient overcome denial by discussing pros and cons of Internet use and overuse. If the patient is already trying to make behavioral changes, it may be

unnecessary or inappropriate for the therapist to continue discussing negative ramifications of excessive Internet use. Support and educational materials are provided according to the patient's readiness to change. A small study of group therapy applying the principles of cognitive behavioral therapy (CBT), motivational interviewing, and stages of change showed improvements in quality of life and depression measures, but no significant changes in the subjects' computer-use behaviors.

Insight-oriented psychotherapy

While people have different motivations to use and overuse the Internet, qualitative studies and case reports illustrated common psychological themes in patients' stories. Internet activities may serve to fulfill some inherent psychological needs – the need for a sense of achievement, for interpersonal connectedness and a sense of belonging to a community, for entertainment, and to discharge frustration. The virtual self on-line can be an extension of the real self, or a compensatory identity to satisfy unfulfilled wishes. This interpretation may explain why role-playing games represent one of the most popular genres. Blogosphere may also provide a space to fulfill the wish to self-reveal. Insight-oriented psychotherapy aims to help patients understand the relationships among their anxieties, inner needs, motivations, and Internet-use behaviors so they can make their own choice to change behaviors and develop alternate ways of coping. Empirical data on this and other psychotherapeutic approaches for problematic Internet use are limited.

Conclusions

Problematic Internet use is a clinically recognizable behavioral syndrome that is associated with significant adverse psychosocial consequences. As is the case with substance-dependence and impulse-control disorders, comorbidity appears to be the rule rather than the exception. The study of the prevalence, phenomenology, pathophysiology, and treatment of problematic Internet use is hindered in part by the lack of standardized criteria and assessment instruments. This behavioral syndrome appears heterogeneous – people have different motivations to use the Internet to excess, and they have problems with different applications. Novelty-seeking individuals may be drawn to the Internet's incessant novelty, while people with harm-avoidance tendencies may find a sense of safety in the virtual world. Nonetheless, both types of individuals could develop problematic patterns of use. The study of intermediary phenotype constructs, such as impulsivity, across diagnostic groups should facilitate further elucidation of neurobiological and genetic bases of problematic Internet use and other theoretically related conditions. Clinically, efforts in subtyping problematic

Internet use may be performed in conjunction with understanding a patient's unique experience with the Internet, and helping him or her reflect on his relationship with the virtual world. Clinicians should be aware of the clinical features of problematic Internet use and its potential consequences, and be equipped to assess computer-use history in the clinical interview.

Glossary

Affective disorder spectrum – A grouping of psychiatric disorders characterized by alterations in mood that share clinical and treatment-related characteristics.

Arachnoid cyst – A sac, filled with cerebrospinal fluid, that forms around the cranial base in the surface region of the brain, or on the arachnoid membrane.

Cerebellar vermis – A midline part of the cerebellum.

Ego-dystonic – The aspects of a person's thoughts, mood, impulses, and behavior which are repugnant and inconsistent with how the person normally views his or herself (opposite of ego-syntonic).

Nucleus accumbens – A brain region where dopamine-secreting neurons terminate, which has been implicated in various addictions, urge-driven behaviors, reward-based learning and motivation; considered part of the brain reward circuitry.

Obsessive-compulsive spectrum – A group of disorders hypothesized to share common clinical and biological characteristics of obsessive-compulsive disorder. These disorders include, but are not limited to, Tourette's syndrome, body dysmorphic disorder, hypochondriasis, depersonalization disorder, pathological skin picking, trichotillomania, and pathological gambling.

Psychopathy – A psychiatric condition characterized by chronic antisocial and immoral behavior.

Topiramate – A sulfamate-substituted monosaccharide derivative used as an anticonvulsant to treat partial seizures.

Ventral tegmental area – A region in the midbrain where the mesocortical and mesolimbic dopaminergic systems originate; dopamine neurons in the ventral tegmental area project to the nucleus accumbens.

deliberate and purposeful fire setting that has occurred on more than one occasion; (2) feelings of tension or arousal preceding a fire-setting act; (3) pleasure, gratification, or relief when setting fires or when watching/participating in the aftermath of the fire; (5) the act of fire setting is not done out of vengeance or for monetary gain; and (6) fire-setting cannot be directly attributed to another mental condition such as conduct or bipolar disorder or impairment due to substance use. Psychosocial problems are common among individuals with pyromania and include impaired functioning and thoughts of suicide. Although pyromania has been documented for almost two centuries, it remains a poorly understood disorder with limited data regarding neurobiology or treatment. This article details what is currently known about the clinical characteristics and treatment of pyromania.

History

Pyromania has been described in medical literature for at least two centuries. The term pyromania derives from the Greek, fire (*pyr*) and madness (*mania*). One of the first descriptions in medical texts was in 1838 by Jean-Etienne Esquirol who referred to the behavior as 'incendiary monomania.' Esquirol included pyromania with kleptomania and erotic monomania of examples of irresistible behaviors. Esquirol differentiated pyromania from simple fire setting by claiming that pyromania was due to an instinctive impulse independent of will. Since that time, although people have debated the validity of the disorder, surprisingly little has been written about pyromania.

Pyromania appeared in the first edition of DSM in 1952 as a supplemental term. Pyromania did not appear in DSM-II. In 1980, DSM-III categorized pyromania as an impulse control disorder not elsewhere classified, the same clinical diagnostic category it currently holds in the DSM-IV-TR.

Introduction

Pyromania, also referred to as pathological fire setting, is a disorder currently included in the *Diagnostic and Statistical Manual*, 4th edition (DSM-IV), as an impulse control disorder not elsewhere specified. Pyromania is defined by the following criteria according to DSM-IV: (1)

Epidemiology

Although documented cases have been reported for centuries, very little is known about the prevalence of pyromania. In the only study to examine the rate of pyromania in a community sample, 791 college students were asked about histories of fire setting. The study found

eight (1.01%) students who met DSM-IV criteria for lifetime pyromania. An additional 10 (1.26%) students met subsyndromal pyromania criteria, which was defined by the behavior causing significant distress and dysfunction but not meeting full criteria for DSM-IV pyromania. In general, the finding that over 2% of the sample had either clinical or subsyndromal pyromania suggests that pyromania may not be an uncommon disorder.

Several studies of clinical, noncriminal samples also suggest that pyromania may not be uncommon. One study of 107 patients with depression found that three (2.8%) met current DSM-IV criteria for pyromania. A recent study of 204 psychiatric inpatients revealed that 3.4% ($n=7$) endorsed current symptoms, and 5.9% ($n=12$) had lifetime symptoms meeting DSM-IV criteria for pyromania. Small studies of individuals with compulsive buying ($n=20$) and kleptomania ($n=20$) have also found frequencies of 10% ($n=2$) and 15% ($n=3$), respectively, for lifetime pyromania. Although adolescent fire setting may be a symptom of various psychiatric disorders, a recent study of 102 adolescent psychiatric inpatients found that after excluding those patients who set fires due to conduct disorder, substance use disorders, bipolar disorder, psychotic disorders, or developmental disorders, seven (6.9%) met the criteria for current pyromania. All seven adolescents with pyromania were girls.

Clinical Characteristics of Pyromania

Little data have been published from clinical samples describing the characteristics of individuals with pyromania. Age of onset for pyromania is generally late adolescence or early adulthood, although onset as late as the fourth decade of life is not uncommon. Pyromania appears to occur equally in men and women. Most individuals with pyromania are single, employed, and have at least a high school education. Some may work in jobs that allow them easy access to fires (e.g., firefighter).

Individuals with pyromania frequently report a rush when watching or setting fires. Stress and boredom are common triggers for starting fires. Many people with pyromania set what they consider to be controlled fires in dumpsters, their bathrooms, backyards, or vacant lots. Considerable time is spent on planning the fires, buying utensils to set the fires, and planning what items will burn well and most intensely. In addition, many individuals with pyromania spend considerable time watching fires and traveling to fires when they hear fire engines. The time spent on planning, setting, and watching fires significantly interferes with other responsibilities. Frequency of setting fires increases over the course of the illness, with less time between fires, and the intensity of the fires also increases over time. Many individuals report switching to other types of impulsive behavior

after stopping fire setting (e.g., compulsive buying, alcohol or drug addiction, pathological gambling).

Although individuals with pyromania report either pleasure or relief when setting fires, the vast majority also report significant distress following their behavior. Suicidal ideation is common subsequent to setting fires. Social or occupational impairment due to activities associated with setting fires is common. Although the behavior of pyromania often results in arson, most individuals have not been arrested. Histories of physical or sexual abuse while growing up are fairly common in individuals with pyromania.

Comorbidity

Psychiatric comorbidity appears to be quite common in persons with pyromania. Lifetime rates of mood (62%; most commonly major depressive disorder), impulse control (47%; most commonly kleptomania), anxiety (33%; most commonly posttraumatic stress disorder), and substance use (33%) disorders have been documented in those with pyromania. The majority of individuals with pyromania with mood or substance use disorders indicate that pyromania preceded the other disorders. In addition, pyromania has been associated with attention-deficit/hyperactivity disorder, learning disabilities, dementia, and mental retardation.

Relationship of Pyromania to Other Psychiatric Disorders

Approximately 10 years ago, researchers suggested that one way to understand an impulse control disorder, such as pyromania, was as part of an obsessive-compulsive spectrum. In addition, other models for understanding pyromania have been suggested, and research suggests that behavioral diagnoses such as pyromania may be far more heterogeneous than initially thought.

Pyromania is characterized by repetitive behavioral engagement and impaired inhibition. The difficult-to-resist and difficult-to-control fire-setting characteristics of pyromania suggest a similarity to the frequently excessive, unnecessary, and unwanted rituals of obsessive-compulsive disorder (OCD). There are, however some apparent differences between pyromania and OCD. For example, unlike individuals with OCD, majority of the individuals with pyromania report an urge prior to engaging in the problematic behavior and report their behavior as pleasurable. Individuals with OCD generally describe their behaviors as ego-dystonic and harm avoidant. Only one study has examined OCD in subjects with pyromania, and it found that a 4.8% co-occurrence of OCD in pyromania. When pyromania has been examined

in subjects with OCD, relatively low co-occurrence has also been found (0.3%). Controlled family studies with pyromania are currently lacking, and therefore any putative familial link between pyromania and OCD cannot be precisely determined.

The model of pyromania as a behavioral addiction also has support from recent research. Pyromania shares certain distinct features with substance use disorders: (1) an urge to engage in a behavior with negative consequences; (2) mounting tension unless the behavior is completed; (3), rapid but temporary reduction of the urge after completion of the behavior; (4) return of the urge over hours, days, or weeks; and (5) a pleasurable feeling or rush. In addition, the majority of individuals with pyromania report that the time between episodes of fire setting decreases over time and the intensity of the fires increases over the course of the illness. This element is reminiscent of tolerance in substance use disorders. Finally, pyromania frequently co-occurs with substance use disorders with a lifetime frequency of approximately 33%.

Mood disorders also co-occur frequently with pyromania and have led to the possible inclusion of pyromania within an affective spectrum. Lifetime mood disorders occur in approximately 62% of individuals with pyromania. However, a study of 107 patients with depression found that three (2.8%) met current criteria for pyromania. Individuals with pyromania often report that their symptoms worsen, or are triggered by negative mood states. Fire setting may have an antidepressant effect. In addition, because of the elevated rates of co-occurring bipolar disorder (14%) and because pyromania behavior is risky, pyromania may also be a symptom of subclinical hypomania or mania in some individuals.

Ultimately, an assessment of pyromania's relationship with other psychiatric disorders needs to consider the respective etiologies. Unfortunately, knowledge of this aspect of pyromania is not yet advanced enough to precisely address this topic.

Differences between Pyromania, Fire Setting, and Arson

There is often confusion about the terms used to describe the various types of fire setting. Pyromania is the proper term for fire-setting behavior only when the DSM-IV criteria have been met. In contrast to pyromania, arson is not a diagnosed psychiatric disorder or medical illness and has a distinct definition that differs from that of pyromania. Although state statutes may differ on the explicit language, arson is generally defined as a crime of maliciously, voluntarily, and willfully setting fire to a building or other property of another person or burning one's own property for an improper purpose (e.g., insurance fraud). In general, the motivation of an arsonist is for

some type of gain, whether it revenge for a wrongdoing, insurance fraud, or for sociopolitical or religious reasons. Pyromania, on the other hand, is an impulse- or urge-driven behavior, which affects, among other things, the social and occupational lives of the individuals suffering from the illness. These urges have been described as addictive, and the act of setting a fire produces a sense of calm for the individual.

Unlike true pyromania, arson appears to be a common occurrence that affects many people, both financially and emotionally. In 2004, there were 68 245 reports of arson offenses in the United States, according to statistics from the Federal Bureau of Investigations, with an average dollar loss per incident of \$12 017. Recent data provided through the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) found that 1.13% of a large community sample acknowledged having started a fire, in their lifetimes, for the purpose of destroying someone else's property or just to see it burn. Very few arsonists, however, suffer from pyromania. One study found that only three (3.3%) of 90 arson recidivists had pure pyromania and that an additional nine subjects met DSM criteria for pyromania only when intoxicated at the time of the fire setting. In addition, not everyone who suffers from pyromania is an arsonist. A person meeting DSM-IV criteria for pyromania may also meet the legal definition of arson, but the DSM-IV criteria for pyromania do not require that a person ever set fire to another person's property.

Fire setting may also be associated with a variety of psychiatric disorders even when the diagnostic criteria for pyromania are not fulfilled or when the legal definition of arson is not met. Previous studies have suggested that the lifetime prevalence of fire setting may be approximately 26% in psychiatric patients. In these patients, fire setting has been linked to other self-injurious behaviors. Fire setting may also result from command hallucinations, delirium related to drug use, and manic grandiosity. In these patients, it has also been hypothesized that fire setting may be a manifestation of impulsivity, psychopathy, or affective dysregulation.

Child and Adolescent Fire Setting

A fascination with fire is an occurrence that has been documented for centuries. Usually beginning about the age of 2 or 3 years, attraction for fire may remain constant throughout an individual's life. In fact, behaviors such as playing with matches have been noted to occur in 24.4% of child psychiatric outpatients while fire-setting rates of 19.4% have been found in this sample. Although it is presently unknown how common this behavior is for children in the general population, the consequences of this behavior can be serious. Burn injuries account for

40% of accidental deaths in children under the age of 5, making these injuries the second leading cause of death for this age group.

While child and adolescent fire setting is serious and fairly common, true pyromania is quite rare in this age group. Children generally set fires out of vengeance, peer pressure, or impulse, and not out of an urge to relieve a building tension or as a response to an urge. For example, when 17 young fire setters were asked to identify their respective reasons for starting fires, their responses included revenge, to conceal a crime, for self-harm, due to group peer pressure, denial of the act or accidental, and a fascination with fire. In this sample, the individual endorsing a fascination for fire would be a possible candidate for a diagnosis of pyromania.

As noted above, fire setting itself is quite common in the child and adolescent age groups. Statistics have shown that nearly 50% of arson arrests are juvenile offenders. Common risk factors for this behavior have been identified within the juvenile population. Males have been shown to set fires 10 times more frequently than females. A study of 205 juvenile fire setters revealed that children who had experienced some form of maltreatment (i.e., physical abuse, neglect, or sexual abuse) were more likely to set fires in response to anger and be motivated by a family stressor than those without a history of maltreatment. Although associated with lower socioeconomic income, research has revealed that a variety of socioeconomic backgrounds is prevalent in the juvenile fire-setting population. Research has also shown that many fire-setting individuals in the juvenile population have experienced parental neglect and both emotional and physical abuse. Consistently, juvenile fire setting has been associated with adjustment and conduct disorder.

Etiology of Pyromania

Although abusive childhoods have been associated with fire setting in children and adolescents, little research has investigated possible neurobiological correlates of pyromania. In a study of a single individual with pyromania, neuroimaging using single photon emission computed tomography (SPECT) found left inferior perfusion deficits in the frontal lobe. New-onset fire setting has also been described in an individual with an arachnoid cyst of the cerebellar vermis.

The underlying biological mechanism of urge-based disorders may involve the processing of incoming reward inputs by the ventral tegmental area–nucleus accumbens–orbital frontal cortex circuit. This circuit influences motivations (e.g., urges and cravings) and related behaviors. Dopamine may also play a major role in the regulation of this region's functioning. One hypothesis is that differences in these regions may result in urges seen in

pyromania and other impulse control disorders. The efficacy of topiramate (see below) lends further support to this hypothesis. Topiramate is thought to modulate dopaminergic function neurons in this area.

Because serotonergic systems have been implicated in impaired impulse regulation, serotonin dysregulation may also contribute to the pathophysiology of pyromania (as well as other impulse control disorders). Selective serotonin reuptake inhibitors (SSRIs) have shown preliminary promise in the treatment of pyromania. The use of SSRIs is based on the hypothesis that the etiology of impulsive behaviors and disorders may relate to low levels of serotonin in selected brain regions.

Treatment

There are no randomized, controlled, clinical trials examining either pharmacotherapy or psychotherapy for the treatment of pyromania. No medications have been approved by the Food and Drug Administration (FDA) for the treatment of pyromania.

Medications that have been described in case reports and which may show benefit in the treatment of pyromania include topiramate, escitalopram, sertraline, fluoxetine, lithium, and a combination of olanzapine and sodium valproate. An equal number of medications have also shown no benefit in the treatment of pyromania in case reports: fluoxetine, valproic acid, lithium, sertraline, olanzapine, escitalopram, citalopram, and clonazepam.

Another case report, illustrating the treatment of an 18-year-old male with pyromania, described the use of a combination of topiramate with 3 weeks of daily cognitive behavioral therapy (CBT), which included imaginal exposure, relaxation training, response prevention, and cognitive restructuring of fire-setting urges. Other studies describing behavioral treatments of pyromania include methods such as fire safety education, aversive therapy, positive reinforcement, stimulus satiation, and operant structured fantasies and prevention programs designed for pyromania.

There is no standard treatment for pyromania at this time. Given existing data, an approach using both psychotherapy and pharmacological treatment may be most beneficial.

Pyromania often may go undiagnosed. Many reasons exist for why such severely distressing behaviors may not be diagnosed. Shame and secrecy are often associated with pyromania, largely due to the illegal or perceived immoral nature of the behavior. Many people are also embarrassed because of the diminished control they exhibit over the fire-setting behavior. Such embarrassment and shame may explain, in part, why so few patients may volunteer information regarding this behavior unless specifically asked. Often related to the shame and secrecy may be a patient's

misunderstanding of what a mental health clinician is required by law to report. Patients suffering from pyromania may believe that the clinician is required to report their illegal behaviors. Clinicians therefore may want to inform patients at the outset of the evaluation concerning what they do and do not have to report.

Conclusions

Pyromania is an impulse control disorder that has received relatively little attention from the psychiatric community. Nonetheless, pyromania may cause significant psychological, social and legal repercussions. Because few individuals volunteer information regarding their fire-setting, it is important that clinicians recognize the disorder and screen patients appropriately. Various treatments have been helpful in case studies but more research examining etiology and treatment is needed.

Glossary

Habit-reversal therapy – A form of psychotherapy with evidence for efficacy in the treatment of trichotillomania, initially developed by Azrin and Nunn for the treatment of nervous habits. This type of therapy involves training patients to recognize situations where they are likely to undertake hair pulling and to perform competing response strategies, such as clenching fists.

Impulsivity – A multifaceted term in psychiatry referring to behaviors that are premature, risky, inappropriate, and which lead to negative long-term outcomes or harm. In the neurosciences, several dissociable manifestations of impulsivity have been described, including notably impaired response inhibition – difficulty suppressing simple motor responses when instructed to stop by a cue. Impaired response inhibition has been identified in trichotillomania, obsessive-compulsive disorder (OCD), attention-deficit hyperactivity disorder (ADHD), and other conditions.

Noradrenaline – Noradrenaline is a molecule that, within the central nervous system, is involved in neurotransmission. Noradrenaline has been implicated in processes such as arousal, attention, and impulse control.

Obsessive-compulsive (OC) spectrum disorders – Disorders characterized by repetitive habits that are difficult to suppress, purportedly linked to OC disorder (OCD) in terms of etiology and comorbid expression.

Putamen – Part of the basal ganglia that has been implicated in the generation of motor habits, such as tics in Tourette's syndrome or hair pulling in trichotillomania. Patients with trichotillomania show abnormally increased gray matter density in this region compared to healthy volunteer controls.

Trichophagia – Referring to the ingestion of hair, it is often observed in association with trichotillomania and can lead to significant medical complications.

Case Example

Mrs. G, a 24-year-old taxi driver, presented to an academic research unit with a history of repetitive hair pulling since the age of 13. She could not identify any obvious triggering factors during adolescence, and had thus far managed to conceal eyebrow loss successfully using makeup. More recently, the hair pulling had escalated, now affecting not only her eyebrows but also her scalp, and occupying 3–4 h per day. Consequentially, hair loss had become noticeable to her partner and friends, and was now associated with functional impairment, social avoidance, and comorbid depression.

Introduction

Trichotillomania (compulsive hair pulling) is a common, chronic, poorly recognized, and ill-understood mental disorder. Responsible for considerable shame and distress, its sufferers expend great energy concealing its effects. Trichotillomania is the most researched of several phenomenologically and possibly psychobiologically related grooming behaviors, along with nail biting and skin picking – which in milder forms are common in the background population. Their psychopathology exists in the focus, duration and extent of the behavior, as well as the resulting impairment (e.g., noticeable hair loss or tissue damage, distress, and functional disability). There is increasing awareness of the morbidity associated with these habit disorders, but to date few research trials into neurobiology, pharmacotherapy, or psychotherapeutic strategies have been performed. Patients diagnosed with trichotillomania show similarities to those with compulsive skin picking with respect to demographic characteristics, psychiatric comorbidity, and personality dimensions. In this article, we focus on the

psychopathology of trichotillomania, comparing, where possible, data on compulsive skin picking and other grooming disorders. Improved understanding of the underlying neuropsychological mechanisms, including affective and cognitive components, may shed light on the nosological relationships between these conditions and with other impulsive/compulsive mental disorders, paving the pathway for more effective targeted treatments.

Clinical Characteristics and Co-Occurring Disorders

The phenomenon of hair pulling has been recognized for centuries. Accounts are found in the *Old Testament (Book of Ezra)*, Homer's *The Iliad*, and the plays of William Shakespeare (e.g., *Romeo and Juliet*). The earliest references to hair pulling in the medical literature are attributed to the Greek physician, Hippocrates. In his work, *Epidemics I*, Hippocrates recommended that physicians examine whether a person 'plucks his hair' as part of their general examination to determine if disease is present. In modern medical texts, accounts of trichophagia (hair eating) appeared before hair pulling. In 1889, the French dermatologist Francois Hallopeau coined the term 'trichotillomania' in describing a young man who pulled out his body hair.

Trichotillomania was not formally incorporated into official psychiatric nosology until 1987, revised, third edition of the *Diagnostic and Statistical Manual (DSM-III-R)*. The DSM-III-R diagnostic criteria were essentially the same as those currently in DSM-IV, except that the phrase "recurrent failure to resist impulses to pull" was removed, one of the criteria was expanded to include tension experienced when attempting to resist hair pulling, and distress or impairment due to hair pulling was added as a diagnostic requirement (**Figure 1**). During the drafting of DSM-IV, trichotillomania was considered for inclusion both in the anxiety disorders (because of presumed similarities to obsessive-compulsive disorder (OCD)) and the disorders first presenting in childhood or adolescence. As in the case of DSM-III-R, the DSM-IV included trichotillomania in the general

category of impulse-control disorders not elsewhere classified, together with pathological gambling, pyromania, intermittent explosive disorder, and kleptomania.

Repetitive hair pulling in trichotillomania is usually from the scalp and/or eyebrows, but any body site with hair can be affected. Although rising tension and subsequent pleasure, gratification, or relief are integral to the current diagnostic criteria, in many cases, clinically distressing and noticeable hair pulling exists in people who do not endorse these strict criteria. These individuals should not be overlooked when it comes to providing treatment, and the DSM allows for some clinician discretion in the application of the criteria more generally. Trichotillomania has, in surveys, been linked with reduced work productivity, disruption of family life, and avoidance of sports/social activities. Comorbidity with other mental disorders occurs in the majority (82%) of cases presenting to psychiatrists, of which depression, OCD, other anxiety disorders and substance abuse are the most common co-occurring Axis I disorders. Medical complications can also arise, including repetitive strain injury, dermatological scarring, and gastrointestinal obstruction following hair consumption (trichophagia). A recent review of 68 trichotillomania patients found that trichophagia was common (16.2%) and most patients with this condition had not received an evaluation for the possibility of medical consequences resulting from the ingestion of hair. Like trichotillomania, compulsive skin picking is also associated with psychosocial distress. For example, researchers found that 12% ($n = 4$) of 34 outpatients with skin picking reported suicidal ideation attributable to their disorder.

In contrast to trichotillomania, there is as yet no specific diagnostic category for other body-focused habit disorders such as skin picking, knuckle cracking, and nail biting. According to the DSM-IV, these may be diagnosed either under the category of stereotypic movement disorder usually first diagnosed in infancy or adolescence (DSM 307.3), or alternatively as impulse-control disorders not otherwise specified (DSM 312.30). Indeed, emerging evidence argues for the inclusion of habit disorders such as trichotillomania and compulsive skin picking in a separate section of OCDs in a revised nosology.

- A. Recurrent hair pulling
- B. Increasing tension immediately before pulling or when resisting the behavior
- C. Pleasure, gratification or relief when pulling out the hair
- D. Not better accounted for by another mental disorder or dermatological condition
- E. Causes clinically significant distress or impairment in social, occupational, or other important areas of functioning

Figure 1 DSM-IV Criteria for trichotillomania (312.39)(APA 1994), abridged by the authors.

Trichotillomania, Habit Disorders, and the Obsessive–Compulsive Spectrum Disorders

The repetitive motor symptoms of trichotillomania and other body-focused habit disorders appear similar to the repetitive motor tics seen in Tourette's syndrome or even compulsive rituals in OCD. These conditions are thought to share overlapping elements of phenomenology, etiology, and neurobiology and to constitute a putative OC spectrum. Such repetitive, unwanted behaviors may persist due to underlying problems with inhibitory executive neurocognitive control governing habits. Comorbidity between different candidate spectrum disorders is common. For example, whereas compulsive skin picking was found most commonly to present in the context of OCD, it also frequently accompanied body dysmorphic disorder, obsessive–compulsive personality disorder (OCPD), and borderline personality disorder. One other study examined OC-spectrum disorders in OCD subjects and found that trichotillomania clustered with pathological gambling and hypersexual disorder within a proposed reward deficiency group. In contrast, disorders such as self-injurious behavior and body dysmorphic disorder clustered within impulsivity and somatic groups, respectively. The finding that relatives of individuals with OCD showed higher-than-expected rates of grooming disorders (hair pulling, nail biting, and skin picking) lends stronger support to the spectrum theory, although further research is clearly needed.

To further characterize the validity of the OC-spectrum approach, large-scale studies are needed to explore whether rates of habit disorder in OCD-patient relatives (and OCD in habit-disorder-patient relatives) are disproportionately elevated relative to other Axis I conditions. Important differences between trichotillomania and other putative OC-spectrum conditions should not be overlooked. For example, hair pulling in trichotillomania is seldom driven by (or associated with) intrusive thoughts, as distinct from the compulsions seen in OCD. Further research examining impulsive–compulsive neurocircuitry may identify a subtype of trichotillomania more like OCD, and another more like other impulse-control disorders or addictions.

Epidemiology

There have been no population-wide epidemiological studies of trichotillomania, compulsive skin picking, or other body-focused habit disorders. Studies of college students have reported prevalence rates ranging from 0.6% to 3.9% for strictly defined trichotillomania. In addition, hair pulling resulting in noticeable hair-loss

(although not meeting diagnostic criteria for trichotillomania) was reported by as many as 1.5% of males and 3.4% of females. Interestingly, one study found that, when the results were analyzed by gender, 4.1% of females and 3.5% of males had trichotillomania. In treatment trials, usually threefold or greater proportions of women than men participated. It remains to be seen whether this reflects genuine female preponderance or selection bias against males in seeking treatment. Archetypal trichotillomania begins in early puberty (age range: 11–13 years) and follows a relapsing-remitting course into adulthood. The majority of sufferers have never received treatment, and patients report disappointing outcomes from the available applied interventions. By contrast, hair pulling in very young children may be regarded as a distinct clinical entity that can resolve before adolescence without the need for medical intervention.

Studies investigating smaller numbers of US and European college students have identified rates of severe skin picking, resulting in significant distress and tissue damage, ranging from 3.8% to 4.6%, of whom the majority (>80%) were female. However, as many as 90% of a cohort of 133 German students reported occasional skin picking. Like trichotillomania, the onset of picking was reported to occur around early puberty. The students primarily squeezed (85%) and scratched (77.4%) the skin, with a primary focus on the face (94.7%) and cuticles (52.6%). About 20% ate the picked tissue afterward. These preliminary findings suggest compulsive skin picking is an under-recognized problem that occurs on a continuum ranging from mild to severe and may be associated with significant medical consequences.

Neuropsychological Models

Affect-Regulation and Reward

Hair pulling is thought to increase during times of both boredom and stress. It has, therefore, been hypothesized that the behavior may, at least in its initial phases, be used to regulate arousal – either by stimulating or soothing. In one study, 39% of individuals with trichotillomania reported pleasure or a sense of accomplishment from the act of hair pulling which may, therefore, contribute to its repetition. Skin picking and nail biting, likewise, may induce a sense of satisfaction or relief, although for many these symptoms appear to run automatically and to cause distress rather than relief. Mechanisms involved in reinforcement are likely to overlap with those involved in addictive behaviors including substance addiction, and may involve dopaminergic projections within the ventral striatal reward neurocircuitry.

Individuals with trichotillomania and other body-focused repetitive behaviors often exhibit comorbid anxiety and depression. In such cases, individuals may engage

in hair pulling to distract themselves from life stressors and unpleasant cognitions. The risk of developing bald spots may be viewed as a relatively minor setback, at least initially. Unfortunately, the development of bald spots can, in turn, exacerbate depression and anxiety, leading to even more pulling as a misguided attempt at symptom management. These findings are consistent with a study that identified negative affective states and poor self-esteem as the primary triggers for trichotillomania. In another more recent study, individuals with trichotillomania were compared to a control group and reported lower life satisfaction, higher levels of distress, and lower self-esteem. Poor self-esteem was related to concerns about appearance, embarrassment, the need to avoid certain activities due to hair loss, and frustration with the inability to control hair pulling.

Nervous habits may begin as a reaction to physical injury or psychological trauma, and there has been speculation over the years as to whether trichotillomania is associated with childhood trauma. Cases of trichotillomania have been described in association with early physical and/or sexual abuse. One study of females with trichotillomania ($n=60$) found that 18% had histories of childhood sexual abuse. However, it remains to be clearly demonstrated in an appropriate study design whether individuals with trichotillomania experience increased rates of childhood abuse versus people with no history of DSM disorders, or those with other Axis I disorders.

Neurocognitive Impairment

Neurocognitive deficits have been hypothesized as potential contributors to the etiology of habit disorders, either representing vulnerability markers or contributing to the manifestation of symptoms themselves. Such a proposal is based mainly on evidence from research into OCD, where impaired inhibitory control and linked frontostriatal abnormalities have been identified in patients and their unaffected first-degree relatives. Unfortunately, there have been no published studies of cognition in patients with skin picking or nail biting to date. The main studies in trichotillomania are discussed below.

The first neurocognitive investigation in trichotillomania used the Stylus maze test, in which individuals attempt to learn the correct path for navigating across a peg-board, using a stylus. Patients with trichotillomania showed problems on several indices of the test involving a range of abilities including memory, planning, motor execution, and error learning. However, a subsequent study using a similar test (the Austin maze task) found no evidence for deficits in trichotillomania patients who were free from major depression and psychosis.

Impulsivity is a multifaceted term in the neurosciences, and represents a focus of attention in body-focused repetitive behavior research. One form of impulsivity is referred

to as ‘motor impulsivity’ – a diminished ability to suppress motor responses when appropriate to the situation at hand. This ability has classically been measured using tasks that require volunteers to make simple motor responses (e.g., pressing a button) on some computer trials but not on others. Translational research suggests that motor inhibition is dependent on the right inferior frontal gyrus and noradrenergic neurotransmission across species. Using a Go/No-Go task where participants responded to the letter ‘X’ but not the letter ‘O’ on-screen (or vice versa) one study reported intact performance in patients with trichotillomania. Another study used a stop-signal task previously validated in ADHD and brain-lesion studies. Using an individually tailored tracking algorithm, the time taken by the brain to suppress an already initiated response – referred to as the stop-signal reaction time (SSRT) – is estimated. In this later study, patients with trichotillomania exhibited impaired inhibitory control compared to healthy controls and patients with OCD. The degree of deficit was similar to that previously reported in studies of adult patients ADHD.

The Wisconsin Card Sorting Test (WCST), which measures rule learning and cognitive flexibility, is a classic test of frontal lobe integrity. Participants attempt to learn a rule governing which of two cards is correct on the basis of trial and error (feedback). The rule is then altered and individuals attempt to show flexibility and acquire the new rule. Two studies have employed this task in patients with trichotillomania, and both reported performance to be intact. A more recent study has used a computerized variant of the WCST called the extradimensional set-shift task (ED-shift task) from the Cambridge Neuropsychological Test Automated Battery (CANTAB). Consistent with these previous WCST studies, patients with trichotillomania exhibited normal performance on all stages of the ED-shift task. OCD patients exhibited cognitive inflexibility on the task, suggesting that there are important differences (as well as some overlap) between the neuropsychological profiles of trichotillomania and OCD. Future work should measure similar functions in skin picking and nail biting in order to clarify the extent of overlap in the cognitive profiles of the body-focused habit disorders.

Neuroanatomical Models

It is important to question whether trichotillomania, skin picking, and nail biting are associated with similar changes in brain structure or function since this would inform neurobiological models, enhance our understanding of the relationships between conditions, and potentially lead to advances in treatment. For example, it is well established that OCD is associated with abnormalities in distributed brain circuitry, including the

orbitofrontal cortices and basal ganglia (especially caudate). To the authors' knowledge, there have been no imaging investigations of nail biting or skin picking at this time. The main results from trichotillomania studies are as follows.

Most imaging studies in trichotillomania have used region of interest (ROI) approaches; that is, they have set out to measure whether specific structures of the brain show differences in patients versus controls. This minimizes multiple comparisons but could lead to important regions being overlooked. Based on a possible link between OCD and trichotillomania, one study measured caudate volumes in trichotillomania but detected no abnormalities. Another study reported reduced left inferior frontal gyrus and increased right cuneal cortex volumes in patients compared to controls, while another study found smaller left putamen volumes. Using parcelation techniques, one other study identified reduced cerebellar volumes in trichotillomania patients compared to controls.

A single study has investigated whether trichotillomania is associated with brain changes without restriction to particular ROIs. This study took advantage of recently developed methods of neuroimaging analysis thought to provide greater power to detect group differences than conventional parametric techniques. Patients with trichotillomania showed increased gray matter density in distributed circuitry including the cingulate cortex, amygdala–hippocampal formation, and putamen. These regions have been implicated in action monitoring, affective processing, and motor habit generation, respectively.

In terms of brain function (as opposed to structure), positron emission tomography (PET), single photon emission computed tomography (SPECT), and functional MRI (fMRI) have been used in some trichotillomania studies. In one PET study, normalized resting cerebral glucose metabolic rates were shown to be abnormally increased in the bilateral cerebellum and right parietal cortex in patients with trichotillomania. Another study used SPECT to explore the effects of 12-week pharmacotherapy with the selective serotonin-reuptake inhibitor (SSRI) citalopram on brain circuitry in patients with trichotillomania. Treatment was associated with reduced activity in frontal cortical regions, the left putamen, and the right anterior-temporal lobe. Using a sequence learning task in conjunction with fMRI, another study found no evidence for abnormal brain activation in trichotillomania patients versus controls.

Animal Models

Comprehensive investigation of the neurobiology of any psychiatric condition, or group of conditions, is enhanced by the development of animal models. Etiological models

focus on spontaneously arising repetitive or stereotypic behaviors, such as tail chasing, fur chewing and weaving, and motor behaviors driven by conflict, frustration, or stress – such as grooming, cleaning, and pecking. Laboratory-study behaviors that are induced and not spontaneous (e.g., as resulting from pharmacological or genetic manipulations) may limit the generalizability of results. Barbering (abnormal whisker and fur trimming) is limited to a subgroup of laboratory mice and has been proposed as a mouse model of trichotillomania and possibly other body-focused behaviors. Mouse barbering appears to parallel trichotillomania in terms of phenomenology (hair plucking from the scalp and around the eyes/genitals), demography (female biased, onset during puberty), and etiology (genetic background). The barbering mouse model might provide useful information on genetic and environmental etiological factors in trichotillomania.

Another key animal model, to date, is based upon the observation that mice with mutations of the Hoxb8 gene groom excessively. This model is potentially useful since the excessive grooming of Hoxb8 mutants is similar to the excessive grooming seen in trichotillomania. Critically, the Hoxb8 gene is expressed in the orbital cortex, the anterior cingulate, the striatum, and the limbic system – circuitry which has been recently implicated in the pathophysiology of trichotillomania based on the whole-brain-permutation brain analysis described above.

Treatment

Multiple psychometrically sound instruments for the measurement of trichotillomania have been developed. Assessments of habits in subjects with intellectual disability are well established and rating scales for skin picking now exist. No formal treatment guidelines exist for these disorders since the evidence base is limited by the lack of satisfactory clinical trials. Treatment-development has been further hampered by a failure to take account of overlap with other Axis I conditions.

Psychotherapy

There is some evidence supporting psychotherapy for trichotillomania and compulsive skin picking, albeit the studies have had limitations. In the first formal treatment study for trichotillomania, 34 subjects were randomized to either habit reversal therapy – a form of cognitive behavioral therapy involving attention to triggering situations and practiced resistance to pulling urges – or negative practice where subjects stand in front of a mirror and act out motions of hair pulling without actually pulling. Habit reversal reduced hair pulling by more than 90% after 4 months, compared to 52–68% reduction for negative

practice at 3 months. Another study examined 25 subjects randomized to 12 weeks (10 sessions) of either acceptance and commitment therapy/habit reversal or wait list. Subjects assigned to active therapy experienced significant reductions in hair-pulling severity and impairment compared to those assigned to the wait-list, and improvement was maintained at the 3-month follow-up. However, the wait-list lacks credibility as a realistic control treatment.

Recent case studies have also described a positive effect for the use of cognitive behavioral therapies involving habit-reversal elements for the treatment of skin picking. Elsewhere, 372 individuals were consecutively enrolled in an uncontrolled, Internet-based, self-help treatment for self-injurious skin picking. Results revealed significant reductions in frequency of picking episodes and symptom-severity ratings from baseline over a 5-month period, suggesting a role for self-help, computer-based treatments in this field.

Pharmacotherapy

Several controlled pharmacological trials have been performed in trichotillomania. Four of the six published double-blind pharmacological studies examined antidepressants, mainly SRIs. One study compared the serotonergic tricyclic clomipramine to the noradrenergic tricyclic desipramine in a 10-week double-blind, crossover design (5 weeks for each agent). Clomipramine significantly outperformed desipramine, and 12 of the 13 subjects showed significant improvement on clomipramine. A preliminary study reported in poster form, using a randomized, double-blind, nonplacebo, crossover design, compared 10 weeks of fluoxetine with 10 weeks of clomipramine treatment. Both agents demonstrated a similar positive treatment effect.

Fluoxetine has been studied in two small randomized trials with negative results in patients with trichotillomania. In one study, fluoxetine was compared with placebo in a 6-week double-blind crossover study with a 5-week washout period between treatment arms (15 completers). No significant differences were found between fluoxetine and placebo on measures of hair-pulling urges, frequency, or severity. Another crossover study compared 16 subjects on 12 weeks of fluoxetine or placebo, with each agent separated by a 5-week washout period. Fluoxetine again failed to show significant improvement compared to placebo.

The opioid antagonist naltrexone (50 mg per day) was examined in a placebo-controlled, 6-week, randomized, double-blind parallel-arm study in trichotillomania. Of a total of 17 subjects completing the study, significantly greater improvement was noted for the naltrexone

group ($n=7$) than placebo ($n=10$) on one out of three trichotillomania measures.

A recent double-blind, placebo-controlled study – presented thus far in poster form only – examined olanzapine (mean dose: 10.8 mg per day) for 12 weeks in 25 trichotillomania subjects. Preliminary data reported in conference poster form revealed that 85% of those assigned to olanzapine, compared to 17% of those on placebo, improved during the trial.

Pharmacological agents have also been the most frequently studied treatment approach for compulsive skin picking, with nearly all studies examining the efficacy of SRIs. Twenty-five adult subjects with severe morbid nail biting and no history of OCD participated in a 10-week, double-blind, crossover trial of clomipramine and desipramine. A high dropout rate was observed. In the 14 subjects who completed the study, clomipramine was superior to desipramine hydrochloride in decreasing measures of impairment associated with nail biting. In another study, 21 skin-pickers were randomized to 10 weeks of either placebo or fluoxetine. Eight of the 10 participants in the fluoxetine condition were classified as much improved or very much improved, compared with only three of 11 participants in the placebo condition. In a subsequent study, eight responders, following 6 weeks of open-label treatment with fluoxetine, were then randomized to 6 weeks of double-blind fluoxetine or placebo. The four patients randomized to double-blind fluoxetine maintained clinically significant improvement, whereas the four randomized to placebo returned to their baseline symptom level.

Psychotherapy versus Pharmacotherapy, and Combination Treatment

Two partially controlled studies have compared pharmacological and psychological treatment interventions in trichotillomania. A placebo-controlled, randomized, parallel-treatment design was used to compare cognitive behavioral therapy and clomipramine. Twenty-three subjects entered the 9-week study. The cognitive behavioral therapy was a modified manualized treatment based on habit-reversal therapy. There was no psychological control treatment. Cognitive behavioral therapy was significantly more effective than either clomipramine or pill-placebo. Although clomipramine resulted in greater symptom reduction than placebo, the difference was not statistically significant, possibly owing to lack of power ($n=6$, in the clomipramine group). In a second comparison study lacking pill-placebo, behavioral therapy was compared to fluoxetine in a 12-week randomized trial using a wait-list control. Forty-three subjects were enrolled and 40 completed the trial (14 in behavior therapy, 11 in the fluoxetine group, and 15 in the wait list).

Behavior therapy resulted in statistically significant reductions in trichotillomania symptoms compared to either fluoxetine or wait-list in the completers. One other uncontrolled study investigated the effects of adding habit-reversal therapy for trichotillomania patients who had received 12-week sertraline but had not responded ($n=24$ completers total). Combination treatment appeared more effective than continuing with sertraline alone.

Treatment: Summary and Future Directions

It is unwise to generate strong recommendations for treating trichotillomania and body-focused habit disorders such as compulsive skin picking on the basis of such limited trial data. Although habit reversal appears promising for trichotillomania, the effectiveness of this treatment requires testing in properly constituted randomized controlled trials. Pharmacotherapy has been studied with more rigor, but trials have been too small and short in duration to be conclusive. For trichotillomania and nail biting, clomipramine demonstrated greater efficacy than did the tricyclic desipramine, but this finding has not been verified against placebo. For trichotillomania, SSRIs have not shown greater benefit than placebo so far, although two small positive studies suggest efficacy for fluoxetine as a treatment for skin picking. Initial promising findings involving olanzapine and naltrexone merit further evaluation. A recent meta-analysis of trichotillomania studies was unable to extend recommendations much further. There exists a need for further double-blind controlled trials to examine potentially beneficial pharmacological treatments in the short and, arguably more importantly, the longer term.

Conclusions

From a phenomenological perspective, trichotillomania and body-focused repetitive behaviors can be considered candidate members of the OC spectrum of disorders. The body-focused disorders may result from the progression of initially mild hair pulling and other grooming behaviors into a repetitive ingrained pathological behavior. Vulnerable individuals may be distinguishable by deficient top-down cortical inhibitory control governing motor habits, or overactive habit-forming circuitry. Brain abnormalities in neural regions involved in cognition and action monitoring (frontal lobes, cingulate cortices, etc.), affect regulation (amygdalo-hippocampal formation), and habit learning (putamen) have been tentatively implicated

in trichotillomania and may also be involved in other grooming disorders. Treatment algorithms are lacking, with habit-reversal therapy showing suggestive efficacy but limited availability. SSRIs show promise for treating compulsive skin picking but not for trichotillomania. Clomipramine produced benefit in trichotillomania and comorbid nail biting. Alternative pharmacotherapies merit exploration.

Glossary

cAMP – An intracellular signaling molecule, or second messenger that usually works by activating protein kinase A and can also have effects independent of such activation.

Gastropod – One of the classes of animals from the phylum Mollusca.

Operant conditioning – A training procedure in which an animal is reinforced contingent on some action of its own. It is also called instrumental conditioning or type II conditioning.

Pavlovian conditioning – A synonym for classical conditioning named after Pavlov, the originator of this training scheme.

Sensitization – This term has several slightly different usages. In the invertebrate learning literature, it usually refers to a nonassociative enhancement of an innate response due to application of some sort of strong stimulus to an animal.

Introduction

The learning abilities of invertebrates have attracted attention since the days of Darwin. Romanes, the father of comparative psychology, collected anecdotes about the learning abilities of all types of animals because he felt that the flexibility that learning imparted to behavior provided a behavioral criterion for the presence of mind, whose evolution he wished to trace. The experimental study of learning in invertebrates derived from Romanes' efforts. Of course, human behavior and culture are largely the products of learning; thus, the question of just what various kinds of animals can learn has been a topic of continuing interest. However, starting in the 1950s, there was a growing recognition that various features of invertebrates made them valuable material for gaining insight into neural mechanisms of learning. It was by that time clearly appreciated that all of the basic mechanisms of neural function that had by then been studied were highly conserved, being almost the same from the very lowest animals to humans, and there was no reason to suppose that this would not continue to be true for the mechanisms that

underlay learning. Since neuron numbers are much lower (invertebrates commonly utilize single neurons where vertebrates would utilize multiple neurons in parallel) and neural circuitry was thought to be simpler in invertebrates, and since invertebrates often had special features offering experimental advantages, such as extraordinarily large cells or rapid life cycles favoring genetic analysis, it seemed likely that invertebrates might be able to provide information about mechanisms of learning, which up to that time had been refractory to fruitful analysis in higher animals.

The first influential work taking advantage of invertebrates was on simple forms of nonassociative learning, such as habituation and sensitization, in the marine gastropod mollusk *Aplysia* ([Figures 1\(a\)](#) and [1\(d\)](#)) and, to a lesser extent, on the freshwater crayfish. Associative learning, in the form of Pavlovian conditioning, also began to be studied with some success. Early papers provided a number of valuable insights that have proved to be general. They confirmed the long-conjectured hypothesis that learning would involve synaptic change. They provided evidence that neuromodulators played important roles in establishing the neural changes that underlie learning. In addition, rather surprisingly, they suggested the possibility that learning may be more a matter of adjusting preexisting neural connections than of forming entirely new ones.

Not long after this pioneering work on invertebrates, long-term potentiation (LTP) was discovered in the mammalian hippocampus. This and other developments led to rapid advances in the analysis of learning in mammals. Vertebrate (mostly mammalian) and invertebrate work then became a two-way street. Findings on mammals have usually been found to apply, at least in a general sort of way, to invertebrates, and conversely. In some cases, some of the experimental advantages of invertebrates for studying certain kinds of issues have led to discoveries there, which have been confirmed in vertebrates. Sometimes, findings on vertebrates have spawned research on invertebrates, both to probe generality and to take advantage of special features of invertebrates that could facilitate analysis.

The cellular analysis of classical conditioning, which began in the sea slugs *Hermisenda* ([Figure 1\(b\)](#)) and *Aplysia* ([Figure 1\(a\)](#)), provides a good example of how related work on invertebrate and on higher vertebrate systems can be mutually facilitatory. Work on these

molluskan models, which took advantage of large neuron size and relatively simple circuitry, led to the first models of how synapses and networks alter during classical conditioning. The *Aplysia* model focused on evidence that Pavlovian training seemed to lead to increased release of transmitter from the neurons representing the conditioned stimulus (CS), and the *Hermissenda* model provided evidence for both synaptic facilitation and enhanced excitability of neurons of the CS pathway. The independent discovery of LTP in mammals eventually led to the recognition that synapses subject to certain kinds of LTP were Hebb synapses, which become enduringly strengthened by paired pre- and postsynaptic activity, and this mechanism provided a seemingly ideal substrate for classical conditioning. However, although indirect evidence was obtained that LTP was somehow involved in certain kinds of associative learning (place and contextual fear learning), it was at that time impossible to prove that LTP actually mediated the Pavlovian conditioning for which it seemed so suited. However, the findings on mammalian LTP motivated further experiments on *Aplysia*, which led to the discovery that, contrary to what had initially been thought, a mechanism with properties very similar to mammalian LTP was, in fact, responsible for the learning, seemingly in combination with the originally proposed mechanism. Thus, *Aplysia* provided the first really clear example of the use of LTP to produce Pavlovian conditioning, and it is still arguably the best such example, though

work on learning mediated by mammalian cerebellum and amygdala may now be regarded as equally convincing. Returning to the two-way street, there is now also some evidence that something like the presynaptic mechanisms originally described in *Aplysia* might also be found in mammalian systems. Likewise, there is increasing evidence that, similar to what was first described in *Hermissenda*, learning-induced changes in neuronal excitability (nonsynaptic plasticity) can also make important contributions to associative memory in mammals.

Although invertebrates are currently mostly exploited for their many technical advantages, comparative study *per se* continues to have great interest. Members of the invertebrate phyla seem as different from us as aliens from another planet, and the evolution of our and their learning abilities must have been largely independent. Thus, any commonalities that are found, and we see below that there are many, must have arisen largely independently. This suggests that primitive conserved features predisposed toward parallel evolution and/or that the inherent logic of what has to be accomplished constrained the learning circuitry and mechanisms to evolve in a particular way.

In this article, we first focus separately on each of several kinds of invertebrate animals that have provided useful information on learning. For each we briefly describe the kinds of learning that have been studied and aspects of the nervous system or other particulars that have been important to the analysis of learning. Having provided this background, we then compare and discuss some of the important findings that have emerged.

Systems Studied

Gastropod Mollusks

A long history of behavioral studies has established the existence of various forms of nonassociative and associative learning in snails such as *Helix* and *Lymnaea* and slugs such as *Aplysia*, *Hermissenda*, *Limax*, *Pleurobranchaea*, and *Tritonia* (see Figure 1). Habituation in mollusks was first described as early as 1910 in the freshwater snails *Physa* and *Lymnaea* and classical conditioning was first described in 1917 in *Physa*.

Starting in the mid-1960s, work on gastropods began to provide some of the first insights into the mechanisms of learning, and these animals continue to provide new and important information that cannot readily be obtained elsewhere. Gastropods have proved favorable for analysis because they have easily accessible central nervous systems with unusually large neurons (up to 800 µm in *Aplysia*; Figure 1(d)), many of which can be recognized from individual to individual; they also have a variety of reflexes and central pattern generator-driven behaviors that are subject to various forms of associative and nonassociative learning and whose circuitry is relatively simple. Analysis of synaptic

plasticity in isolated ganglia as well as at synapses between cultured neurons that have become synaptically connected has uncovered mechanisms that have then been found to be utilized for behavioral learning, and there also has been considerable success in analyzing changes within nervous systems of intact animals that have actually learned. Finally, an ever increasing amount of genomic and proteomic information has become available on mollusks, which has facilitated molecular analyses of learning and memory mechanisms and has provided strong evidence that these mechanisms are highly conserved between invertebrates and vertebrates. Most recently, the sequencing of the *Aplysia* genome has been completed.

We discuss below work on learning affecting defensive withdrawal reflexes of *Aplysia*, learning of a protective response in *Hermisenda*, and an appetitive Pavlovian conditioned reflex in *Lymnaea* as illustrative of a set of analyses too large to recount fully here.

***Aplysia* defensive reflexes**

The first successful cellular analyses of learning addressed mechanisms of habituation and sensitization in *Aplysia*. *Aplysia* has delicate respiratory organs, the gill and siphon, which are reflexively retracted when it is touched. However, when a specific spot is repeatedly touched, retraction wanes (habituation); this habituation persists up to a few hours after one bout of stimulation (short-term habituation) but can last many days after repeated, spaced bouts (long-term habituation). If an animal is given a painful or traumatic stimulus (e.g., electric shock), retraction to touch all across the body becomes exaggerated (sensitization); following one noxious stimulus, sensitization lasts perhaps 30 min or less, but after repeated spaced bouts of noxious stimulation it lasts days or weeks (short- and long-term sensitization, respectively).

Illustrating the simplicity common in invertebrates, it was found that the sensory neurons that react to touch make monosynaptic connections with the motor neurons involved in retraction (see **Figure 2(a)**). Excitatory postsynaptic potentials (EPSPs) produced in the motor neurons by the mechanoreceptors decrease in amplitude when the mechanoreceptors are repeatedly stimulated, at least partly accounting for habituation; and EPSPs increase following traumatic stimulation, accounting for sensitization. It was rapidly discovered that the facilitation is associated with an increased release of transmitter from sensory neuron terminals (the facilitation was therefore referred to as presynaptic) and also discovered that it is release of serotonin (5-HT) and perhaps also peptide neuromodulators from facilitator neurons onto sensory-motor synapses of the gill/siphon retraction circuit that is the proximate cause of presynaptic facilitation. Slightly later work established that direct puffs of 5-HT onto sensory-motor synapses, even in culture, could cause facilitation; furthermore, repeated exposures separated by rests, which mimic the patterns of repeated spaced traumatic events that cause long-term

behavioral sensitization, also cause long-term synaptic facilitation. These seminal discoveries opened the floodgates to a huge amount of experimental work aimed at elucidating the ionic and molecular mechanisms of serotonin-induced facilitation in *Aplysia* (for which Eric Kandel received the Nobel prize in 2000).

The mechanisms whereby 5-HT causes increased spike-evoked transmitter release provided insights into mechanisms of plasticity that had considerable generality. First, it was found that 5-HT exerts its effect through production of cAMP and, in turn, activation of PKA in the sensory neurons. Single-channel recording experiments then led to the discovery that 5-HT-induced activation of PKA causes phosphorylation of certain species of K^+ channels, which are thereby made more prone to close. As a result, durations of presynaptic terminal calcium elevations increase, providing a possible explanation for release of more quanta per action potential. More recent work has shown that this is far from the whole story, but at the time the idea that behavioral sensitization could be explained in terms of altered channel function attendant on phosphorylation of the channel molecule itself, seemed like Lashley's dream of identifying the physical-chemical change responsible for learning, the engram, come true. Although the modern study of LTP and LTD has tended to emphasize the role of insertion and deletion of postsynaptic receptor molecules in synaptic plasticity, the phosphorylation of existing receptors generally occurs first and works to modulate their actions, much as proposed for the K^+ channels of *Aplysia* sensory neurons. Moreover, whereas other kinases (PKC, CaMKs, MAPKs, etc.) have subsequently also been found to have crucial roles in plasticity at both mammalian and *Aplysia* synapses, the importance of kinases as such was established by this early work.

By the 1980s, it had been known for several decades that long-term as opposed to short-term behavioral learning requires new translation and often gene transcription. Transcription and translation were also found to be needed for long-term serotonergic, PKA-mediated, facilitation in *Aplysia*. This led to experiments establishing that the cAMP-responsive element (CRE) of the genome initiated transcription needed for establishment of long-term facilitation. These findings were the direct motivation for mammalian experiments showing the role of the CRE-binding (CREB) protein in late LTP and in long-term learning in mammals. Subsequent experiments showed that one of the products of the protein synthesis needed to establish long-term facilitation is a molecule that breaks down the regulatory subunit of PKA, rendering existing PKA molecules constitutively active. This presaged recent findings on PKMzeta, which appears to play a crucial role in the persistence of late LTP. These findings constitute examples of the two-way street mentioned in the introduction of this article.

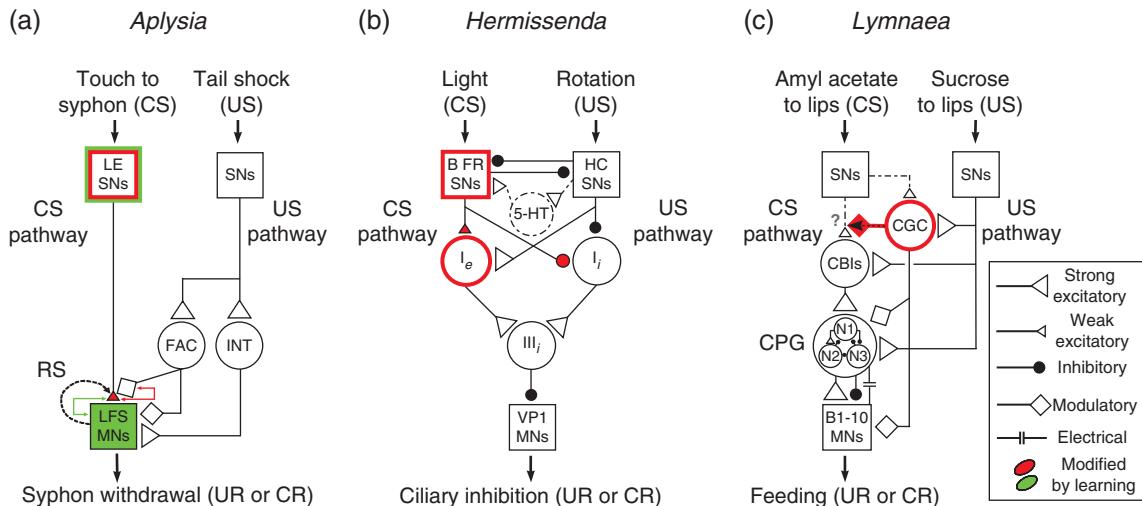

Figure 2 Cellular mechanisms of classical conditioning in mollusks. The location of learning-induced alterations is indicated in color. (a) Classical conditioning of the syphon withdrawal reflex in *Aplysia*. During conditioning, the conditioned stimulus (CS, touch to the syphon) weakly activates LE sensory neurons (SNs), which make monosynaptic connections onto LFS motor neurons. The unconditioned stimulus (US, electric shock to the tail) strongly activates tail sensory neurons that excite both facilitatory interneurons (FAC) that release 5-HT and other neuromodulators to produce presynaptic facilitation at the LE to LFS synapse, and other types of interneurons (INT) that postsynaptically excite the LFS motor neurons leading to syphon withdrawal, the unconditioned response (UR). A retrograde signaling (RS) mechanism (dashed arrow) has been suggested to operate between the postsynaptic motor neuron and the presynaptic sensory neuron. Red and green double-ended arrows indicate neuronal elements that must be activated conjointly for the induction of either activity-dependent presynaptic facilitation (red) or Hebbian LTP (green) at the LE-LFS synapses. After conditioning, the synaptic connections of the LE sensory neurons with the LFS motor neurons are strengthened (red synaptic terminal). The postsynaptic response to glutamate is also increased (green LFS motor neurons). The excitability of the LE sensory neurons is also increased both by classical conditioning and in simple sensitization (nonsynaptic plasticity, bold red and green outlines). These changes lead to an increased syphon withdrawal response to the touch CS, the conditioned response (CR). (b) Classical conditioning of the phototactic response in *Hermissenda*. I_e and I_i interneurons are sites of convergence between identified components of the CS (light) and US (rotation) pathways. Statocyst hair cells (HCs) have indirect excitatory synaptic connections with B-type photoreceptors (B FR) through a proposed 5-HT-mediated interneuronal pathway (dashed lines). Hair cells and photoreceptors also have reciprocal inhibitory monosynaptic connections. After classical conditioning, components of the CS pathway become involved in ciliary inhibition. Changes in both cellular excitability (bold red outlines) and synaptic efficacy (red synaptic terminals) contribute to CS-elicited inhibition of ciliary locomotion. The net effect of cellular and synaptic plasticity is to increase the spike activity of type III $_i$ inhibitory interneurons during light, which produces an inhibition of VP1 ciliary activating motor neurons in conditioned animals. (c) Single-trial chemical classical conditioning of feeding responses in *Lymnaea*. In naive animals, the proposed excitatory connections (dashed line) between the CS chemosensory neurons (SNs) and the command-like cerebral-buccal interneurons (CBIs) are weak; the CGCs are at their normal membrane potential (~ -65 mV), and the presynaptic modulatory input from the CGCs to the SNs is inactive or weak. During training, the food unconditioned stimulus (US) activates the feeding CPG through direct and indirect excitatory inputs (through the CBIs) to produce an unconditioned feeding response. There is already associative memory as early as 2 h after training, and this is assumed to be supported by some form of presynaptic plasticity (red question mark) in the SN to CBI pathway, lasting for up to 20 h after training. In conditioned animals, >20 h after training, the CGC soma and proximal axon segments are depolarized compared with naive and unpaired control animals; this leads to an enhancement of the CGC presynaptic modulatory inputs to SNs and a consequent strengthening of the SN to CBI excitatory synapse, which enables a conditioned feeding response to the CS. The bold red outlines of the CGC soma and axon indicate learning-induced nonsynaptic plasticity (membrane depolarization), which increases the strength of CGC to SN and SN to CBI synaptic connections in a remote-controlled manner. This particular type of extrinsic modulation may be crucial (black dashed arrow) for the memory trace to be expressed >20 h after training. The effect of somal depolarization does not spread onto the more distal modulatory connections of the CGC with the CPG or motor neurons leaving the normal modulatory function of the CGC unaffected by learning. (a) Modified from Antonov I, Antonova I, Kandel ER, and Hawkins RD (2003) Activity-dependent presynaptic facilitation and Hebbian LTP are both required and interact during classical conditioning in *Aplysia*. *Neuron* 37: 135–147. (b) Modified from Crow T and Tian L-M (2006) Pavlovian conditioning in *Hermissenda*: A circuit analysis. *Biological Bulletin* 210: 289–297. (c) Modified from Benjamin PR, Kemenes G, and Kemenes I (2008) Non-synaptic neuronal mechanisms of learning and memory in gastropod molluscs. *Frontiers in Bioscience* 13: 4051–4057.

When the early experiments on nonassociative learning were done, it was not entirely clear to what extent gastropods like *Aplysia* were capable of associative learning. However, behavioral demonstrations of classical conditioning in *Aplysia*, *Hermissenda*, and other mollusks

were soon forthcoming, and it was then rapidly found that the neural changes responsible for classical conditioning in *Aplysia* seemed to be similar to those seen in simple nonassociative sensitization (see Figure 2(a)). The conclusion at the time was that 5-HT, which by itself was

thought to cause facilitation of the synapses between the sensory and motor neurons of the gill and siphon reflex by enhancing the amount of transmitter released per presynaptic spike, produced similar changes in exaggerated form when 5-HT was applied to a sensory-neuron terminal whose free calcium was elevated due to the just-prior arrival of a presynaptic spike. Classical conditioning was thus said to be due to activity-dependent enhancement of heterosynaptic (serotonergic) facilitation.

More recent work has changed, or elaborated, this picture substantially. It is now clear that both sensitization and classical conditioning involve increased reactivity of the motor neurons to glutamate as well as increased pre-synaptic release. 5-HT acts postsynaptically as well as presynaptically. The postsynaptic effect of 5-HT is to increase the number or efficacy of postsynaptic AMPA-type receptors. In addition, activation of postsynaptic N-methyl-D-aspartic acid (NMDA) receptors and depolarization caused by the unconditioned stimulus (US) are crucial to the production of conditioning. Moreover, retrograde signaling from the motor neurons back to the sensory-neuron terminals innervating them probably plays a crucial role in enhancing transmission.

Operant conditioning in Aplysia

Most work on the cellular basis of learning has utilized classical conditioning because of its experimental convenience. However, there have been some interesting findings on operant conditioning in which an animal is reinforced when it spontaneously carries out some particular action. Withdrawal of *Aplysia*'s gill, the classical conditioning of which has been so extensively studied, can also be controlled by shocking an animal whenever the gill relaxes by more than a certain amount. These experiments, similar to ones first done on cockroach leg position, suggest the occurrence of operant conditioning. The frequency of spontaneous swallowing movements in *Aplysia* can also be greatly increased if reinforced by food, and/or by the electrical stimulation of nerves that normally sense the presence of food. Command-like neurons whose activity correlates with feeding movements and whose stimulation increases the likelihood of such movements have been identified. After operant conditioning (or its *in vitro* equivalent), these neurons have an elevated input resistance (which amplifies incoming EPSPs), and their membranes become much more prone to burst in response to externally imposed depolarizations. As would be the case for similar kinds of learning in mammals, these changes depend on the integrity of dopamine transmission, and it has been found that the same changes can be produced by briefly squirting dopamine on these cells at the end of a burst of activity that is produced by direct depolarization.

Classical conditioning of a protective response in *Hermisenda*

In the untrained sea slug *Hermisenda*, light evokes positive phototaxis. However, if light is repeatedly paired with turbulent conditions that cause the animal to stop forward progression and hold fast to the substrate, simulated in the laboratory by vigorous rotation, the normal positive taxis to light is replaced by a cessation of locomotion; this is caused by an inhibition of the ciliary movements that underlie forward locomotion.

Figure 2(b) schematizes the circuit underlying the neural control of cilia by the CS and the US, as currently understood. Ciliary activity is promoted by VP1 motor neurons, which are subject to inhibition by type III_s inhibitory neurons. The III_s are excited by two classes of interneurons, the I_es and I_is, one of which receives excitatory input from both the CS- and US-responsive sensory neurons. The interneurons and motor neurons are all spontaneously active. As indicated by the connectivity as shown in the figure, USs cause excitation of the I_es, which promotes cessation of ciliary activity by exciting the type III_i inhibitory interneurons. The US also causes inhibition of the I_is, which reduces their spontaneous activity and thus promotes continued ciliary activity; however, the former effect dominates the latter, and thus USs stop the cilia. As also seen from the circuit's connectivity, light tends to increase activity of the I_es, which promotes stoppage of the cilia, but it decreases activity of the I_is, which promotes ciliary beating. In untrained animals, the former effect dominates. However, pairing of light (the CS) and rotation (the US) causes three changes: (1) excitability of the CS-representing B photoreceptors increases, (2) the strength of the excitatory photoreceptor–I_e synapse increases, and (3) the strength of the inhibitory photoreceptor–I_i synapse increases. The first two of these changes favors stoppage of ciliary activity in response to light; the third does the opposite, but the factors favoring stoppage dominate, leading to the observed conditioned response.

All three changes occur at points in the circuit where CS- and US-evoked activity converges, consistent with the fact that these changes only occur if CS and US are paired together, not if they are separated in time. It is noteworthy that at least some of these changes seem to depend on activity of the to-be-modified cell occurring in combination with serotonergic input, as in the conditioning of *Aplysia*'s protective withdrawal reflex.

Appetitive classical conditioning in *Lymnaea*

Paired application of food as a US and a tactile or suitable chemical stimulus as a CS to the lips of the pond snail *Lymnaea* produces a conditioned appetitive response in which the CS comes to evoke rhythmic feeding movements. Learned feeding responses can be seen as fictive feeding in semi-intact preparations and recorded in

various parts of the neural circuitry that mediates unlearned and learned feeding behavior. During feeding, a population of cerebral–buccal command interneurons (CBIs) fire at the feeding frequency and drive feeding movements that are orchestrated by a central pattern generator circuit (CPG) (**Figure 2(c)**). USs provide strong excitation to both the CBIs and CPG neurons and also increase the tonic firing of the cerebral giant cell (CGC), a modulatory neuron that releases 5-HT to most elements of the feeding circuit. In untrained animals, the CBIs are weakly excited by the CS through a pathway that is not yet fully characterized. However, soon after a single pairing of amyl acetate as a CS and sugar as a US, which results in very fast learning, amyl acetate alone causes fictive feeding initiated by CBI activity. This conditioned reflex is maintained for many weeks. It seems likely that early postpairing responsiveness is due to changes intrinsic to the still uncharted CS–CBI pathway, but work on this is still in progress. However, about 20 h after pairing the CGCs become depolarized due to upregulation of persistent sodium current. This depolarization, though it does not alter the tonic-firing rate of the CGCs, does increase the amount of transmitter released from the CGCs by ongoing tonic firing, and increases of a comparable magnitude imposed on an untrained animal allow the CS to produce feeding. So far technical issues have made it impossible to determine whether this change in the CBCs merely supports a response that would still occur without it or is actually necessary for the maintenance of responding at long times after pairing. In either case this extrinsic modulation, which is capable of causing conditioned responding, is of considerable interest (see further below).

Insects

The modern study of learning in insects derives from two lines of endeavor. One is the pioneering work of von Frisch, Tinbergen, and other ethologists, who established that learning could play important roles in the navigation, food finding, and reproductive activities of insects. The other stemmed from attempts to take advantage of the techniques of fruit fly genetics to look for and study mutants with altered learning and memory capabilities. The small size of insect nervous systems has rendered difficult electrophysiological approaches used in other kinds of animals. However, small size is an advantage for modern optical recording and stimulation techniques, because in small brains and ganglia individual neurons can be directly imaged *in situ* without disruption. Thus, the kinds of experiments that in larger-brained animals have had to be done on tissue slices, where probably crucial neuromodulatory and other inputs are lost, can be done in insects with the nervous system entirely intact and the animal, though restrained, still behaving.

Kinds of learning analyzed in insects

Insects naturally make use of learning capacities in courtship and mating, food finding, navigation, defense, and many other arenas. We focus here on honeybees and fruit flies (*Drosophila*) (**Figure 3a, c**). Using behavioral tests that take account of insects' natural way of life, rapid and thorough learning and long retention can be demonstrated.

In honeybees, many experiments have been done in which bees are allowed to settle and feed on visual discriminanda. The bees remember and will later fly to those stimuli if given the opportunity; this has allowed extensive analysis of their visual processing and visual memory abilities. A large body of work has also been done on Pavlovian olfactory conditioning in bees. Touching a bee's antenna with sugar water leads to proboscis extension. If an odorant is presented just before sugar water, the odorant comes to elicit a conditioned proboscis extension response (**Figure 3(a)**). Experiments utilizing this Pavlovian conditioning paradigm have shown that bees learn, generalize, acquire second-order conditioned responses, extinguish, etc., in much the same way as rats and other mammals.

If *Drosophila* are exposed to one odorant in the presence of food and another with food absent, and then given a choice between the two odorants in a T-maze, they choose the previously rewarded odor. If, on the other hand, they are subjected to electric shock in the presence of one odor and not another, they learn to avoid the shocked odor. More work has used the aversive than the appetitive situation; findings are similar, but there are also some interesting differences (discussed below).

Mutants and stages of learning

As had been hoped, screening of randomly mutated flies led to the discovery of a number of mutants with abnormal learning or memory. Analysis and comparison of these mutants with each other and with wild-type flies led to the recognition that following training, memory goes through a number of stages that require products of different genes. At least four stages are generally recognized. Training leads initially to a briefly retained or short-term memory (stage 1, operative for up to about an hour after training) and then to an intermediate or middle-term memory (stage 2, operative from about 15 min to 3 h post training). Middle-term memory generates two independent forms of longer-term memory, anesthesia resistant memory (stage 3, lasting 1–2 days), which unlike its precursors is not lost if a fly undergoes a period of anesthesia, and also long-term memory (stage 4, starting about 5 h posttraining and continuing for days or weeks), which requires multiple, spaced training trials for development and is dependent on new genetic transcription. Initial learning and short-term memory are greatly disrupted by mutations affecting a gene called *rutabaga*

(the gene is commonly referred to by the name of the mutant) that codes for a calcium-dependent adenylate cyclase and, like the calcium-stimulated adenylate cyclase of *Aplysia* sensory neurons, is envisaged to be a detector of the coincidence of neural activity and reinforcing neuromodulatory input. Middle-term memory is dependent on a gene (*amnesiac*) whose product is an adenylate-cyclase-stimulating peptide that is released as a neuromodulator and also is dependent on genes for NMDA receptor subunits. Anesthesia-resistant memory is dependent on a gene (*radish*) which makes a protein whose function is as yet little understood, and long-term, protein-synthesis-dependent memory depends on genes that produce CREB and is prevented by mutants that produce excessive amounts of isoforms of CREB that prevent transcription (e.g., CREB2). These and other mutants have played key roles in further analysis.

Anatomy of olfactory learning

The above findings, used in conjunction with anatomical information and modern genetic/molecular technology,

have led to localization of at least parts of the engram underlying olfactory conditioned responses.

As seen in Figure 4, olfactory receptors terminate in the antennal lobes where they excite projection neurons directly and also inhibit them through interneurons. The projection neurons project to both the cerebral mushroom bodies and the lateral horn. In the mushroom bodies, they form synapses on the principal intrinsic cell type, the Kenyon cells, which, in turn, make synaptic contact within the mushroom bodies on extrinsic neurons that, along with the antennal lobe projection neurons, send axons to the lateral horn. The lateral horn output is, in turn, thought to provide access to motor circuitry. The mushroom bodies also receive other important inputs: (1) they receive processed sensory input from other parts of the brain; (2) they receive major innervation from peptidergic/cholinergic DPM cells, which themselves project back to the mushroom bodies (see further below); and (3) they, and also the antennal lobes and lateral horn, receive octopaminergic and dopaminergic innervation that conveys information about rewarding and aversive events, respectively. In the honeybee, the octopaminergic

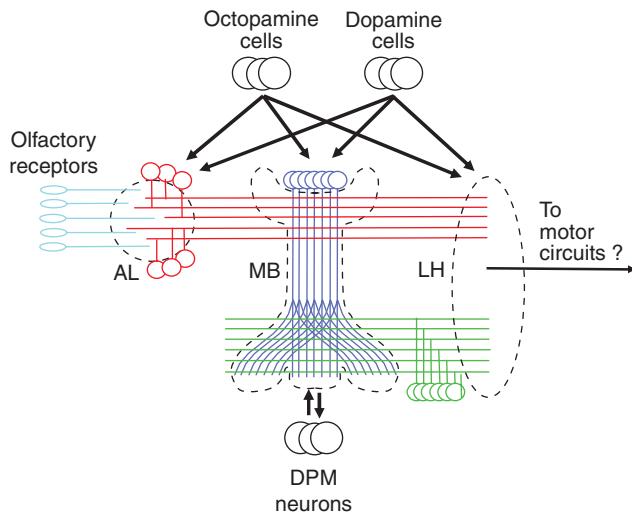

Figure 4 Brain circuitry involved in appetitive and aversive olfactory learning in insects, as discussed in text. Olfactory receptors (cyan) excite projection neurons (red) of the antennal lobes (AL) and also interneurons (not shown) that inhibit the projection neurons. The antennal lobe projection neurons innervate both the intrinsic neurons of the mushroom bodies (MB), the Kenyon cells (blue), and neurons of the lateral horn (LH). The Kenyon cells make synapses extrinsic neurons (green) that also innervate the lateral horn. Octopaminergic and dopaminergic neurons richly innervate all three of the illustrated regions. Dorsal paired median (DPM) neurons receive input from and project back to the mushroom bodies.

innervation is, in part, through a type of unpaired VUMmx1 neuron that has a remarkable and elegant branching pattern that innervates all three of the regions diagrammed in **Figure 4** and **Figure 3(b)**.

Most of the proteins coded by genes whose mutation diminishes learning and memory abilities have enriched or sole expression in the mushroom bodies or in neurons that project strongly to them, and damage to or developmental reduction of the mushroom bodies has major effects on learning ability. Thus, these structures have long been thought to be major players in learning. This belief has recently been reinforced by experiments in which the learning abilities of mutants have been rescued by Kenyon cell-specific expression of the wild-type form of the mutant genes.

Such targeted expression experiments rely on lines of flies into whose genome effector genes of interest have been inserted, linked to an upstream sequence that causes transcription only when bound to regulatory protein made by the yeast GAL4 gene. Such lines are crossed to other lines constructed so that GAL4 expression occurs only in specific cell types (and/or at certain temperatures). One can use the GAL4 system to control expression of genes coding for most any protein. Proteins that allow imaging of calcium levels, or synaptic vesicle release, proteins that block transmitter release, and proteins that cause light-evoked depolarization, and thus cell firing, have all been used.

This technology has been used to show that for a short time after forward odor CS-US pairings, odor-evoked calcium elevations and transmitter release of antennal

lobe projection neurons increases specifically for the paired CS. CS odor-specific calcium elevations also occur in Kenyon cells with a time course and under induction conditions that correspond to those of long-term memory (**Figure 3(d)**). It is tempting to think that these responses are expressions of the memory traces that cause conditioned responses. In fact, these responses certainly must contribute to effective conditioned responding. However, it is important to keep in mind that it is not possible for the antennal lobe to control what kind of response an animal makes, because the antennal lobes are purely sensory structures that have no way of controlling particular responses. The situation in the mushroom bodies is more interesting. The aminergic neurons that innervate olfactory processing structures respond to USs; their activity is required for conditioning, and, when they are stimulated directly, their activity can substitute for an actual US. Moreover, the octopamine cells are specific for appetitive, and the dopaminergic cells for aversive conditioning. Thus, if the sets of Kenyon cells innervated by the octopamine and dopamine neurons were separate, and if they made differential downstream connections to motor circuitry for approach versus avoidance responses, they could perhaps be responsible for CS-specific response selection. Whether this is so is not known. However, this concept cannot be carried too far; insects can presumably learn a greater variety of responses to odors than just approach and avoid, and it seems unlikely that one could have separate classes of Kenyon cells for each type of response that can be selectively associated with a CS.

Consequently, response selection at the level of the Kenyon cells seems improbable. It appears more likely that the crucial cellular changes responsible for associating specific odors with particular responses reside at the synapses between the Kenyon cells and downstream response-evoking neurons. In flies, the recorded calcium responses are in fact in the region of Kenyon cell output synapses; thus, they could perhaps reflect enhanced release from cells responsive to the CS odor onto neurons producing the conditioned response. In bees, there is some direct evidence that synapses between Kenyon cells and the extrinsic output neurons are subject to LTP and LTD.

Nematode worms

The nematode worm, *Caenorhabditis elegans* (Figure 5), was selected for neurobiological analysis because it has an extraordinarily simple nervous system and, like *Drosophila*, it is highly suitable for genetic analysis. The total central nervous system is comprised of about 300 neurons that interact through some 5000 chemical and 600 electrical synapses! Because of the worm's small size (~ 1 mm) it has been possible to make serial electron microscope sections of the entire animal, and from these to generate a complete wiring diagram of the nervous system. The identity of the transmitters found in many of the neurons has been determined, and the transmitters and neuromodulators are the same as those common in vertebrate and other invertebrate nervous systems, including ACh, GABA, glutamate, serotonin, dopamine, and others. Transmission at the electrical junctions is believed to be generally excitatory, but it cannot be determined from anatomy which chemical junctions, most of which are glutamatergic, are excitatory and which inhibitory (glutamatergic synapses can be of either sign). Neurohumoral release also occurs.

Laser ablations of individual neurons has led to the delineation of circuits that appear to be involved in particular behaviors, and remarkably, given the simplicity of

the nervous system, several of these circuits seem to mediate behavior that is subject to forms of learning.

In nature, *C. elegans* lives in soil where it feeds on bacteria. Undisturbed on a moist surface it moves forward in a snake-like sinusoidal wave pattern. Worms (i.e., *C. elegans*) have rather complex reproductive behavior and certain kinds of social behavior. Most relevant to learning paradigms that have been studied, worms congregate in regions rich in suitable food and leave regions lacking it, while they innately avoid or escape certain kinds of chemical and mechanical stimuli.

Neural mechanisms of retraction-response habituation

All animals seem to be subject to habituation when stimuli that innately cause responses are repeated. In worms, anterior mechanical stimulation causes a retraction and rapid backward movement, while posterior stimulation causes forward acceleration. Diffuse vibrations that stimulate both anterior and posterior mechanoreceptors produce retraction, but this is thought to be attenuated somewhat at the level of behavior by the competing forward response. Responses to repeated vibrations gradually wane (habituate), while a brief harsh stimulus causes a temporary reinstatement of reactivity (dishabituation). Habituation produced by stimulation occurring a few times per minute abates within hours (short-term habituation), but habituation induced by spaced training consisting of repeated bouts of training separated by rests of about an hour lasts for more than 24 h (long-term habituation; e.g., responsiveness about 50% down after a 24-h rest). Persistence of habituation for a day or more in worms, as with all kinds of learning in most animals, requires new protein synthesis. Certain training regimens can also cause a form of protein synthesis-independent habituation with longevity in-between that of short- and long-term habituation, which could correspond to the middle- or intermediate-term forms of memory seen in mollusks and insects.

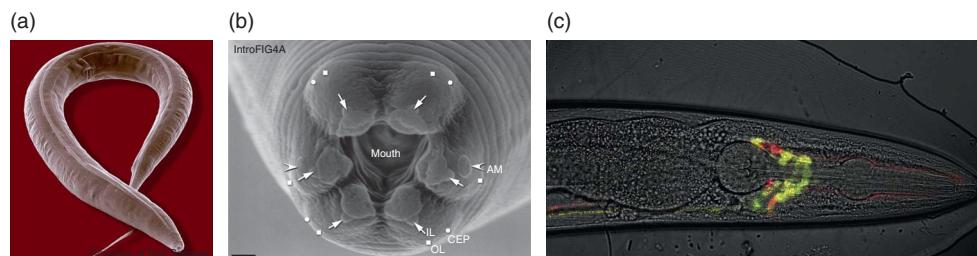

Figure 5 *Caenorhabditis elegans*. (a) The entire worm, anterior end at lower right. (b) Detail of mouth region with location of sensilla marked by arrows (c) Micrograph of head region of *C. elegans* showing neurons expressing green or red fluorescent protein conjugated to neuron-specific proteins. The somata of these neurons are located in the peri-esophageal nerve ring that comprises the worm's largest congregation of neurons. Axons run rostrally to the mouth (right) and caudally in the ventral nerve cord (left) (some faint colors enhanced for clarity by the authors; from a micrograph kindly provided by Cathy Rankin). Figure 6 Neural circuitry for retraction responses to vibration (a) and for approach and avoidance of thermal and chemical stimuli (b) of *C. elegans*, as discussed in text. Based mainly on serial electron microscopy and observing behavior following laser ablations of individual neurons. Sensory neurons (triangles), interneurons (hexagons), and motor neurons (circles) with their names included are indicated. In (b) first-order interneurons are green and premotor interneurons are lavender.

The neurons that, based on laser ablations and connectivity, seem to be involved in the retraction and forward acceleration responses are shown in **Figure 6(a)**. Anterior and posterior mechanoreceptors make electrical (excitatory) synapses on pre-motor interneurons that drive retractions and forward accelerations, respectively. Each pathway also sends glutamatergic chemical inputs that are thought to be inhibitory to the other pathway (glutamatergic transmission in *C. elegans* can be either excitatory or inhibitory depending on properties of the postsynaptic receptors). The inhibitory connections would be expected to attenuate the forward accelerations that compete with retraction; therefore, any decrease in the activation of the anterior sensory neurons or in the potency of their synapses would be expected to increase competing forward acceleration, decrease net retraction, and thus support habituation of retraction (see further below).

Optical recording of calcium responses in sensory neurons of this circuit during habituation training show response decreases in the sensory neurons mediating the backward but not the forward response. Moreover, the extent of this decrease co-varies with several manipulations that influence development rate of short-term

habituation. This suggests that the decreased sensory responses are at least part of the mechanism of habituation. If the reduced activation of sensory neurons causes reduced inhibition of the interneurons mediating forward acceleration, the increased activity of these neurons would, as explained above, be expected to increase behavioral habituation of retraction.

It has also been found that mutations which disrupt either glutamate vesicle recycling in ALM/AVM (named neurons are labeled in **Figure 6**) or disrupt non-NMDA glutamate receptor subunits (found on all four interneurons) prevent long-term though not short-term habituation. Moreover, green-fluorescent protein (GFP)-labeled glutamate receptor subunit is reduced at synapses on interneurons following long-term but not short-term training. It seems clear that the crossed inhibitory pathways of **Figure 6(a)** are glutamatergic, but the excitatory synapses between the anterior sensory neurons and the interneurons that mediate backward responding appear to be electrical, not glutamatergic. The exact synapses at which glutamate transmission is decreased in long-term habituated worms has not yet been reported. If the inhibition of the forward-acceleration interneurons AVB/PVC were decreased by LTD, the forward acceleration that

normally competes with retraction would be increased, and this would presumably be seen as habituation of the retraction response. Furthermore, although we do not usually think of electrical synapses as plastic, electrical synapse-mediated input to fish Mauthner neurons from auditory nerve fibers is subject to LTD. This occurs when auditory input is activated along with inhibitory input, as happens to worm AVA/AVD neurons when vibration stimuli drive both anterior and posterior touch sensory neurons. Thus, LTD of electrical transmission in the retraction circuit is a possibility.

If protein synthesis, which is needed for the production of long-term habituation of retraction, is blocked just following testing of long-term habituation, recovery from habituation occurs by the next day, and the previously established reduction of GFP-conjugated glutamate receptors is reversed. This is consistent with the finding in a variety of animals that protein synthesis is required to maintain long-term memory of associatively learned responses after they are recalled (i.e., reconsolidation is needed after performance of a learned response).

Particularly interesting, given the simplicity of the worm nervous system, are experiments suggesting some sort of context specificity to habituation. The findings are somewhat complex but have been interpreted as providing evidence for the formation of an association between the context and habituation of retraction. The complexities have been interpreted as being consistent with Wagner's comparator theory of habituation and might also seem somewhat parallel to findings from mammals on context specificity of extinction, but interpretations in terms of the properties of the neural circuits known to underlie retraction behavior have yet to be offered. Nevertheless, the surprising suggestion that nematode worms can form associations is upheld by experiments directed specifically to that point.

Associative learning

A number of experimental procedures are thought to provide evidence of associative leaning. All involve accumulation of worms in the vicinity of stimuli (chemical or thermal) that had been associated with presence of food, or away from stimuli that had been associated either with starvation or with innately aversive chemical stimuli. Training might consist, for example, of incubating worms on a substrate with an inherently attractive salt (the CS) paired with either an aversive US (e.g., the absence of food or the presence of garlic) or an attractive one such as food. After such training, worms act as though they have formed an association between the CS and the US. If placed on a gradient with the CS salt at one end and an equally attractive control salt that had not been paired with a US at the other, they move toward the CS salt if it had been paired with something attractive and away if it had been paired with something aversive. Retention of

such learning is often not followed for more than a few hours, but at least under some circumstances retention has been reported to be more than a day. While some experiments seem to provide firm evidence of associative learning, some have been structured in such a way that the appearance of associative learning is in fact due to expression of separate stimulus and/or response biases established by the training.

The neurons that seem, based on laser ablations and connectivity, to be involved in learning to approach stimuli associated with food and to avoid stimuli associated with noxious stimuli or starvation are shown in **Figure 6(b)**. Primary afferents such as AFD, ASEL, and AWC code information about temperature, chemical environment, etc., which are the modalities of the CSs used in learning experiments. These sensory neurons provide input to first-order interneurons such as AIY and AIZ that, in turn, interact with further interneurons that do not receive any direct sensory input and that largely stand between the first-order interneurons and motor neurons.

Only a few sensory neurons serve each modality. In contrast to the situation found in animals that use neurons less parsimoniously, each *C. elegans* chemosensitive neuron has independent receptors for many molecules. This allows the possibility of substance-specific adaptation to many chemical agents. However, any associations formed will necessarily generalize to other agents that are represented by the same sensory neurons.

The first-order interneurons are often categorized with respect to their presumed behavioral effects, but such characterizations tend to be contingent on the particular circumstances under which they were determined. For example, it has been proposed that AIY causes movement from cooler to warmer temperatures and AIZ the opposite (and would perhaps be expected to have similarly antagonistic effects on chemical gradients). However, it has also been proposed that AIZ promotes changes of direction, while AIY suppresses them. These are not incompatible characterizations. One is stated in terms of effects of the neurons on net migrations and the other in terms of the kinds of movements that may lead to such migrations. A generally agreed, comprehensive account is not yet available but work on this is advancing.

Although, as in the insects, optical recording methods are beginning to be employed, the more common approach to finding neurons involved in associative-like learning has been to begin by screening for mutants that fail to learn some specific assay task, and then to try finding the gene's homolog in better known animals and thus identify its product. This done, the wild-type gene can be expressed, one neuron at a time, in cells that normally express it to see what will rescue the lost kind of learning. The cells where the gene product is needed for learning can thereby be identified. In recent work,

molecules allowing imaging of calcium or other signaling molecules have also been expressed in neurons that had been identified by the genetic analysis, and physiological changes associated with learning sought.

At the time of writing, only a few specific learning paradigms have been studied with all these techniques. However, in each of these cases, it appears that learning may involve altered synaptic transmission between sensory neurons known to code the CS and first-order interneurons whose altered activity promotes the particular kind of response that was learned. In some cases, it seems most likely that the alterations are postsynaptic, in others presynaptic. For example, in worms that have learned to avoid a temperature at which they were previously starved, the calcium response of the first-order interneuron AIZ to temperature change, which in untrained worms is substantial, is greatly reduced, suggesting reduced transmission from X to AIZ (see **Figure 6(b)**). The proposal that this response reduction is due to factors operating in AIZ comes from the fact that the learning requires intact signaling by several neuromodulators (e.g., insulin) whose receptors and downstream signaling molecules are expressed in AIZ and that this learning requires normal calcineurin function in AIZ. It should be noted that, in the hippocampus, calcineurin signaling plays a central role in establishing LTD and that insulin modulates LTP and LTD formation. Several possible examples of altered presynaptic release of transmitter are offered by experiments in which worms learned to avoid naturally attractive chemical agents. Avoidance of NaCl appears to be due to altered transmission from ASER to AIA. The learning depends critically on release of an insulin homolog from AIA and on the presence of normal insulin receptors on, as well as insulin signaling pathway molecules in, ASER. Since the calcium responses of ASER to NaCl are not altered by training, the proposed theory is that activity of ASER in the presence of neuromodulatory signals produced by starvation cause release of insulin from AIA, which feeds back and contributes to reducing transmitter release from ASER. Fairly comparable results also suggest that learning to avoid attractive chemicals can involve reduced transmission from AWC to AIB. Although *C. elegans* appears to have homologs of NMDA receptors, these have so far been seen to play only minor roles in associative conditioning. Thus, whereas the mechanisms seen so far in *C. elegans* do not mirror the working hypotheses that are currently based on studying mammals, neither are they without mammalian precedents.

That these changes seen during associative learning appear to be synaptic should be contrasted with findings that sensory adaptation to chemicals and at least short-term habituation to mechanical stimuli are due to changes within receptor cells themselves. These later findings show that sensory responses are potentially plastic, and

one might imagine that this plasticity would also be used during associative learning. However, what worms seem to typically learn is which stimuli to approach and which to avoid, and this can be learned only by altering the effective connectivity between neurons that represent the stimulus and others that represent the desirable response.

However, a kind of exception to this rule occurs when worms learn to avoid or approach a temperature at which they have been starved or fed. There is evidence that synaptic transmission alters between neurons that sense temperature change and neurons that mediate approach or avoidance. However, there are not different sensory neurons to represent different temperatures. Therefore, an animal cannot learn to approach one temperature coded by one set of neurons and avoid another temperature coded by a different sensory neurons. Rather, temperature-sensitive neurons, of which there are only a few, become sensitive to any temperature at which a worm spends several hours, independent of any US that may be present. Approach or avoidance then becomes associated with temperature as a modality but not with a specific temperature. Evidence that this is the case can be seen if a worm is starved at a given temperature long enough for it to accommodate to that temperature and also long enough for it to go into a starved state. The worm will now tend to avoid the temperature at which it was starved if tested in the absence of food. However, if the worm is fed at any temperature before testing, it will rapidly switch into a fed state and when tested will approach the temperature at which it was protractedly starved. Feeding has put it into a state where it will approach whatever temperature is familiar. Thus, there seems to be no association between a specific temperature and food availability.

The neurotransmitters/neuromodulators serotonin, octopamine, and dopamine appear to play essential roles in establishment of associations. For example, serotonin seems to be able to act as a proxy for food availability and octopamine for starvation in food-conditioning experiments. However, these modulators are also involved in other kinds of signaling by other neurons, where their meaning may be quite different. Thus, serotonin, which signals food availability under some circumstances, is released by neurons that detect aversive stimuli and that drive aversive learning in other kinds of learning situations.

Comparisons and Commentary

Are Changes Extrinsic or Intrinsic to Conditioned Response-Mediating Circuitry?

Prior to the period of rapid progress that began with analyses of nonassociative learning in *Aplysia* and crayfish, a crucial unanswered question was whether learning was

due to intrinsic changes within the neural circuitry that mediates learned responses or whether, after learning, these circuits were biased to operate differently by input from parts of the nervous system extrinsic to the mediational circuitry itself. The early work on *Aplysia* and crayfish provided evidence for intrinsic change, and subsequent analyses of simple forms of associative learning in a variety of invertebrate systems, as well as in mammals, has supported the importance of intrinsic change. However, it is widely believed that in mammalian declarative learning, change is initially confined to the hippocampus, which then controls behavioral choices by reconstructing patterns of cortical activity that were operative at the time of learning. Only later do changes, intrinsic to cortical circuits, themselves develop and come to mediate performance. It has also been suggested that new learning may sometimes involve prefrontal cortex modulation of other parts of the brain, and that the latter change only slowly with the aid of the input from prefrontal cortex. These are, of course, examples of advanced learning done by the highest parts of the mammalian brain.

However, many older studies of nonassociative learning even in insects and annelid worms suggested that habituation might be attributable to extrinsic inhibitory control of mediational circuitry. Furthermore, whereas habituation of crayfish escape provided some of the first direct evidence of intrinsic synaptic modification in (non-associative) learning, recent work has found that extrinsic inhibitory input is crucial to producing habituation, at least initially. Interestingly, such extrinsic inhibition becomes dispensable once habituation is well established.

It has also been found that about 20 h after establishment of a classically conditioned feeding response in *Lymnaea*, transmitter output from a tonically active serotonergic cell that modulates the feeding circuitry increases due to development of a persistent depolarization. Although soon after conditioning, conditioned responses occur in response to CS in the absence of the depolarization of the serotonergic neuron, at later time points, and well after protein-synthesis-dependent consolidation has occurred, conditioned responding is caused or at least supported by the persistently enhanced transmitter output of the serotonin cell. In this case, then, a learned extrinsic influence is involved in the performance of established learning.

Varieties of Intrinsic Change

The kind of learning that most interests us, at least in part because it is so central of our own way of life, is associative learning in which animals learn to associate many particular stimuli, each with a particular action or perceptual response (the sets of possible stimuli and responses being very large). Intuitively, the most

straightforward way to achieve such association is to alter transmitter release or postsynaptic receptor responses, specifically at synapses between stimulus-representing and response-producing neurons. There is now a great deal of evidence that this happens. Alterations of synaptic efficacy were first found for nonassociative learning in crayfish and *Aplysia*. Soon afterwards, alterations of transmission were found to mediate learned associations in several mollusks, and at about the same time synapses with Hebbian properties were discovered in mammals. There is now evidence of altered synaptic transmission due to associative training in all of the kinds of animals we have discussed, from nematode worms, to gastropod mollusks, to insects, to mammals.

Although perhaps crucial for establishing stimulus and response-specific associations, alterations of synaptic transmission are not the only kinds of alterations that have been found to be produced by training and to contribute to adaptive learned responses. One of the earliest analyses of classical conditioning, the clamping-down of the gastropod mollusk *Hermissenda* to a light when the light reliably warned of oncoming turbulence, found that training altered the membrane conductance of a cell whose activity promoted the conditioned response. In addition, sensitization of defensive withdrawal in *Aplysia*, which provided the first evidence for enhanced synaptic transmission as the basis of a learned response to a stimulus, is accompanied by altered electrical excitability of the sensory neurons. Changes in excitability, membrane conductance, or resting membrane potential have now also been found after induction of LTP in CA3 of the hippocampus, after induction of conditioned eye-blink responses in the deep nuclei of the cerebellum, and after various kinds of classical and operant conditioning of feeding responses in the gastropods *Aplysia* and *Lymnaea*.

Changes of this kind were unexpected, because they seem to work against stimulus or response specificity. Generalized changes in the electrical excitability of a CS-representing neuron would be expected to enhance any kind of response to the activity of that neuron, not just the desired conditioned response. Cell-wide changes in the excitability or membrane potential or conductance of a response-producing cell would be expected to alter the likelihood of the response to any stimulus, not just the CS. Thus, it may be seen as something of a paradox that such changes often develop. Moreover, they often do so only in response to paired presentation of CS and US, not to unpaired presentation. To some extent, there may be no paradox, because it now appears that excitability changes can develop locally within dendritic trees and need not be cell wide. However, even in the case of cell-wide changes, lack of associative specificity becomes a problem only if an animal has to learn and concurrently hold multiple associations. Thus, an animal in which repeated pairings of CS A and US B lead independently to increased

sensory responsiveness to A and increased tendency to make B will tend to make response B when presented with stimulus A just as it would if there were a true association. However, if C–D training were added, both A and C would each evoke both B and D. This sort of situation may never arise for uses to which learning is put in many invertebrates. However, it commonly arises in mammals. Nevertheless, it does appear to be the case in mammals that associative training causes increased responses to the CS in strictly sensory parts of the brain and comparable alterations in CR-producing motor regions. Presumably, these changes support associative responding that is selective because of strictly associative changes elsewhere in the circuit, and they do not necessarily cause undesirable stimulus or response generalization. Nonassociative changes in invertebrates may be comparable.

Reinforcement Mechanisms

It is commonly the case that USs, or CSs that have come to evoke learned responses, cause the release of chemical transmitters/neuromodulators that start cascades of intracellular signaling.

The early experiments on sensitization and classical conditioning of defensive withdrawal in *Aplysia* implicated US-driven release of serotonin to sensory neuron terminals as a reinforcing signal needed for establishing both simple facilitation and the activity-dependent facilitation of transmission that was thought to be responsible for associative change. Dopamine, serotonin, or octopamine (octopamine is commonly viewed as an invertebrate analog of epinephrine) appear to play reinforcement-like roles in every case of invertebrate learning that has been suitably studied. Dopamine is also widely thought to play an essential reinforcing role in mammalian learning tasks mediated by the striatum, and LTP and LTD in the striatum are profoundly affected by dopamine. The working hypothesis that emerges from such findings is that, at a cellular level, changes responsible for learning of stimulus-driven responses generally require three ingredients: presynaptic activity, postsynaptic activity, and some form of neuromodulatory input that is a response to the occurrence of biologically important stimuli. For operant conditioning, activity of a response-promoting cell and neuromodulatory input seem to be crucial. Perhaps the only clear exception to a role for neuromodulators in learning comes from the study of cerebellar eye-blink conditioning and Purkinje cell LTD, where reinforcement, instead of being mediated by a neuromodulator, is mediated by the overwhelmingly powerful synaptic input provided by the climbing fibers. Thus, in most cases where evidence of neuromodulatory involvement is lacking, one might guess that it is waiting to be found.

Despite the above considerations and a wealth of evidence that acetylcholine, dopamine, serotonin, and

norepinephrine significantly modulate LTP and LTD at hippocampal synapses, at the time of this writing, findings from hippocampal slices are commonly discussed without much acknowledgment that, in the intact brain, neuromodulators probably greatly alter the properties of these synapses.

In mammals, dopamine is widely accepted as crucial for appetitive reinforcement, but its role in aversive reinforcement is less resolved. Whether a separate modulator exists for aversive reactions has not yet been established. However, a precedent is provided by the use in insects of dopamine for reinforcement of aversive reactions and octopamine for appetitive ones. In mammals, opiates and serotonin have been suggested as possible mediators of reinforcement in aversive learning, but to date this is largely speculation. Use of different modulators for reinforcement in different kinds of learning is also suggested by work in both nematodes and mollusks. In worms, there is some evidence that octopamine might signal conditions of starvation while serotonin might signal the availability of food. However, there is also evidence that, in some kinds of worm learning, serotonin may reinforce avoidance rather than approach. In *Aplysia* and *Lymnaea*, both dopamine and serotonin seem to play roles in reinforcement, but what the differences are in the roles of these two agents is not yet clear. Nitric oxide is another extracellular signal that has been found to be crucial for inducing or stabilizing synaptic or other cellular changes in insects, mollusks, and mammals, though its exact role is yet to be understood.

Pavlovian conditioning requires that change occur specifically at synapses that connect CS-representing neurons and US-representing or response-producing neurons that the CS must come to activate. This requires that coincident occurrence of pre- and postsynaptic activity and, in most cases, also of neuromodulatory input, which is itself usually highly distributed, be detected. Such coincidence must then set in motion intracellular signaling events that will lead to altered synaptic function.

The mechanistic scenarios used to make change contingent on coincidence seem to be numerous. Most familiar is that of hippocampal-type Hebbian LTP where coincident pre- and postsynaptic activity causes local postsynaptic Ca^{2+} elevation because glutamate supplied by active presynaptic neurons primes NMDA receptors so that postsynaptic depolarization will cause them to open to calcium ions. In striatal Hebbian LTD, metabotropic glutamate receptor-mediated release of Ca^{2+} from internal stores acts synergistically with dopamine-dependent entry of Ca^{2+} through voltage-dependent calcium channels to cause changes of synaptic efficacy. Both at other mammalian synapses and in invertebrates, there are further variations on these themes. For example, in sensory neurons of *Aplysia*'s gill/siphon withdrawal reflex, serotonin and calcium that enters active

terminals act synergistically to activate calcium-dependent isoforms of adenylate cyclase so that when serotonergic reinforcement occurs, PKA becomes activated to an exaggerated extent in presynaptic terminals that have been active. Something similar is believed to occur in insects. In *Aplysia*, postsynaptic NMDA receptor-dependent changes that depend on the US also occur and, through retrograde signaling, contribute to further presynaptic events that help stabilize both pre- and postsynaptic changes. Both mammalian and invertebrate works are uncovering complex interactions between pre- and postsynaptic cells that act in the initiation and stabilization of change.

Intracellular Signaling Molecules

As described in part above, PKA, PKC, CaMKs, MAPKs, PI3K, and various isoforms of CREB, and their associated signaling pathways consistently play roles in initial learning or the production of persist cellular change. It is of considerable interest that these same molecules should play similar roles in learning in mollusks, arthropods, and mammals, given the diverse evolutionary origins of these animals.

Blocking and Prediction Errors

Modern work on classical conditioning in mammals has led to the conclusion that new learning occurs when and only when an animal receives new information about rewards or punishments. Thus, unexpected, but not expected, USs act as reinforcers (the ineffectiveness of expected reward is called blocking). Unexpected occurrences of previously conditioned CSs also produce new learning (higher-order conditioning; secondary reinforcement). These facts are often summarized by saying that prediction errors are what drive new learning. Because blocking and higher-order conditioning are so prevalent in mammals, either or both might be expected to be a product of the basic cellular mechanisms responsible for conditioning. Alternatively, these phenomena might be consequences of the way that the circuitry that mediates reinforcement is organized.

In bees and *Drosophila*, neurons that release neuromodulators responsible for reinforcement are activated by already trained CSs. This is thought to be the basis for higher-order conditioning in insects and is consistent with findings on midbrain dopamine neurons in mammals, which are also driven by established CSs. Thus, available evidence from both mammals and insects suggests that higher-order conditioning derives from the organization of circuitry rather than being an inherent consequence of cellular plasticity mechanisms.

The same appears to be true of blocking. In mammals, analyses of blocking mechanisms in both amygdala-mediated fear conditioning and cerebellum-mediated

eye-blink conditioning seem to show that blocking occurs because CR-producing neuron activity inhibits neurons that mediate reinforcement. There have been a few reports suggesting that blocking may occur in the slug, *Limax*, and in *Hermisenda*. However, more extensive investigation in bees has yielded results that are either negative or equivocal. Consonant with this, it has been reported that *Drosophila*'s dopaminergic reinforcing neurons continue to be activated by shock even when a well-established CS warns that the shock is about to occur; this is very much in contrast to what is seen in cerebellar climbing fibers or the midbrain dopamine neurons of mammals when expected primary reinforcing events occur. These observations suggest that blocking is a circuit-based phenomenon, is not universal, and is not a product of the way that basic cellular-level associative learning machinery works.

Stages of Memory

In invertebrates that have been studied, as in mammals, learning has been found to be coded initially in one or more unstable forms that later become stabilized by events which depend on new protein synthesis (and often new genetic transcription) occurring during or within a short time after initial learning events. In addition, common to mammals and invertebrates is the use of the CREB protein to initiate transcription. As in mammals, the formation of protein-synthesis-dependent long-term memory in invertebrates is favored by spaced as opposed to massed training; the need for spaced practice for generating persisting memory may be an adaptation ensuring that only those environmental contingencies that are stable over time will be encoded into long-term memory.

It seems to be generally the case that memory on the order of a day or more requires protein synthesis. In a few cases, memory somewhat longer than a day can develop independent of protein synthesis, but even in these exceptional cases, slightly longer-term persistence does require new macromolecular synthesis. In mammals, learning is commonly thought of as passing through two stages of memory, protein synthesis-independent short-term memory and protein synthesis-dependent long-term memory. However, in insects and mollusks, one commonly finds evidence for at least three separate stages, with the second, intermediate-, or middle-term stage being of variable mechanism and in some cases itself requiring *de novo* protein and/or messenger RNA synthesis. The discovery of late LTP in mammals suggests that mammals may in fact conform to the three-stage model. However, as discussed below, it seems likely that the third, so-called long-term, stage will soon be further divided.

Intermediate/middle-term storage (on the order of hours) in invertebrates has been seen to utilize a variety of mechanisms. These include calpain-mediated cleavage of regulatory subunits of PKC to form constitutively active kinase (seen in both honeybees and *Aplysia*, and possibly also in some hippocampal LTP), protein synthesis (but not mRNA synthesis)-dependent persisting activation of PKA, and transcription-dependent hydrolysis of PKA (*Aplysia*) as well as undefined translation-dependent actions in a number of gastropod mollusks. There is also evidence that autophosphorylation of CaMKII, implicated in intermediate-stage LTP in mammals, is implicated in *Drosophila* learning and perhaps also in some forms of synaptic plasticity in *Aplysia*.

The involvement of genetic transcription in production of long-term memory has raised the question of how the proteins then synthesized come to affect only particular synapses of a given cell. An apparent answer was provided for LTP when it was discovered that the stabilization of LTP at specific hippocampal synapses is due to a selective effect of the relevant proteins at synapses at which shorter-term LTP had already been established (synaptic tagging). The same discovery was made at about the same time for long-term facilitation in *Aplysia* using cultured sensory neurons with two branches, each innervating a different motor neuron. One pulse of 5-HT to a synaptic region caused only transient facilitation of that synapse, but following multiple spaced pulses long-term, protein-synthesis-dependent facilitation developed at the stimulated synapse but not the other. However, if a single 5-HT pulse was applied at the synapse onto one of the motor neurons soon enough before or after multiple pulses were applied at the other, both synapses underwent long-term facilitation. As in the hippocampus, establishment of short-term facilitation apparently causes production of a tag that allows stabilizing protein that is distributed cell-wide to have a local effect.

The *Aplysia* bifurcated axon preparation, which allows longer periods of study than is usual in the hippocampal slices used to study mammalian LTP, shows that major changes continue well beyond 24 h. Although facilitation and associated morphological changes are present at 24 h, local protein synthesis, dependent on certain local intracellular signaling events, must operate over several more days if these changes are not to later regress. Of course, still later events may turn out to be required to achieve ultimate stability. Although the evidence is, so far, less complete, somewhat comparable events probably operate during establishment of stable mammalian engrams.

A problem for the establishment of very long-lasting memory is that most cellular constituents turn over continually. Therefore, whatever synaptic changes underlie long-term memory must somehow regenerate themselves if memory is to persist. In the 1980s, Francis Crick and

John Lisman independently proposed that self-regenerating changes at individual synapses could be produced if change were mediated by some species of protein kinase that could be activated locally, not only by its normal signaling molecules, but also by phosphorylation of the kinase itself catalyzed by already active kinase molecules of its own kind. Soon, it was discovered that CaMKII has just this property and plays a crucial role in establishment of LTP. However, protein synthesis plays no role in the autophosphorylation of CaMKII, so this specific mechanism could not be the basis for protein-synthesis-dependent long-term change. Currently, two kinds of potentially self-regenerating synapse-specific changes are under active investigation.

One of these is the translation of preexisting mRNAs local to individual synaptic regions of an atypical, auto-active form of PKC, PKM ζ , which lacks the repressive, signal molecule-controlled regulatory domain of the more common isoforms of PKC. PKM ζ causes potentiation of the synapses where it is present, and there is increasing evidence that it plays an important role in several kinds of learning and/or in establishment of late LTP in both mammals and *Drosophila*. Existing PKM ζ appears to promote its own further synthesis, potentially creating a positive feedback loop that could maintain elevated levels locally once these were established by learning.

The other locally synthesized signaling molecule that is currently receiving attention as the possible basis for a positive feedback loop that could maintain synapse-specific change is a molecule, cytoplasmic polyadenylation element binding protein (CPEB), that plays a role in translation of preexisting synaptic mRNAs somewhat analogous to that played by CREB in nuclear transcription. In *Aplysia*, this protein is synthesized locally during development of long-term facilitation and is crucial in the stabilization of recently established functional and morphologic changes that underlie facilitation. The local elevation of this protein's titer due to local synthesis is thought to lead to a conformational change that both increases the protein's effectiveness in promoting translation and promotes a similar conformational change of nearby CPEB molecules, with the result that the altered, more active form of the molecule is maintained locally despite turnover of the population of CPEB molecules over time. The self-regenerating, contagious changes thought to occur in CPEB are analogous to those occurring in the prions responsible for transmissible spongiform encephalopathies. Evidence is emerging for a possible role of these prion-like mechanisms during learning and synaptic change in mammals and *Drosophila* as well as *Aplysia*.

The evidence for the roles of both of these kinds of locally contagious molecular events in learning is intriguing. It remains to be seen whether either or perhaps both of these mechanisms working together really are part

of the sequence of events leading to stabilization of engrams. Whether they are or not, it seems virtually certain that the simple division of memory into two homogeneous stages, short-term and long-term storage is a thing of the past.

Perhaps also indicative of the continued transformation of memory after protein-synthesis-dependent consolidation has already occurred (or begun), is the observation, both in mammals and invertebrates, that if a memory is recalled, a period of protein synthesis is again necessary if the memory is not to be lost, that is, the memory must be reconsolidated. This reconsolidation process is still poorly understood, but there is some evidence in mammals that sufficiently well consolidated memories might not in fact be degraded upon recall. It has also been found in the pond snail *Lymnaea* that reconsolidation of more freshly consolidated memories requires PKA activity as well as protein synthesis, whereas reconsolidation of longer-established memories requires only protein synthesis, again suggesting that consolidated memories continue to change their properties. In mammals, it is often proposed that reconsolidation is involved in integrating new memories into a complex network of previously existing associations. However, such conjectures may seem less appealing when it is appreciated that reconsolidation also seems to occur in lower animals where the amount of stored information may be limited and postlearning reorganization of memory not required.

Discovery of the role of CREB in establishing long-term memory first arose from experiments on long-term facilitation in *Aplysia* and then rapidly extended to *Drosophila* and mammals. When it was discovered that there are isoforms of CREB that suppress CREB-stimulated transcription, the possibility was recognized that the long-established and phylum-general failure of massed training to cause consolidation might be explained if training trials caused not only an activation of transcription-promoting CREB but also a shorter lasting activation of transcription-suppressing CREB that had to abate before transcription could occur. *Drosophila* mutants, in which exaggerated amounts of either isoform could be induced at will, provided compelling evidence supporting this hypothesis, which was also supported in *Aplysia*. A few years later, evidence for similar mechanisms was obtained for fear learning in mammals. This is yet another instance of the remarkable generality across phyla of the cellular mechanisms of memory and of progress in our understanding being facilitated by taking advantages of the experimental opportunities presented by characteristics of animals in different phyla.

In mammals, a (systems) consolidation process, which is much slower than cellular-level protein-synthesis-dependent consolidation processes, is involved in transforming learning that initially depends on the hippocampus for retention to a form where it is

independent of the hippocampus. Systems type consolidation is thought to involve endogenous neural activity that causes transfer of the hippocampal memory to extra-hippocampal (presumably cortical) circuitry. Reminiscent of this, recent work seems to indicate that the transfer from short-term to middle-term memory in *Drosophila* may depend on mushroom-body-driven activity of dorsal-paired midline (DPM) cells feeding back onto (perhaps other parts of) the mushroom bodies (see **Figure 4**). In mammals, systems type consolidation is thought to be involved in recoding engrams so that new and old information become integrated. The significance of the insect findings has yet to be addressed theoretically.

Concluding Remarks

The facts described above seem to show that learning mechanisms in mammals, mollusks, arthropods, and round worms, animals that segregated from each other a very long time ago in evolution have marked similarities. There is considerable diversity, but it is all diversity of detail in how a seemingly common set of possible mechanisms is utilized. As has been repeatedly suggested by investigators of *Aplysia*, it is as though there were a common alphabet of mechanisms that get combined in different ways in different animals (or different parts of the same one). All of the animals studied have as common distant ancestors the first multicellular animals with nervous systems, the coelenterates. Neural plasticity, particularly interneuronal (i.e., synaptic) facilitation that can last for many hours or possibly even days plays roles in the behavior of these ancient animals. Coelenterates even appear to have NMDA receptors, though there as yet is no evidence that these play any role in their synaptic plasticity. Perhaps the commonalities we have seen are a consequence of evolution of learning from the ancient forms of neural plasticity of our very early progenitors.

Animal Models of Bipolar Disorder

J W Young and M A Geyer, University of California, San Diego, La Jolla, CA, USA

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Construct validity – It refers to the degree to which a model accurately reflects the processes or disorder for which it is intended.

Endophenotypes – They represent the internal characteristics discoverable by biochemical test or microscopic examination.

Etiological validity – It occurs when the biological basis of a disease is recreated in the model.

Face validity – It assumes the usefulness of an animal model or a preclinical test solely on the basis of phenomenological similarities between the model/test and the disorder/domain.

Predictive validity – It constitutes the manipulation of a model whereby the results mirror those observed in the human from the same manipulation.

Receptor tautology – Occurs when using an assay, either *in vivo* or *in vitro*, whereby a ligand challenge to a specific neurotransmitter target is reversed by an oppositely acting ligand to the same neurotransmitter target.

depression, cognitive deficits are apparent in nearly every cognitive domain. While this cognitive disruption has been largely overlooked in the past, recent evidence indicates that cognitive deficits are also apparent during the euthymic phase and that these deficits correlate with functional outcome (reintegration to their everyday lives). To date, the underlying causes of these cognitive deficits as well as the episodes of mania and depression have yet to be elucidated.

Difficulties in Generating Animal Models of Bipolar Disorder

One rate-limiting step in bipolar disorder research has been the paucity of suitable animal models. Attempts have been made to model this disorder in animals, including specific modeling of the manic, depressive, and cyclic aspects of the disorder. Numerous hurdles exist that have increased the difficulty in developing suitable models. These hurdles include the fact that there are limited data with regard to pathophysiological mechanism(s) contributing to the disorder. In addition, despite the 50–80% heritability of the disorder, specific genetic contribution(s) have yet to be identified. Another difficulty arises from the lack of knowledge on the mechanism by which existing treatments exert their effects. Moreover, bipolar disorder does not have clearly defined endophenotypes that would provide the empirical basis for cross-species models. The limited amount of available information with regard to the cause of cycling in the disorder has also proven to be a considerable obstacle to producing suitable animal models of bipolar disorder. In fact, given the heterogeneity of psychiatric symptoms among bipolar disorder patients, identifying an all-encompassing animal model may be impossible. The overlap of cognitive deficits to those of schizophrenia – another major psychiatric illness – is another source of difficulty when attempting to develop animal models of bipolar disorder that are distinct from animal models of other disorders such as schizophrenia. Finally, consistent with schizophrenia, the lack of effective procognitive treatments for the deficits in bipolar disorder means that there are no positive controls with which to validate putative animal models of cognitive deficits in bipolar disorder. Unfortunately, the lack of universally accepted animal models of bipolar disorder has limited the development of specific treatments. Current treatments have been discovered via serendipity or by testing the efficacy of treatments that

Introduction to Bipolar Disorder

Bipolar disorder is a serious and chronic psychiatric illness that is classically associated with alternating episodes of either elevated or depressed mood states. The lifetime prevalence of bipolar disorder is approximately 1%. Heritability estimates between 50% and 80% indicate that there is a strong multigenetic component to bipolar disorder. The *Diagnostic and Statistical Manual*, Version IV (DSM IV) subdivides bipolar disorder into type I and type II disorders. Type I bipolar disorder is characterized by manic behavior of at least 7 days, with or without the occurrence of depression. Type II bipolar disorder is characterized by hypomanic behavior (manic-like behavior occurring for 4 days) with major depression. The time between episodes of mania is referred to as the euthymic phase, where the patient attempts to recover from an episode as well as reintegrate into their everyday life. Symptoms and deficits are still apparent in the euthymic period, however. These symptoms, coupled with increasing episode occurrence, lead to substantial social disruption contributing to a near 15% suicide rate. During episodes of mania and

were originally approved for other disorders, such as antipsychotics. Taken together, there is very limited information available to guide the generation of viable animal models of bipolar disorder having face, predictive, and construct validity. Nevertheless, the attempts undertaken to create animal models have provided some insights into possible neurobiological underpinnings of the disorder, as is discussed below.

Models of Mania

Pharmacological

Psychostimulants are known to precipitate a state of mania or hypomania in the healthy human. Hence, there has been great interest in the psychostimulant effects on behavior in animals. Amphetamine is the psychostimulant used most commonly in animal models of bipolar disorder. Amphetamine acts by blocking the reuptake of norepinephrine and dopamine, although it is sixfold more potent at the norepinephrine transporter than at the dopamine transporter (DAT). The most common behavioral measure of mania in animals is that of locomotor hyperactivity, commonly assessed in an open field test or photocell chamber. Low doses of amphetamine induce hyperactivity in open field tests, putative evidence of face validity for increased activity of patients during manic phases. Amphetamine-induced hyperactivity can be susceptible to reversal by bipolar disorder treatments, exhibiting some predictive validity in terms of known treatment effects. Not all studies demonstrate a reversal of amphetamine-induced hyperactivity, however. In fact, the most consistent reversal effects are observed following antipsychotic treatments that were developed for treatment of schizophrenia, but are now also used to treat mania. Given that antipsychotic-induced reversal of amphetamine-induced hyperactivity is also used as a model for schizophrenia, the specificity of this model for mania remains questionable. In addition, since antipsychotics primarily act as antagonists to the dopamine system while amphetamine acts as an indirect agonist, there exists the limitation of receptor tautology. The lack of specificity of amphetamine-induced hyperactivity as an animal model of mania introduces another confound, because it is also used as a model of drug abuse and tardive dyskinesia, as well as for antipsychotic efficacy. Finally, numerous reports have evaluated the use of amphetamine challenge in the human as a model of bipolar disorder. To date, such clinical amphetamine studies have not supported its use as an appropriate model. One attempt to avoid such receptor tautological/antipsychotic efficacy confounds has been to combine amphetamine and an anxiolytic administration, such as chlordiazepoxide. It has been hypothesized that both mood stabilizer and antipsychotic treatments can reverse

this combined-model-induced hyperactivity, while mood stabilizers alone cannot reverse stimulant-alone-induced hyperactivity. While studies have been limited to date, this combined model may offer another avenue to develop novel therapeutics. Other pharmacological models of bipolar disorder have used other psychostimulants such as methamphetamine and cocaine. As with amphetamine and the combined model described above, most models report only hyperactivity as a measure of mania. Consistency among these studies is also limited since induced hyperactivity has been reversed by acute antimanic treatments, while other studies have reported no effect. In the human, acute administrations of antimanic drugs do not induce a full reversal of manic symptomatology. Thus, the interpretation of these findings in terms of translational validity has proven difficult. Studies on acute-stimulant mania models with chronic antimanic agent administration via repeated injections, osmotic minipumps, food chow, or drinking water have also been conducted. To date, these chronic studies have not provided conclusive evidence for the suitability of these acute-stimulant models.

Genetic

Developing genetic models of bipolar disorder can be accomplished in different ways. Strain comparisons can be made across a range of behaviors such as activity levels. The effects of antimanic agents on these behaviors can then be assessed to identify the strain exhibiting the largest antimanic effects for putative evidence of predictive validity. Retrospective gene analysis is then performed to identify differences that may contribute to that strain being more receptive to the effects of antimanic agents, and thus possibly reflecting a genetic contribution to bipolar disorder. A major benefit to this type of model is that the investigation into putative underlying neurobiological differences is not limited by experimental design and *a priori* hypotheses. The suitability of the strain differences approach can be readily investigated. In fact, numerous mouse strains have been assessed and compared in multiple behavioral assays not necessarily specifically addressing their suitability to psychiatric conditions. In terms of locomotor activity alone, Black Swiss, Friend leukemia Virus B strain (FVB/NJ, Jackson Labs, Bar Harbor, ME), and NOD/LTJ mice may be among the most active strains. Thus, future studies could assess the effects of antimanic agents on the high activity levels of these strains in order to determine their suitability as models for bipolar disorder. Subsequently, the specific genetic contributions to these effects could be investigated.

Prospective genetic models of bipolar disorder can also be generated by utilizing our limited understanding of the neurobiological underpinnings of the disorder. Suspected genetic abnormalities contributing to bipolar disorder can be recreated in mice to investigate the behavioral effects of such genetic modification. These models confer a degree of etiological validity and benefit from testing a specific hypothesis. Moreover, the effects of genetic mutations are theoretically more selective than administering a drug that may act on multiple neurotransmitter systems. To date, genetic mutant models of bipolar disorder have been developed both in response to genetic susceptibility studies in bipolar disorder, as well as to studies on the putative mechanism of action of antimanic treatments. Numerous genetic linkage studies have implicated the DAT in the development of bipolar disorder. Mice with no (knockout mice) or reduced (knockdown mice) DAT function have been created. These DAT-mutant mice exhibit a hyperactivity profile as accompanied by other behavioral abnormalities that are consistent with bipolar disorder. One confound inherent in using such genetic models, however, is encapsulated in the DAT-knockout mice. DAT-knockout mice exhibit a variety of behavioral abnormalities that are linked to their lack of DAT expression from birth. Such abnormalities, combined with the development of remarkable compensatory changes to counter the loss of this major monoamine transporter, may reduce the utility of these mice when assessing putative therapeutics. DAT-knockdown mice exhibit only a reduced expression of the DAT and appear healthy and viable, despite their hyperactivity profile. Thus, DAT-knockdown mice may prove to be a more suitable animal model of bipolar disorder than the full DAT knockout when assessing putative treatments.

Another gene putatively, although not consistently, linked to bipolar disorder is the glycogen synthase kinase-3 (GSK-3). Although GSK-3 acts at multiple levels to regulate over 40 proteins, it is generally accepted that it acts as a proapoptotic agent. While increased apoptosis is consistent with the cellular loss that has been reported in bipolar disorder patients, the main interest in this target derives from the reports suggesting that antimanic treatment effects are mediated by GSK-3. Heterozygous GSK-3-mutant mice have been created and display increased activity levels and other behavioral abnormalities. The behavior of GSK-3 heterozygous mice resemble that of lithium-treated mice, however; thus, this model may be more applicable as a drug screen for lithium-like compounds. Moreover, there appears to be greater evidence linking GSK-3 inhibition with antidepressant-like activity than with mania-reducing effects. Hence, the suitability of the GSK-3 mutant mice as a model of bipolar disorder mania has been questioned.

Models of Depression

Numerous animal models of depression exist, although none have been developed with specificity to modeling the depression that occurs in bipolar disorder.

Cycling

The cycling nature of bipolar disorder represents possibly one of the most difficult aspects of the disorder to model in animals. Only a few groups have attempted to develop animal models of such cycling behavior. Each group acknowledges that their models do not necessarily exhibit homology to the disease states of bipolar disorder. In fact, modeling behavioral symptoms is of secondary consideration as the groups are simply developing potential models of cyclic behavior in order to investigate drug effects on the observed cycling. These models include intermittent cocaine injections and the 'kindling model.'

In the intermittent cocaine model of cycling in bipolar disorder, cocaine is injected in rats intermittently once per week. Fluctuations in cocaine-induced dopamine efflux and freezing behavior are observed, where injections in a week increased such behavior, but the following week the same injection reduced such behavior. While chronic lithium attenuated some of these effects, it has yet to be determined whether the effects observed have relevance to cycling in bipolar disorder.

The kindling-behavioral sensitization model of recurrent affective disorders is based on the hypothesis that initial episodes occur following major psychological stressors, while future episodes can occur following only minor stressors. The model encompasses two neurophysiological phenomena: electrophysiological kindling (progressive vulnerability to seizures) and behavioral sensitization (progressive sensitivity to stimulants). However, these two phenomena make it implicitly difficult to test this model, as experimental results can be interpreted to lend support to the model or argue against it. The kindling phenomenon is generated by repeated electrical stimulation-induced seizures evoking after-discharges from the amygdala which eventually increase in complexity to affect other areas of the brain. These after-discharges eventually result in spontaneous seizures. Thus, spontaneous cycling is observed and attempts can be made to delay or reduce such spontaneous seizure events. Of course, the cycling behavior observed is measured in terms of seizures and not behavior related to bipolar disorder. Hence, its suitability as an animal model of bipolar disorder has yet to be determined.

Mania beyond Hyperactivity

Other Symptoms of Mania

Numerous attempts have, therefore, been made to generate animal models of bipolar disorder. Because mania is the cardinal feature of bipolar disorder (exhibited in type I and type II disorders), most attempts have focused on modeling mania in animals and have focused on observations of hyperactivity. Mania is not limited to hyperactivity, however, with other facets of mania that can also be viewed as endophenotypes. Other endophenotypes of mania include irritability, aggression, reduced sleep, poor judgment, increased sexual arousal, and drug abuse or hedonistic behavior. Each of these endophenotypes can putatively be measured in animal models of mania. For example, irritability defined as hyperreactivity to innocuous stimuli could be measured by increased startle reactivity. Aggressive behavior could be quantified using a resident–intruder paradigm. Circadian rhythms to quantify sleep patterns can be generated using simple telemetry devices, while poor judgment could be assessed by assaying levels of risk-taking behavior. Finally, drug abuse and hedonistic behavior can be assessed using intracranial self-stimulation or progressive ratio breakpoint paradigms.

Cognitive Dysfunction

During periods of mania and depression, bipolar disorder patients exhibit deficits across nearly all cognitive domains. Such deficits contribute to the difficulties faced by patients during such episodes and their subsequent rehabilitation. Cognitive dysfunction is not limited to such episodes however. During the euthymic period, bipolar disorder sufferers also experience cognitive deficits, but in more selective cognitive domains. These domains include attention and vigilance as well as executive functioning. Attention and vigilance deficits have been identified using tests that require the subject to attend to relevant, while ignoring irrelevant, stimuli – such as the continuous performance test. Executive functioning deficits have been identified using the Wisconsin Card-Sorting Task, which requires subjects to learn novel rules and shift their focus from one set of rules (attentional set) to another. There is increasing evidence suggesting that these cognitive deficits most closely correlate to functional outcomes such as reintegration to their everyday lives and vocation opportunities. Thus, the need to develop therapeutics for these cognitive deficits is increasingly apparent. Animal analogs of these attention and executive functioning tests are available. Tests of vigilance include the sustained attention task and the 5-choice continuous performance test, for rats and mice respectively. A direct animal analog of the

executive functioning tasks named above exists and is called the attentional set-shifting task. Therefore, future animal models of bipolar disorder could and should also include a cognitive profile that encompasses these deficits.

Conclusions and Future Directions

At present, there are limited viable animal models of bipolar disorder. The limited knowledge of endophenotypes of bipolar disorder that can be assessed in animals further reduces the chances of developing viable animal models. While the behavioral measure in most animal models of bipolar disorder is that of hyperactivity, it is only recently that the activity levels in bipolar disorder patients have been quantified. Specific exploration and locomotor patterns have also been quantified providing a phenotype of bipolar disorder that can be modeled specifically in animals. Attempts are also being made to model other aspects of mania in animals, such as aggression and irritability. Increased knowledge of the cognitive deficits in bipolar disorder also provides further opportunity to provide directly translatable models. Developing an animal model that encompasses each of these quantified domains may lead to more appropriate animal models of bipolar disorder. Finally, increased knowledge of the genetic contributions to bipolar disorder may allow the creation of a combined genetic and pharmacological model, providing greater insight into the neurobiological underpinnings of bipolar disorder, as well as allowing testing of putative therapeutics.

Animal Models of Learning and Memory

R R Miller, State University of New York at Binghamton, Binghamton, NY, USA

© 2010 Elsevier Ltd. All rights reserved.

Glossary

A, B, C, X – The specific cues that initially do not control behavior but ordinarily gain behavioral control when they are paired with an unconditioned stimulus (US; i.e., they become conditioned stimuli [CSs]).

A1 – The high activation state of a specific memory representation in the sometimes opponent process (SOP) model.

A2 – The low activation state of a specific memory representation in SOP.

Conditioned stimulus (CS) – A stimulus that, although it initially has no influence on behavior, comes to control behavior as a result of its being paired with a biologically significant stimulus (US).

I – The inactive state of a specific memory representation in SOP.

Rescorla–Wagner (1972) model – This model of learning assumes that learning a CS-US relationship requires the CS be followed by a surprising US. It posits that learning is driven by a total error reduction algorithm.

Rate expectancy theory (RET) – This model, put forward by Gallistel and Gibbon in 2000, assumes that learning consists of encoding temporal relationships between events (i.e., stimuli and responses), and that subjects respond to CSs to the degree that they signal a decrease or increase in the expected time to the next outcome (usually a US).

Sometimes competing retrieval (SOCR) model – This model, proposed by Stout and Miller in 2007, assumes that learning depends on contiguity of a CS and US, but responding to the CS is directly related to the extent that the CS predicts a change in the likelihood of the outcome relative to background cues (including the context).

Sometimes opponent process (SOP) model – This model, put forward by Wagner in 1981, assumes that there are three different states of activation of the representation of an event (high [A1], low [A2], and null [I]). Learning and performance are both functions of the different memory states that the relevant CS and US representations are in.

Unconditioned stimulus (US) – A stimulus that on first encounter elicits responding; such stimuli are said to be biologically significant.

Acquired changes in stimulus control of behavior (i.e., learning, retention in memory, and behavioral expression of knowledge) can be described at many different levels of analysis ranging from neural to associative to higher-order cognitive. The level of analysis here is associative. Associations are often viewed as analogous to the connections between neurons that are presumably responsible for learning and memory. An association is a link between the mental representations of two events (stimuli or responses), such that activation of one representation by the presentation of its stimulus, hereafter called a conditioned stimulus (CS) or cue (e.g., a tone or light), results in the activation of the associated representation, hereafter called an outcome, even if it is physically absent. If the retrieved representation is of a biologically significant event (i.e., an unconditioned stimulus (US), e.g., food or electric shock), a conditioned response appropriate for the outcome is ordinarily emitted. Here, a summary is provided of fundamental phenomena that are reliably observed in simple situations that engage learning and memory by both human and nonhuman subjects. Similarities in operations (i.e., experimental manipulations) and consequent changes in behavior among these phenomena are used to organize the phenomena. Then the more widely cited contemporary models of associative learning are briefly described. The more successful models provide central principles that call for a search for the underlying neurophysiological mechanisms.

Benchmark Phenomena of Learning and Memory

Contiguity

As early as the ancient Greek philosophers, it has been recognized that stimulus control of behavior indicative of an association between two events (e.g., a cue and an outcome) is most apt to appear when the events occur in close temporal and spatial proximity to one another. Shorter intervals between the cue onset and the outcome onset enhance later responding to the cue. Conditioned responses are stronger when the cue precedes the outcome (i.e., forward pairings) than when the two events are simultaneous or the outcome comes first (i.e., backward pairings), but whether this reflects weaker simultaneous

and backward associations or merely weaker behavioral expression of equally strong associations is currently unclear. Despite the wide recognition of the critical role of contiguity, only a few models (e.g., Gallistel and Gibbon's 2000 rate expectancy theory (RET); Wagner's 1981 sometimes opponent process (SOP) model) actually try to account for it as opposed to merely assuming its role.

With A, B, and other single letters denoting specific cues that do not initially control behavior, second-order conditioning (B-US pairings followed by A-B pairings yield responding to A that is indicative of an A-US association) and sensory preconditioning (A-B pairings followed by B-US pairings yield responding to A that is indicative of an A-US association) are examples of A-US acquired behavior without pairings of A and US. This appears to contradict the view that contiguity is necessary for acquired behavior. However, the principle of contiguity has been sufficiently successful in so many other situations that, rather than discard it, it has been reframed to focus on contiguity between activation of neural representations rather than contiguity between the actual occurrences of physical events.

Contingency

Stimulus control of behavior is encouraged when a cue and outcome occur together (i.e., are contiguous) and when subject spends time in the training context during which neither stimulus occurs, although the benefit of co-nonoccurrence is far weaker than the benefit of co-occurrence. In contrast, behavioral control is weakened when one of the two stimuli occurs in the absence of the other. Presentations of the cue- or outcome-alone degrade responding to the cue when they occur before the cue-outcome pairings (i.e., CS- and US-pre-exposure treatments) or are interspersed among the cue-outcome pairings (i.e., partial reinforcement and degraded contingency treatments). Cue-alone presentations after the pairings (i.e., extinction treatment) also attenuate subsequent responding to the cue; however, this decrement is often followed by spontaneous or induced recovery of stimulus control. Most contemporary models account for these contingency phenomena, but few address recovery from extinction.

Stimulus Salience (Attention)

Appearance of conditioned responding occurs in fewer pairings and behavioral control is stronger at asymptote when the cue and/or outcome are more salient (increased intensity is one means of enhancing salience). Most models assume that salience is positively correlated with associability (i.e., ease of entering into an association) or attention. However, models based exclusively on

information processing independent of stimulus characteristics (e.g., Gallistel and Gibbon's 2000 RET) are challenged by stimulus salience effects.

Stimulus Interaction

When there are more than two stimuli (e.g., another stimulus, C, in addition to target cue A and outcome B in a given situation, where C is another cue or outcome), such that each stimulus is associated to at least one other stimulus, the presence of C can influence the A-B association or at least its expression. Control of excitatory behavior by the target cue (A) can be either impaired (e.g., cue competition such as overshadowing and blocking, conditioned inhibition, and stimulus interference) or enhanced (e.g., cue potentiation, augmentation, second-order conditioning, and sensory preconditioning) as a result of these interactions. Detrimental interactions are by far the more common (or at least they have received far greater attention). The conditions that favor detrimental as opposed to facilitative interactions are still unclear, but larger numbers of trials appear to more strongly favor detrimental interactions. When cues C and A share a common relationship to outcome B (e.g., AC-B), the altered behavior based on the A-B association is called a cue interaction. Outcome interaction is said to occur if A shares a common relationship with C and B (e.g., A-CB). If the interacting stimuli are presented simultaneously (or at least on the same trials) and the interaction is detrimental to excitatory responding, the interaction is called competition and may depend on the establishment of a within-compound association between the competing stimuli. When the interacting stimuli are presented apart (i.e., on different trials, e.g., A-B followed by C-B), detrimental interactions are called interference and facilitative interactions are rarely observed. Majority of research and theoretical models have attended to cue competition to the exclusion of other forms of stimulus interaction. When interference has been studied, the focus has been on outcome interference far more often than cue interference. When the interacting stimulus, C, is independently revalued (i.e., reinforced or extinguished) following its presence during A-B pairings, the observed change in behavior control by the A-B association is called retrospective revaluation. Retrospective revaluation is a reliable phenomenon, but one that is clearly weaker than changes in behavior obtained by direct manipulations of A or B (i.e., pairings or presentations alone).

Whether stimulus interaction (i.e., modified responding to A) produced by the presence of C is due to a direct change in the A-B association or a change in responding to A that is mediated by C at the time of testing is unclear. For example, a decrease in responding to A based on an A-B association may be due to either a weakened A-B

association or a decrease in the behavioral expression of the A–B association, which is often viewed as a retrieval failure. Both likely occur as a function of parameters. Stimulus competition (competition between stimuli presented together) and stimulus interference (interference between stimuli presented apart) are both subject to recovery through (1) extinction of the competing or interfering stimulus, (2) reminder treatments that preclude new learning, and (3) spontaneous recovery as a result of delayed testing. Such recovery of behavior has been viewed as arising from retrieval of latent memories by some researchers and as new learning by others. Accounts of cue competition as a result of impaired learning at the time of training usually assume that learning depends on a discrepancy between the expected outcome based on all cues present on that learning trial and the outcome that actually occurs. Learning in such models (e.g., Rescorla and Wagner) is said to work to reduce total error in outcome expectation. If learning an A–B association did not occur when subjects were exposed to AC–B pairings (i.e., overshadowing of A by C), this would indicate that contiguity alone was not sufficient for learning to occur in that A and B were paired. Contemporary accounts of cue competition as a product of impaired retrieval assume that learning concerning each separate cue depends on a discrepancy between the expected outcome based on that individual cue and the outcome that actually occurs (i.e., local error reduction). Retrieval-failure accounts of cue competition do not contradict the view that contiguity alone is sufficient because learning is assumed to have occurred but not be expressed. Most contemporary models account for competition, but not interference (however, Bouton accounts for interference, but not competition).

Factors that Differentiate Contemporary Models of Associative Learning

Stimulus Definition

As associative learning is the formation of links between the mental representations of stimuli (or responses), it is essential that the meaning of stimulus is well understood. An early and still prevalent view treats a stimulus as would the layman; for example, a tree is a single elemental stimulus. This position is taken by Rescorla and Wagner's 1972 model and many other more contemporary models. In contrast, some models deconstruct gross stimuli such as a tree into a large number of stimulus elements, thereby replacing the representation of the tree with individual branches, twigs, leaves, or even leaf fragments (i.e., microelements). Such models often concern themselves with the consequences of associations between the elements, which can provide powerful explanatory mechanisms. At the other end of the spectrum of what constitutes a stimulus is Pearce's 1987 configural model,

which treats the entire momentary perceptual field (except for the US) as a single integrated stimulus (i.e., a configured stimulus). Here, rather than perceiving the tree, subjects are assumed to perceive the entire forest including hearing the birds sing. As such, stimuli are not apt to ever exactly repeat from training trial to training trial, or training trial to test trial. Much explanatory power is based, with considerable success, upon generalization between stimuli on different trials being a function of differences in stimulus similarity.

Emphasis on Acquisition or Performance

The chain of events required for associative control of behavior obviously must include acquisition (sometimes called encoding or learning), retention (sometimes called storage), retrieval, and behavioral expression. Acquired behavior would be disrupted by a failure of any of these links in the chain. Thus, any serious model of learned behavior should speak to each of these steps. Surprisingly, most associative models focus their attention on either the acquisition phase or the retrieval/expression phase, paying little heed to the other phases. That is, to explain differences in stimulus control of behavior between treatment groups, most models emphasize differences in acquisition to the exclusion of differential retrieval of stored memories. Other models emphasize differential information processing after acquisition as a function of treatment, rather than differential acquisition. Few models seriously concern themselves with information processing during both acquisition and testing (i.e., retrieval and expression). Notably, neuroscientists have largely focused on acquisition, generally ignoring information processing that occurs during test.

Most acquisition-focused models follow the Rescorla-Wagner model by assuming that acquisition is driven by one or another form of total error reduction. The assumption here is that, on a given trial, learning about each cue present is proportional to the difference between the maximum associative strength that the outcome delivered on that trial can support and the expectation of the outcome based on all cues present on that trial. Models subscribing to this principle use it to account for stimulus interactions (e.g., conditioned inhibition and cue competition). Some models that subscribe to total error reduction assume that this principle results in cue competition by decreasing processing of US representations, whereas other models assume that the total error reduction principle leads to cue competition by decreasing processing of CS representations. Models that focus on processing at the time of performance typically reject the total error reduction principle and use a local error-correction rule to prevent unlimited acquisition across many CS–US pairings (an approach popularized by Bush and Mosteller). Here, acquisition for each specific cue is assumed to be proportional to

the difference between the maximum associative strength that the outcome delivered on that trial can support and the immediate expectation of the outcome based on that specific cue. Such models account for stimulus interactions through processes that occur at the time of testing.

Trial-Wise or Real-Time Processing

Whether they emphasize information processing during acquisition or during performance, most models of learning are trial-wise models. That is, on a given trial on which stimuli are presented, these models assume that organisms first compute responding, then perceive the outcome of the trial, and finally engage the learning mechanism based on what transpired on that trial. Trial-wise models are to be contrasted with real-time models, which assume that organisms are encoding new information instant by instant throughout the treatment sessions, that is, during both the so-called trials and the intertrial intervals. In reality, there is no doubt that organisms are real-time processors of information, but real-time models are often mathematically intractable. Hence, in practice, researchers simulate them by assuming that treatment sessions have a trial-like structure, composed of very small temporal windows throughout the so-called trials and the intertrial intervals. Moreover, trial-wise models sometimes address learning about context that can occur during intertrial intervals by treating each intertrial interval as many trials on which the target cue and outcome are absent (the specifics of parsing intertrial intervals can be critical). When this is done, trial-wise models can closely resemble real-time models that are simulated by parsing the entire treatment session into many trials of short duration. Hence, in simulation, trial-wise models sometimes do not differ greatly from real-time models, despite the fundamental difference in the underlying assumptions.

Learning during test trials must be considered because early parts of a first test trial can influence behavior in later parts of the same test trial. This is fully expected in real-time models (but not trial-wise models) and is commonly observed in some preparations. For example, tests of fear conditioning often consist of a so-called flooding measure, which involves exposing the subject to a potentially fear-inducing cue (or context) for a single long period of time. Initially, the cue disrupts the behavior that was ongoing prior to presentation of the test cue, but as exposure to the cue continues, the ongoing behavior recovers. Clearly, the recovery of ongoing behavior reflects information processing that occurred earlier on that test trial. Alternatively stated, unlike experimenters, subjects do not differentiate between training and test trials; they are real-time information processors.

Context

Context usually refers to the total physical environment exclusive of nominal CSs and USs. The contexts of both treatment (i.e., acquisition, extinction, etc.) and testing can play several important roles in determining associative responding to a target cue. Both types of context can act as another punctate cue that competes with or facilitates responding to the target cue. Most models attempt to account for this by treating the training context as an additional long-duration cue that is present during both CS presentations and intertrial intervals. This approach is conceptually sound, but in simulations it does not perform well because the predicted behavior varies greatly based on the assumed duration of each context-only trial. Less readily addressed at the conceptual level by most contemporary models is the role that the context (or a punctate stimulus) can play as a discriminative stimulus (aka an occasion setter), in which the context at test can serve to direct the organism to respond using information from only one of two contradictory learning experiences regarding the same cue to which the organism has been exposed. For example, after X -US trials in context #1 and X -noUS trials in context #2, responding to X is observed in context #1 but not context #2. Only a few models of associative learning even begin to account for such occasion setting. Bouton does account for such phenomena, but does not provide a general model of learning.

Contemporary Models of Associative Learning

Here, we very briefly describe a few of the more popular contemporary models of associative learning. One might ask why these models are featured as opposed to the many other possible models that could be cobbled together by merging various principles borrowed from the models described below. The aspect that makes the present models popular is that they feature a limited number of principles which makes them tractable; that is, they tend to make unambiguous testable predictions in contrast to more complex models that are often hybrids of these simpler models. Rank-order predictions between groups by the more complex hybrid models tend to be highly dependent on parameters. In contrast, although the predictions of the simpler models are also parameter dependent, rank-order predictions between groups are less dependent on specific parameters.

Acquisition-Focused Models

As previously mentioned, the various contemporary models tend to place most of their explanatory weight on either acquisition or retrieval/expression. There are no

associative models that focus on storage (the time between acquisition and testing) because storage is widely assumed to be reliable, although, in practice, behavior suggests some limited decay of associations with increasing retention intervals.

The Rescorla and Wagner 1972 model assumes that simple stimuli (i.e., neither deconstruction into many elements nor configuration of the entire perceptual field) are processed. This model has long been the most widely cited model of learning. Each stimulus (CSs and USs) is assumed to have an inherent associability (potential to enter into association) that does not change as a function of experience. Acquisition on any given trial is a direct function of how surprising the US is based on all stimuli present (i.e., learning is driven by reduction of the total error in expectation of the US (aka the delta rule), a principle challenged by recent data reported from the laboratories of Rescorla and Miller). Associative strength between a CS and an US varies from positive values, which result in excitatory conditioned responding, to negative values (i.e., a negative expectation of the US), which result in behavior indicative of conditioned inhibition. This contrasts with most other acquisition-focused models which assume that there are two variables of association between a given CS and US, one for conditioned excitation and the other for conditioned inhibition. In order for a CS to change its associative value with respect to a US, the CS (but not the US) need be present. This feature, which is shared with many other acquisition-focused models, prevents the model from explaining retrospective revaluation. Van Hamme and Wasserman proposed a revision of the Rescorla–Wagner model which allows changes in associative value of a CS even when the CS is absent, provided an associate of the CS is present, thereby accounting for retrospective revaluation. Miller, Barnet, and Grahame provide a review of many of the Rescorla–Wagner model's successes and failings.

The Pearce and Hall 1980 model accounts for many phenomena, including cue competition and some contingency phenomena such as CS- and US-pre-exposure effects, through variation in processing of the CS representation, in contrast to Rescorla and Wagner's emphases on variation in US processing. Specifically, Pearce and Hall posit that a cue's associability (potential to enter into an association, as distinct from the cue's potential to elicit responding) changes as a function of experience. Associability to the CS is presumed to increase when the US is surprising and decrease when the US is expected based on all cues present on that trial. Hence, total error drives CS processing, not US processing. Permitting associability to vary contrasts with Rescorla and Wagner's approach which assumes that associability of a given CS or US is constant.

Mackintosh's 1975 model completely rejects total error correction as the key process underlying learning.

Rather, error correction is assumed to occur independently for each individual cue; thus, US processing varies for each cue present depending on the associative status of that cue. To explain phenomena such as cue competition that Rescorla and Wagner address through total error reduction, Mackintosh depends upon variation in CS processing. CSs that best predict their consequences increase in associability, whereas CSs trained in the presence of another cue that is a better predictor of the outcome USs decrease in associability.

The Pearce 1987 configural model, like the Rescorla–Wagner model, assumes that acquisition is driven by variation in the effectiveness of US processing, which is implemented by total error reduction. However, the emphasis of the model is on how stimuli are represented. As previously stated, on a given trial learning presumably occurs with respect to the entire perceptual field (excluding the US) as a single configured stimulus. US anticipation and, hence, conditioned responding is a function of the excitatory status of the configured stimulus presented on that trial plus generalization from other stimuli that are similar to the test stimulus. The model has clear rules for estimating similarity between two (configured) stimuli.

Wagner's 1981 SOP model assumes that all stimuli are composed of many elements, each mentally represented by a node. All nodes are always in one of three states of activation. The first memory state is one of inactivity (I), the second is one of high activity (A1), and the third is one of low activity (A2). Initially, all elements are in state I. Upon presentation of a stimulus, each node of that stimulus that is in state I has a probabilistic chance of being activated into state A1. Unconditioned responding reflects nodes that are in A1. Nodes in state A1 decay rapidly into state A2, and nodes in state A2 decay slowly back into state I. Nodes in state A2 cannot be activated directly into state A1. If a stimulus which is an associate of an absent stimulus is presented, there is a probabilistic chance of any node of the absent stimulus currently in state I being activated into state A2. Conditioned responding reflects nodes in A2. Excitatory learning occurs when two nodes are simultaneously in state A1. Inhibitory learning occurs when nodes of a CS are in A1 and nodes of the US are in A2. Extinction is due to conditioned inhibition; presentation of the CS without the US causes CS nodes to initially go into A1 and US nodes to be activated into A2. Changes in activation and concomitant learning are ongoing, making this a real-time model in contrast to the previously sketched models. SOP does not account for retrospective revaluation, but an extension of it by Dickinson and Burke does. In 2003, Wagner updated his model to accommodate the configuring of stimulus elements (i.e., learning about the compound of several elements independent of the associative status of the individual elements).

There are a large number of additional acquisition-focused models – hybrid models. Most of them combine various features from those already sketched. Among the most notable of these are those of Harris, LePelley, and McLaren and Mackintosh.

Expression-Focused Models

[Stout and Miller's 2007](#) sometimes competing retrieval (SOCR) model assumes that learning *per se* is driven by spatiotemporal contiguity alone, and limited for each stimulus by local error reduction. Unlike the prior models, conditioned responding is not simply a reflection of the association between the test stimulus and the US, plus generalization from other CSs that are similar to the test stimulus. Rather, conditioned responding is assumed to be not only directly related to these sources of US anticipation, but also inversely related to the expectation of the US based on other cues that were present during training; these companion cues can be contextual or punctate. Thus, conditioned responding reflects not the absolute strength of the test CS-US association, but the extent to which the CS predicts an increase (or decrease) in the likelihood of the US over that of the background of training. Notably, unlike the preceding models, the model assumes that there are no negative associations or positively valued CS-no US associations. Instead, behavior indicative of conditioned inhibition arises from the interaction of excitatory associations, specifically, the background being a strong predictor of the US relative to the target CS. This model readily accounts for retrospective revaluation as well as stimulus competition and contingency effects. However, like the previously mentioned trial-wise models, it fails to account for changes in behavior as a function of the interval between two events, such as the interval between CS onset and US onset, or between cue onset and termination (i.e., interval timing effects).

[Gallistel and Gibbon's 2000](#) RET model assumes that subjects encode rates of reinforcement in the presence of each CS and separately in the presence of the training context alone. Conditioned responding emerges when the reinforcement rate in the presence of the CS becomes significantly higher (as assessed by a statistical test) than in the conditioning context alone. This model is similar to Stout and Miller's SOCR model except that subjects are presumed to encode temporal intervals between events and rates of reinforcement rather than CS-US associations; hence, this model can account for interval timing effects. In addition, the model is a real-time model and assumes that animals retain memories of all prior events (not just summary statistics like associative strength) as well as the intervals between them. However, the model erroneously predicts no effect of stimulus salience.

Behavioral Benchmarks Waiting To Be Met

Overemphasis on Acquisition

The study of stimulus-controlled acquired behavior is called learning. However, learning is an intervening variable; all that is observed is a change in behavior. Stimulus-controlled changes in behavior require perception, encoding (i.e., acquisition and learning), maintained storage, retrieval, and mapping of retrieved information into behavior. However, researchers working with animal models of associative learning have largely focused on acquisition to the exclusion of the other steps in the chain of information processing. Gallistel and Gibbon as well as Stout and Miller stand out in emphasizing information processing that occurs at the time of performance. Researchers studying cognition with humans appear more attuned to the importance of retrieval processes (e.g., Bjork; Roediger; and Tulving). There is a need for more uniform attention to each phase of information processing.

What Is a Stimulus

Despite discussion for almost 100 years, there is still controversy concerning how best to describe a stimulus. The layman's view of a stimulus is still the dominant approach. In contrast, some models that assume a simple stimulus is deconstructed into a large number of perceptual elements that get processed independently, whereas other models assume that the entire perceptual field at any given instant (except the US) is treated as a single configured stimulus. If testing later occurs with some fraction of that configured stimulus present, then responding is a function of the similarity of the configured test stimulus to the configured training stimulus. A consensus concerning how to conceptualize a stimulus has not yet been reached.

Summary Statistics

With the exception of Gallistel and Gibbon, contemporary models of learning assume that organisms store a singular association between A and B that is revised with each subsequent relevant event. These stored summary statistics seemingly serve to provide animals with what is sometimes called procedural knowledge, but the approach fails to address animals' memory of specific past events (i.e., episodic knowledge). Much human data and some data from nonhumans document the existence of episodic memories that encode for a specific episode what happened, when it happened, and where it happened. There is a need for associative models to account for

episodic memories, perhaps taking an approach similar to exemplar models of category learning.

Stimulus Interference

Although the occurrence of stimulus interference (competition between stimuli presented on different trials) is widely documented, no contemporary model of learning adequately accounts for all the major interference phenomena. Commonly observed forms of interference include (1) extinction following acquisition (i.e., A–B followed by A-alone), (2) counter-conditioning (i.e., A–B followed by A–C degrading behavior reflecting an A–B reflecting A–B). Bouton, and Miller and Escobar have proposed accounts of stimulus interference, but these accounts by themselves fail to address many non-interference learning phenomena. There is a need for comprehensive models of learning that account for stimulus interference.

Summary

Associative models of learning serve to organize phenomena observed in acquired behavior and they generate contrasting predictions that direct research. In the former role, models also guide neuroscientists who are seeking underlying mechanisms for not a single behavioral phenomenon, but a family of phenomena. The models tell us what constitutes a family of phenomena. That is the good news. The bad news is that all contemporary models of learning are gross simplifications. However, we have to start somewhere and these models are the best currently available.

Animal Models of Sexual Function

D S Reynolds and C P Wayman, Pfizer Global Research and Development, Sandwich, UK

Glossary

Erectile function – Penile erection is characterized physiologically by a hemodynamic event that results from increased penile blood flow, corpus cavernosal relaxation, venoconstriction, and ultimately increased intracavernosal pressure. In rodent, erection can be facilitated pharmacologically using brain-acting agents, or secondary to sexual stimulation (presence of female, tactile stimulation).

Female consummatory behavior (receptive e.g., lordosis) – A reflex stimulated by pressure on the hind flanks of estrous females when mounted by a male. The female arches her back, which raises the hips to make intromission (penetration) easier. She also moves her tail to one side. Lordosis is displayed by many quadruped mammals, but does not occur in humans.

Female sexual motivation behavior (proceptive) – Appetitive behaviors are displayed by the female rodents to solicit the male to engage in sexual intercourse. In rats, these manifest as approaching the male, crouching, and then darting away to encourage the male to follow (termed ‘hops’ and ‘darts’). The female may also ear wiggle, a very fast flutter of the ears, which is thought to release pheromones to attract the male.

Male consummatory behaviors – A series of complex coordinated motor behaviors and spinal reflexes that underlie mounts, intromissions, and ejaculation.

Male preconsummatory behaviors – Male rodent copulation begins with appetitive behavior and the male approaching the female, followed by anogenital investigations, and this allows the male to understand the female’s estrous state and the degree of female receptivity to his approaches, and if appropriate, then copulation can occur. This then leads to precopulatory behaviors such as pursuit.

or so, there has been an increasing number of studies investigating pharmacological manipulation of sexual function with a view to developing drugs for sexual dysfunction. Early studies were largely focused on male disorders, primarily erectile dysfunction (ED), but also on premature and delayed ejaculation. The successful launch of phosphodiesterase type 5 (PDE5) inhibitors, such as sildenafil, tadalafil, and vardenafil, has demonstrated that animal models can be used to predict human sexual function, at least for ED. More recently, there has been increased attention paid to female sexual disorders, such as deficits in desire and arousal. Studies in women with desire and/or arousal disorders have shown that subjective effects seem to be far more important in modulating sexual responses than in men, which has posed additional challenges to modeling female sexual function in laboratory animals.

The rat is by far the most common laboratory species used for sexual studies, although mice, hamsters, quail, and primates are also used. Rat sexual activity appears somewhat different from that of human, because the specific motor patterns are different, but the overall function of these activities has human correlates (Figure 1). Ethological studies in rats determined that females often mate with several males at the same time in the wild. Appetitive behaviors are displayed by the female to solicit the male to engage in sexual intercourse. These manifest as approaching the male, crouching, and then darting away to encourage the male to follow (termed ‘hops’ and ‘darts’). The female may also ear wiggle, a very fast flutter of the ears, which is thought to release pheromones from behind the ears to attract the male. Mating occurs in bouts with mounting by the male and brief intromission (penetration; ~1 s) before the male and female separate. Each male generally intromits 5–10 times before achieving ejaculation. A female may receive intromissions from multiple males before ejaculation. Given the opportunity, the female paces her contact with the male(s) such that intromission occurs at her preferred interval (typically 60–200 s), which triggers a neuroendocrine reflex that makes pregnancy more likely. Microdialysis studies have demonstrated greater increases in extracellular dopamine levels in the nucleus accumbens when mating occurs at the female’s preferred pacing interval (PPI), suggesting that this is most rewarding for the female. Research has not yet demonstrated for certain whether or not female rats experience orgasm. Male rats prefer to intromit at a faster rate (<60 s), which means that the female must ‘escape’ from the male in order to pace interactions to her PPI.

The field of sexual research in animals is approximately a century old. Despite this, the volume of studies in this area is far lower than most other areas exploring physiological/behavioral functions. Early studies were largely aimed at developing a framework to understand animal, particularly rat, sexual activities, and to start determining the roles of the endocrine and neurotransmitter systems and behavioral manipulations on sexual performance. In the last 20 years

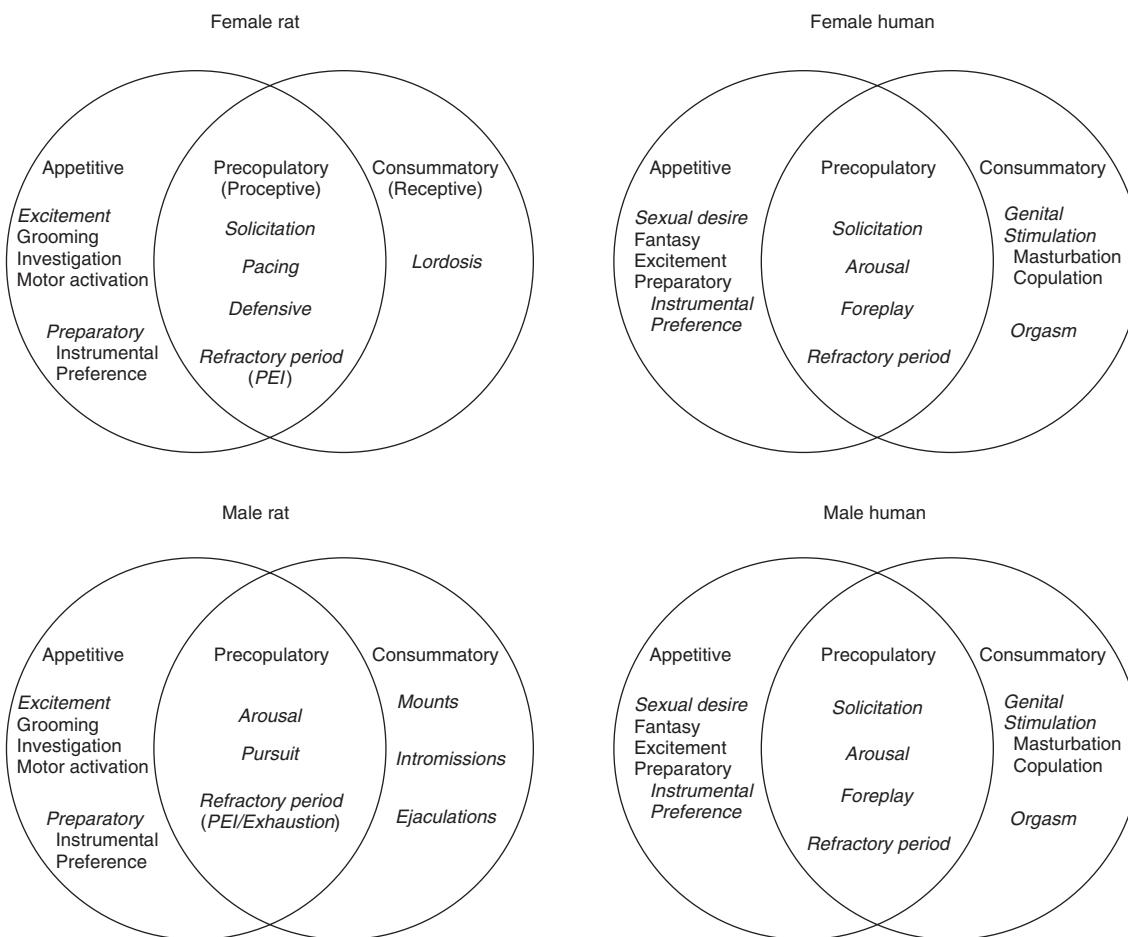

Figure 1 Comparison of sexual behaviors displayed by rats and humans. Redrawn from Pfau JG (1999) Revisiting the concept of sexual motivation. *Annual Review of Sex Research* 10: 120–157.

Female Sexual Behavioral Models

When considering animal models of sexual function, the first thing to take into account is the tight coupling of the estrous cycle with sexual activity. In human females, sexual interest is relatively uniform across the estrus cycle, with a slight rise around the ovulatory period. In contrast, females of most laboratory species will display interest and engage in sexual intercourse only during the estrous stage of the cycle and with very low levels of interest at other times. This presents a practical problem in running animal models of sexual function, especially in species that mate seasonally, such as the dog. To overcome this limitation, the field has concentrated on the use of ovariectomized (OVX) females which are then administered estrogen (for rats, typically 1–100 µg kg⁻¹, 48–52 h before testing) and sometimes progesterone also (250–2000 µg kg⁻¹, 3–8 h before testing) to bring them into an estrous-like state. An additional, important practical advantage is that the OVX prevents pregnancy occurring after copulation, although this could also be

achieved in intact females through the use of vasectomized males. The similarity of this state, physiologically and behaviorally to that of estrous in naturally cycling animals, is fairly well established, although exhaustive studies have not been carried out. For drug studies aimed at assessing pro- or antisexual effects, the hormonal prime can be manipulated: a low level of sexual activity for prosexual studies, and maximal sexual activity to examine drugs that reduce sexual activity.

The only drug approved for use in women to improve sexual function is a testosterone patch. Low levels of testosterone (200–300 pg ml⁻¹ of serum) are required for female sexual activity, although this is a threshold effect and a dose dependency is not observed. Hence, the drug is only approved for use in surgically postmenopausal women with ovary removal, which is known to lower testosterone levels. The lack of widely applicable and clinically approved prosexual agents for women makes it difficult to know which drugs to use as positive controls for preclinical prosexual pharmacological studies. There are some nonhormonal agents have been shown to be

effective in rats and for which there is limited positive data in women with sexual disorders: bremelanotide (melanocortin receptor agonist), apomorphine (nonselective dopamine receptor agonist), buproprion (dopamine agonist, nicotinic acetylcholine receptor antagonist, and noradrenaline reuptake inhibitor), and some serotonergic drugs, such as mCPP (1-(3-chlorophenyl) piperazine).

When testing compounds for pro- or antisexual effects, the hormonal prime used in female rats should be carefully considered. The majority of published studies use fairly large estrogen and progesterone priming doses such that robust sexual activity is observed. A limited number of pharmacological studies have demonstrated an increase in sexual activity above that induced by the high hormonal primes alone, but how to define ‘maximal’ sexual activity is not clear. Despite this uncertainty, it is likely that the window for observing an increase in sexual activity may be limited. One simple solution is that such studies would better run using a suboptimal prime: sufficient to induce some sexual behavior, but of a low-enough level to facilitate potentiation. For antisexual pharmacological studies, an optimal prime is ideal to maximize the effect window for the test compound.

Consummatory Models

By far, the most widely used consummatory sexual model in the laboratory is the lordosis assay. Lordosis is a reflex stimulated by pressure on the hind flanks of estrous females when mounted by a male. The dorsiflexion raises the female’s hips to make intromission easier and also moves her tail to one side. The lordosis test is usually carried out in a small test arena, often a standard husbandry cage bottom. The female, usually OVX with hormonal priming, is introduced into the cage which contains a sexually vigorous male. The female’s response to mount attempts by the male is recorded, typically in a binary (yes/no) manner. The male is allowed a prespecified number of mount attempts (e.g., 10), within the test period (e.g., 5–10 min). The lordosis quotient is calculated as the percentage of mounts resulting in lordosis divided by the total number of mounts/mount attempts. Pro- or antisexual drugs can be tested by administering to the female before testing, although it is important to use an appropriate hormonal prime. The female may be moved between cages of males in order to avoid ejaculation by a male, which would alter the behavior of both partners. The lordosis quotient is a relatively crude measure and the data are often not normally distributed, which make statistical analysis more difficult. Thus, some groups have started using a rating scale for the female’s response, scoring zero for rejection of the male through to three for a willing, full lordosis. This score is then summed over the number of mount attempts. The score has the advantage of giving greater granularity to the female’s response

and the mean group data are normally distributed which facilitates statistical analysis.

The lordosis model is relatively quick to run, simple to execute, and requires no specialist equipment. However, the results are driven largely by the male, as the female has no means to escape from him if she wants to reject mounting and pace her interactions. Additionally, intromissions occur at the male’s preferred rate, which is much faster than that of the female’s PPI. Finally, although lordosis is displayed by many quadruped mammals, it does not occur in humans and so is not a directly translatable endpoint.

Sexual Motivation Tests

Tests designed to examine the motivation of the female for interactions with a male are particularly important for understanding what drives sexual desire, especially as sexual desire disorder affects a significant proportion of women suffering from female sexual dysfunction (FSD). The lordosis test described above largely gives a measure of consummatory sexual behavior (the actual copulation) and can tell us relatively little about the motivation (desire) the female has to approach and engage a male. Sexual motivation tests are designed to prevent full physical contact of the female with the male, so that mounting/intromissions do not confound the measurement of sexual motivation. Early studies of sexual motivation used modified operant methodology which had been successfully applied to drug-abuse motivational studies. Female rats were required to press levers within the test apparatus to obtain access to a male. Although successful, such studies suffered from relatively low response rates, thus making quantitative analyses difficult. Additionally, relatively complex training schedules were required and they have subsequently fallen out of favor. Another early model used classical runway tests, which had been adapted from studies of goal-directed behavior in other fields. In these studies, the speed at which the female runs down the runway to gain access to a male in the goal box at the far end is taken as a measure of motivation for the stimulus animal, in comparison with the speeds where castrated males, other females, or no stimulus (no rat) are used to separate out sexual motivation. In a variation on this test, the runway was fitted with an electrified grid and the current applied could be varied. The theory being that motivation could be inferred from the pain the rat was willing to endure to cross the grid. For example, estradiol benzoate treatment of OVX females increased grid crossings compared with untreated OVX rats.

An alternative experimental approach is to give a female rat the choice between investigating two different stimulus animals and infer that her preference for one over the other is a measure of her sexual desire for that

stimulus animal. This model is run in a large round or oval arena with two small satellite chambers attached on either side of the main arena. The stimulus animals are placed in the satellite chambers, most commonly a sexually active male in one and either a female or a castrated male in the other. The satellite chambers are linked to the main arena through a perforated grid wall, such that the test female in the main arena can see, hear, smell, and have limited tactile contact with the stimulus animal, but cannot fully interact with it. The behavior of the test female is recorded either by direct observation or by an overhead camera. The preference score is the time spent investigating the grid behind which the sexually active male is located, divided by the total time spent investigating either stimulus animal. A score of 0.5 indicates no preference and would be observed for OVX females that have not been hormonally primed. Estrogen and progesterone priming increases the preference score up to a maximum of about 0.75, indicating a preference ('greater desire') for the active male. Likewise, prosexual compounds, such as apomorphine, increase the preference score to a similar degree as hormonal priming.

Combined Motivation and Consummatory Tests

Paced Mating

This test is designed in such a way that the female can escape from the male and thus control the rate of copulation. The apparatus is usually a test arena split into two sections by a divider that has one or more holes in it (**Figure 2(a)**). The test females used are smaller than the males and the holes are small enough such that only the females can pass through them. Alternatively, the males are trained prior to the main test to remain on one side of the chamber by aversive conditioning (e.g., a tap on the nose with a pencil) each time they cross the barrier. Another version of this apparatus tethers the males to one side of

the chamber through a jacket harness. Finally, a bilevel chamber has also been used as a pacing chamber (**Figure 2(b)**). This apparatus is a relatively narrow chamber with a lower and upper platform linked by a ridged ramp. The theory is that the female is more agile than the male and so can outpace him by running up and down between the levels. Both the bilevel chamber and the use of tethered males can have the disadvantage of limiting the movement of the animals and thus, disrupting copulatory behavior.

All pacing chamber studies rely on observers carefully recording the behaviors and interactions of the male and female as well as the time interval between these behaviors. The most common measure used is the exit return latency: the time a female takes to reenter the male's side/area of the chamber after exiting. Additional measures include subcategorizing exit return latency into mount and intromission return latency, recording the number of mounts, intromission, and ejaculations the female receives and also measuring the number of times the female moves between the two chambers. A decrease in the exit return latency and an increase in the amount of time the female spends in the male's part of the chamber are generally taken to indicate a prosexual effect.

Partner-Preference Models

In order to determine whether a female finds different types of sexual interaction rewarding, partner- and/or place-preference models have been used. The place-preference model is widely used to investigate the rewarding effects of pharmacological agents and drugs, such as cocaine or morphine, which will produce a strong preference. The test relies on the observation that when given the choice between two environments, an animal will spend more time in the environment associated with rewarding experiences versus less rewarding/aversive experiences. In the partner-preference test, the female is placed into a test chamber which is usually divided into

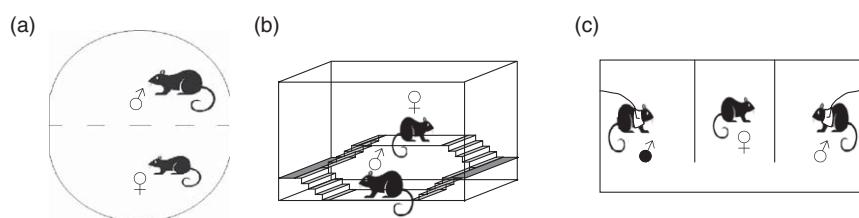

Figure 2 Models of sexual interaction. (a) A paced mating (also known as 'escape chamber') apparatus. The male and female are placed on opposite sides of a dividing wall in the test arena. The dividing wall has four holes, which are large enough to allow the female to pass through, but too small for the larger male rat. The female can control interactions with the male by escaping to the other half of the apparatus. (b) A bilevel chamber is a narrow testing arena with two platforms, one above and the other, linked by ramps. The more agile female can control copulation rates with the male by out-maneuvering him in the apparatus. (c) A partner preference arena has three sections linked by doorways. The test female is placed in the middle and can choose to spend time interacting with either of the stimulus animals tethered in the other chambers through a jacket harness. In this example, there is a sexually vigorous male stimulus (open ♂) and a social stimulus: a castrated male rat (filled ♂).

two or three compartments linked by a doorway or tunnel (**Figure 2(c)**). She is free to move between these chambers and there is a stimulus animal in each compartment. The stimulus animals may be sexually vigorous males, castrated males, or females all with or without drug treatment. The time spent with each animal in a single or repeated test is recorded and expressed as a percentage preference. There are arguments that the presence of the stimulus animals can affect the behavior of the female and thus not give a true representation of her preference. Hence, a place-preference paradigm can be used instead. Here, the female is exposed to a stimulus animal in one compartment of the apparatus with no access to the other compartment. Subsequently, she is exposed to the other compartment with a different stimulus. There may be more than one pairing of the compartment with the stimulus to strengthen the association with that compartment. Finally, the test is run with the female having free access to both sides of the apparatus in the absence of stimulus animals. She will spend more time in the previously rewarding side of the apparatus. An important point in running this study is that the two compartments of the apparatus are contextually different to aid the development of a place-reward relationship. A distinctive context can be provided by distinct wall patterning, smells, and textures such as different flooring types or bedding.

Male Sexual Behavioral Models

Copulatory Behavior/Ejaculation

Rodents are the most commonly used animals in male copulatory behavioral studies, although higher species, such as primates, have been described. There are no pathophysiological rodent models of human sexual dysfunctions, such as ED or premature ejaculation, so studies are performed on 'normal' animals. Male rodent copulation begins with appetitive behavior and the male approaching the female, followed by anogenital investigations, and this allows the male to understand the female's estrous state and the degree of female receptivity to his approaches, and if appropriate then copulation can occur. This then leads to precopulatory behaviors such as pursuit and then, a series of complex coordinated motor behaviors and spinal reflexes that underlie consummatory behaviors such as mounts, intromissions, and ultimately, ejaculation.

Sexually active male adult rats are used in these behavioral assays. Prior to behavioral testing, all rats are habituated to the testing environment, often a perspex observation arena (50–60 cm diameter), for 5 min prior to each trial. Generally, behavioral tests occur between 4 and 8 h after the onset of the dark phase of the light-dark cycle. Following habituation, a receptive female

(usually OVX with hormonal priming) is introduced in the observation arena and copulatory behavior is generally assessed for 30 min. Baseline ejaculatory latencies (ejaculatory latency time, ELT) can be assessed (time taken for rat to ejaculate, from first intromission, following addition of a receptive female into the arena). ELT, similar to humans, varies considerably but is generally fairly reproducible for each animal from study to study. It is possible to reduce the variability in ELT by focusing on a subset of animals, which could be described as rapidly ejaculating animals (ELT < 300 s) proceeding to the main study. There has been some debate as to whether this could be a model of premature ejaculation. Alternatively, rats that show prolonged ELT (>1200 s) can be used to investigate the effects of prosexual pharmacological agents, and these sluggish rats may be considered as a model of delayed ejaculation.

Within 3–4 min after placing the male in the arena, a receptive female is introduced into the arena and the following behavioral parameters noted:

1. *Mount latency (ML)*. The time between addition of a receptive female into the arena and the first mount – a biomarker of sexual drive/desire/libido. A mount is when the male rat mounts the female from the rear and grasps her flanks with his front feet.
2. *Mount frequency (MF)*. The number of mounts to ejaculation (there is no vaginal penetration during a mount – a biomarker of sexual drive/desire/libido).
3. *Intromission latency (IL)*. The time between addition of a receptive female into the arena and the first intromission – a biomarker of sexual drive/desire/libido. An intromission is when the male achieves vaginal penetration during a mount.
4. *Intromission frequency (IF)*. The number of intromissions to ejaculation – a biomarker for erectile function.
5. *ELT*. Time taken from first intromission (vaginal penetration) to ejaculation. Following a mount or intromission, the male usually dismounts from the female, and at the end of a series of intromissions, the male ejaculates. Ejaculation is readily identified by a prolonged intromission, often with energetic thrusting and a slower withdrawing 'crucifix' posture postejaculation.
6. *Copulatory efficiency (CE)*. Ejaculatory latency/the number of intromissions to ejaculation, that is, the number of seconds between intromissions – a biomarker of sexual drive/desire/libido.
7. *Intromission ratio (IR)*. The number of mounts with intromissions divided by the total number of mounts with and without intromission – a biomarker of erectile function/dysfunction.

There are no approved therapies for the treatment of rapid or premature ejaculation. Currently, the only available treatments for premature ejaculation are the off-label

use of selective serotonin transporter inhibitors (SSRI's) and tricyclic antidepressant drugs, and/or behavioral therapy. Behavioral counselling does provide short-term symptomatic relief for some patients; however, long-term relapse rates are high. The clinical efficacy of on-demand SSRI's is frequently debated and a more robust delay in ejaculatory latency is observed after daily dosing. SSRI's, such as paroxetine and sertraline, have been shown to increase ejaculatory latency in rodents on acute administration and greater increases in ejaculatory latency are observed after chronic dosing. However, the doses used are proportionately significantly higher than those approved in humans.

Penile Erection

Assessing penile erection in conscious animals is far more complex than behavioral copulatory studies and to date erection has been routinely assessed by quantification of intracavernosal pressure in terminally anesthetized animals following electrical stimulation of the nerves that innervate the penis, that is, pudendal, cavernosal, or dorsal penile nerves and by direct electrical stimulation of brain centers that control erection, for example, medial preoptic or paraventricular nuclei of the hypothalamus. In conscious animals, two techniques have been employed to assess erections, and these possess an advantage over anesthetized models in that ascending and descending neuronal pathways are left intact. Additionally, the animal can be studied in its home cage, which helps to avoid any secondary behavioral influences such as anxiety. The two main quantification techniques are:

1. *Observational quantification of the number of penile erections.* Seeing rodent erections directly is difficult, but generally erection is followed by distinct genital grooming which is easy to observe and count.
2. *Radiotelemetric recording of intracavernosal or intraspengiosal pressure (ICP or ISP) during penile erection.* Penile erection is a hemodynamic effect and the hardness is produced by large increases in cavernosal/spongiosum blood pressure within the constricted cavernosal bodies (**Figure 3**).

Once the method to quantify penile erection has been determined there are a number of experimental paradigms that can be used to initiate a sexual response. These can include the use of pharmacological agents and behavioral paradigms where the male rats are kept in isolation in the presence of a female partner whom he cannot access, that is, noncontact erection, and if ICP/ISP radiotelemetry is being used during copulation itself with a receptive female animal. During 'pharmacological agent-induced erections,' the test compound is administered to male rats in the absence of a female and the animal is monitored for erectile events over a period of time depending on the pharmacokinetic properties of the agent. Active agents in this test are mostly centrally acting (spinal and/or supraspinal), such as serotonin 5HT2C agonists (e.g., m-CPP), dopamine agonists, such as apomorphine, or melanocortin agonists, such as bremelanotide or MB243 ((2S)-N-[(1R)-2-[4-cyclohexyl-4-[[[(1,1-dimethylethyl)amino]carbonyl]-1-piperidinyl]-1-[(4-fluorophenyl)methyl]-2-oxoethyl]-4-methyl-2-piperazinecarboxamide). Care must be taken when performing these type of studies as handling rats or the presence of

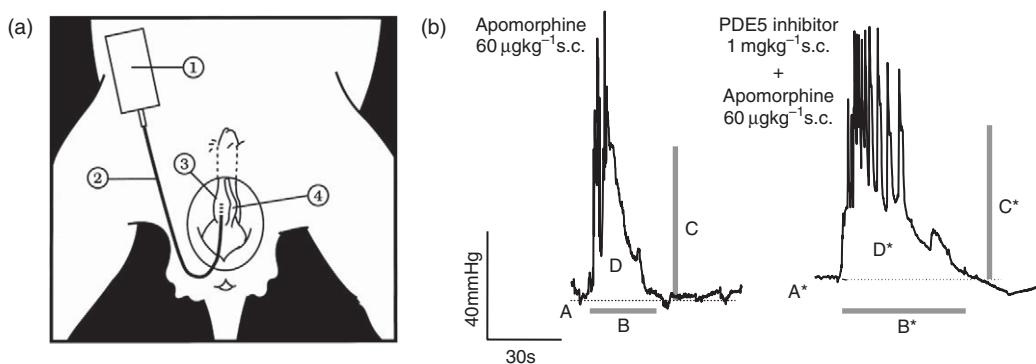

Figure 3 Radiotelemetric recording of rodent penile erection (a) implantation of radiotelemetry device and cannulation to cavernosal/spongiosal body. From Bernabé J, Rampil O, Sachs BD, and Giuliano F (1999) Intracavernous pressure during erection in rats: An integrative approach based on telemetric recording. *American Journal of Physiology* 276: R441–R449. Ventral view of rat pelvic area. Device (1) is subcutaneously located. Open-tip catheter (2) is inserted in corpus cavernosum (3). Dashed line in circled area is intracavernosal route of catheter. Corpus spongiosum (4) is laterally shifted to correctly expose corpus cavernosum during surgery. (b) Intracavernosal pressure (ICP) traces illustrating apomorphine-induced penile erection, in the presence and absence of a PDE5 inhibitor. Typical measurements include (A) basal ICP, (B) duration of erectile response (C) increase in ICP (a measure of erection hardness), and (D) area under ICP time response curve. In this study, apomorphine induced erectile responses, and the duration of the erectile response and the area under ICP curve were increased in the presence of a PDE5 inhibitor (B* and D*), while the amplitude and baseline ICPs were largely unaffected (A* and C*). There were no erectile responses following treatment with a PDE5 inhibition alone.

female odors can induce spontaneous erections. The disadvantage of this type of model is that the erection is directly induced by drug treatment. While this has a positive end result (erection), it is not linked to sexual motivation, which would certainly be preferred for treatment of human erectile disorders.

The ‘noncontact erection model’ uses a female stimulus animal to increase sexual arousal resulting in ‘natural’ erections. A male rat is placed in the presence of an estrous female rat in a cage or observation chamber divided into two halves. Direct physical contact is prevented by the partition wall. The Perspex or plastic/metal mesh dividing wall still allows the passage of auditory, visual, and olfactory cues and it is these that elicit a genital response from the male. The number of erections or changes in ICP/ISP can then be quantified over a set period of time.

A third method to induce erection in conscious animals is through tactile stimulation, and these erections are often referred to as ‘*ex copula* penile erections.’ The rat is restrained, lying on its back, and a tactile reflexive mechanism is triggered by making physical contact with the skin surrounding the penis. This response is believed to be under the influence of forebrain regions of the brain, and centrally acting agents, such as MB243, have been shown to enhance the number of excopula erections.

In the last 10 years, the treatment of impotence or ED has been revolutionized by the development and approval of selective PDE5 inhibitors, such as sildenafil, tadalafil, and vardenafil, and these agents have become the gold standard in ED therapy. Interestingly, PDE5 inhibitors have very little effect in normal conscious rats, and preclinically the effects can only be observed using anesthetized preparations, where ICP/ISP are assessed following nerve stimulation. This suggests that these agents are facilitators of erectogenic mechanisms, as clearly illustrated above, when a PDE5 inhibitor facilitated the proerectile effects of an inducer of erection, yet had no direct effect by itself (**Figure 3(b)**). Novel, centrally acting agents are currently being developed as future therapies for ED; and the conscious models described here may prove highly valuable in the

assessment of inducer mechanisms that initiate proerectile effects. Moreover, conscious animals are useful for the simultaneous determination of therapeutic windows between efficacious doses and centrally mediated side effects, for example, nausea/vomiting, hemodynamic effects, or sedation/somnolence or ataxia.

Glossary

Antidepressants – Drugs traditionally used for the clinical management of major depressive disorder and, increasingly, the anxiety disorders. These include first-generation compounds (monoamine oxidase inhibitors (MAOIs), tricyclic antidepressants (TCAs)) and second-generation compounds (serotonin-selective reuptake inhibitors (SSRIs), noradrenaline-selective reuptake inhibitors (NARIs), noradrenaline and serotonin reuptake inhibitors (NSRIs), reversible MAOIs, atypical antidepressants).

Anxiolytics – Drugs traditionally used for the clinical management of anxiety disorders, including the benzodiazepines, beta-blockers, and serotonin (5-HT)_{1A} receptor partial agonists (e.g., buspirone). The related term ‘anxiogenic’ refers to treatments that induce and/or increase anxiety.

Benzodiazepines – A group of drugs originally developed in the late 1950s and which work by facilitating the function of GABA_A receptors in brain. Benzodiazepines (such as Librium® and Valium®) have a limited therapeutic spectrum (primary clinical application in the treatment of generalized anxiety disorder) and a variety of acute and chronic side-effects.

Buspirone – A serotonin (5-HT)_{1A} receptor partial agonist, buspirone is the only truly novel anxiolytic drug to have received regulatory approval in the last 45 years and is believed to work by reducing 5-HT activity in the forebrain. Although equi-effective with benzodiazepines in clinical trials, buspirone is relatively ineffective in benzodiazepine-experienced patients and, like SSRIs, suffers a therapeutic delay.

Cognitive behavior therapy – Commonly known as CBT, this is a form of psychological therapy widely used in major depression and the anxiety disorders. It is based on the combined use of conditioning techniques to alter behavior and psychotherapeutic techniques to alter negative thinking. In clinical trials, CBT and drugs appear equi-effective although CBT has a better relapse profile. Combination treatments are increasingly being advocated in clinical practice.

DSM – The accepted abbreviation for the *Diagnostic and Statistical Manual of Mental Disorders*, published by the American Psychiatric Association, and now in its fourth and text-revised edition (i.e., DSM-IV-TR (2000)). Alongside ICD-10 (*International Classification of Diseases*, published by the World Health Organization

(WHO), DSM is the major diagnostic/classificatory source in modern psychiatry.

Endophenotype – Coined by Gottesman and Shields some 35 years ago, the term endophenotype refers to an internal, intermediate phenotype (e.g., neuroanatomical, neurophysiological, biochemical, perceptual, cognitive, motivational, and/or affective) that is not obvious to the unaided eye but which fills the gap in the causal chain between genes and distal diseases.

Panicolytics – Drugs used specifically for the treatment of panic disorder as distinct from other subtypes of clinical anxiety. These agents include the first- and second-generation antidepressants, a pharmacotherapeutic profile fundamental to the DSM-IIIR classification of panic as a clinical condition distinct from other anxiety disorders. The related term ‘panicogenic’ refers to treatments that induce/increase panic.

Over the past three quarters of a century, numerous animal tests have been developed to enable and facilitate preclinical research on anxiety and its treatment. These procedures typically involve the exposure of laboratory rodents to stimuli (threats) that provoke physiological and/or behavioral responses (defenses) similar, if not identical, to those seen in anxious or frightened humans. This strong cross-species correspondence in the overt expression of anxiety/fear not only provides high face validity for the animal tests but is also consistent with evidence that the neural circuits for detecting and responding to danger have been highly conserved in evolution. Although widely referred to animal ‘models’ of anxiety, it is important to note that this terminology is simply a convenient (although, as we shall see, misleading) shorthand. Quite apart from problems surrounding the implied unitary nature of anxiety, these tests are by definition limited to physiology and/or behavior and do not access the subjective experience of anxiety. The reader is therefore asked to bear in mind that, as commonly used, animal models of anxiety are really no such thing; rather, they are tests for anxiety-like physiological and/or behavioral responses in animals. Models are something altogether different. Despite this caveat, preclinical tests have been invaluable both in advancing our understanding of the basic neurobiology of anxiety and in laying the foundations for the treatment of its disorders.

Anxiety and its Disorders

Anxiety can be both normal and abnormal. Normal anxiety is adaptive insofar that it helps organisms to cope with a wide variety of threats using a range of stimulus- and context-specific defenses. Pathological or maladaptive forms of anxiety are defined as a marked, persistent, and excessive/unreasonable fear that is experienced to a degree that significantly impairs quality of life. Such disorders of anxiety are thought to reflect the exaggeration and/or inappropriate activation of normally adaptive defenses. It should therefore come as no surprise that the major diagnostic tools in psychiatry (e.g., DSM-IV-TR) recognize multiple disorders of anxiety including generalized anxiety disorder (GAD), panic disorder (PD), agoraphobia, posttraumatic stress disorder, obsessive-compulsive disorder, specific phobia, and social phobia.

Until quite recently, many of these illnesses have either been untreatable or treatable only by psychological techniques, for example, behavior therapy and cognitive behavior therapy (CBT). The historical exceptions to this rule have been GAD and PD, the former having been successfully treated since the late 1950s by benzodiazepines (e.g., Librium® and Valium®) and the latter since the 1980s by first- and then second-generation antidepressants (e.g., MAOIs, TCAs, and SSRIs). Indeed, this pharmacotherapeutic distinction formed a (if not the) core element of the case for the nosological separation of GAD and PD in earlier versions of DSM. More recently, however, things have begun to change. Stemming from clinical dissatisfaction with the acute (e.g., sedation and cognitive impairment) and chronic (e.g., tolerance and dependence) side-effects of benzodiazepines, the search for safe and effective alternate medications has led to identification of the broad-spectrum efficacy of SSRIs – not only in major depression and PD but also in other anxiety disorders such as GAD and social phobia. Indeed, with the exception of short-term crisis management (for which benzodiazepines are still recommended), these developments have culminated in the widespread acceptance of SSRIs as the first line treatment for virtually all anxiety disorders. As will become apparent, these advances present both a considerable challenge and a major opportunity to those engaged in preclinical research.

Animal Tests for Anxiety: Applications and Validation

Tests involving physiological and/or behavioral observations in animals have long been employed in the search for novel therapeutic agents (screening) and as a means to unravel the complex etiology and neural mechanisms of fear and anxiety (simulations). These applications are by no means mutually exclusive in that the same test may be

used for several purposes while advances in our basic understanding of the causes and mechanisms of anxiety disorders should, at least in principle, inform refinement of the basic screening tests. Over 30 animal tests for anxiety, mostly behavioral, have been developed since the invention of the classical open field and conditioned emotional response tests in the 1930s and 1940s. Before examining some of the procedures in some detail, it is pertinent to ask why they are generically referred to as tests for anxiety.

In contrast to tests that bear little or no resemblance to the condition in question ('predictive only' tests such as antagonism of drug-induced seizures), most behavioral tests for anxiety possess a reasonable degree of face validity. In other words, as already noted, the fear/anxiety responses displayed by rodents and other nonhuman mammals appear analogous with human reactions to similar circumstances. While analogy is by no means indicative of homology (i.e., common origin; construct validity), these tests share another common property – namely, sensitivity to established anxiolytics and, in particular, to benzodiazepines such as Librium® and Valium®. Historically, this criterion (known as predictive or pharmacological validity) has been the 'gold standard' in establishing the credentials of a given procedure as a test relevant to anxiety as opposed to depression or schizophrenia. However, there are several disadvantages in using this criterion or at least this criterion alone. First, there is the risk of simply rediscovering the wheel ('groundhog day'), that is, identifying me-same compounds as opposed to those with a truly novel mode of action. Second, there is very real possibility that benzodiazepine validation produces models not of anxiety-like responses but of benzodiazepine (or, more correctly, GABA_A receptor-related) psychopharmacology. For example, the test may just happen to induce/elicit a benzodiazepine-sensitive subtype of anxiety-like behavior or, worse still, some unrelated facet of behavior that just happens to be sensitive to drugs with this mechanism of action. Third, as traditionally employed, predictive validity is curiously retrospective in that it involves detection of compounds with already known clinical indications. Such pitfalls were recognized long after the introduction of most currently available tests, a chronology that undoubtedly goes some way toward explaining the relative insensitivity of these tests to more recently developed anxiolytics such as buspirone.

Animal Tests for Anxiety: Classification and Overview

The conventional grouping of animal tests for anxiety is into two broad categories involving either unconditioned or conditioned defense responses. For reference purposes,

Table 1 Defensive behaviors commonly displayed by mammals, including laboratory rodents

<i>Behavior</i>	<i>Brief description and eliciting stimuli/contexts</i>
Freeze	Sudden and complete cessation of all movement except respiration (e.g., pain)
Startle	A reflex twitch or jump (e.g., sudden noise or tactile stimulation)
Bury	Covering of noxious object with substrate (e.g., shock prod)
Flee	Running away from source of danger (e.g., approach by predator or aggressive conspecific)
Threat and attack	Rearing to face threat, vocalizing (sonic) jumping, and biting (e.g., cornered by predator or aggressive conspecific)
Tonic immobility	Death feigning: inhibition of all reactivity including pain (e.g., captured by predator or persistent conspecific attack)
Ultrasonic vocalization (USV)	Vocalizations in ultrasonic range for humans (18–25 kHz), for example, pain (adults), separation from mother (pups)
Thigmotaxis	Staying close to vertical surfaces (wall-hugging), for example, potentially dangerous (unfamiliar) environments
Risk assessment	Information-gathering (stretched attend postures), for example, potentially dangerous (unfamiliar) environments

Table 1 summarizes the most common defensive behaviors in mammals and the contexts in which they can most readily be observed, while **Tables 2 and 3** summarize many of the more widely used animal tests for anxiety. Irrespective of classification, all tests require careful attention to alternative explanations of treatment effects on the main dependent measures (i.e., the fear/anxiety responses). Control data (from within the same test or independent tests) are invariably necessary to rule out indirect drug effects mediated via changes in locomotor activity, motor coordination, pain sensitivity, hunger, thirst, learning and memory, and body temperature. Some of these controls (e.g., locomotion) are test-general while others (e.g., pain sensitivity and body temperature) are very much more test-specific.

Tests of Unconditioned Behavior

A wide variety of unconditioned behaviors (and a smaller number of unconditioned physiological responses) have been used as tests for anxiety (**Table 2**). These may be

grouped into six broad categories which, conveniently, divide equally into those involving response emission (aggression, antipredator behavior, and somatic stress responses) and those involving response suppression (consummatory, exploratory, and social behaviors). An anxiolytic-like response in the former is generally indicated by a reduction in the dependent measure/s and, in the latter, by a disinhibition of the dependent measure/s.

Aggressive Behavior

The earliest documented behavioral effect of the benzodiazepines was their ability to calm aggressive zoo animals. Unsurprisingly, therefore, inhibition of aggressive behavior has since been used by some to screen for anxiolytic-like activity in laboratory rodents. While there is little doubt that diverse anxiolytics can and do inhibit aggression (particularly its defensive forms), anti-aggressive activity is by no means limited to drugs of this type. Furthermore, paradoxical pro-aggressive effects have quite frequently been reported with benzodiazepines both in animals and humans. For these reasons, a

Table 2 Common animal tests for anxiety based on unconditioned responses

<i>Type of test</i>	<i>Examples</i>	<i>Typical anxiolytic-like response</i>
Aggressive behavior	Isolation-induced fighting	Reduction in offensive elements of the behavioral repertoire
Antipredator behavior	Fear (FDTB) and anxiety (ADTB) defense test batteries	Reductions in subcomponents of the defensive repertoire (defensive threat, biting, risk assessment) but not freezing or flight
Consummatory behavior	Food consumption in novel environments	Increased consumption of preferred food in novel (but not home) cage
Exploratory behavior	Open field test; elevated plus-maze; elevated zero-maze; light/dark exploration; free exploratory task	Increased exploration of potentially dangerous open/brightly lit areas of environment
Social behavior	Rat social interaction test; separation-induced ultrasonic vocalizations (USV)	Increased conspecific social interaction under brightly lit unfamiliar test conditions; reduction of separation USV
Somatic stress responses	Responses elicited by aversive stimulation: hypertension, hyperthermia, elevated plasma corticosterone, and USV	Reductions in all stress-elevated parameters

Table 3 Common animal tests for anxiety based on conditioned responses

Type of test	Examples	Typical anxiolytic-like response
Aversive brain stimulation	Electrical or chemical stimulation of the dorsal periaqueductal gray (dPAG)	Reduction of stimulation-produced defense responses (freezing or escape); elevation of stimulation thresholds for such responses
Conditioned taste aversion	Biologically prepared learning: avoidance of novel flavors as consequence of prior association with illness-inducing chemical (e.g., lithium)	Attenuation of the avoidance or aversion
Defensive burying	Biologically prepared learning: burying of noxious objects (e.g., shock prod)	Reduction in the burying response and disinhibition of approaches to noxious object
Drug discrimination	Two-choice lever task; animals trained to selectively respond to drug cue on one lever, saline on other	For animals trained on anxiolytic – generalization to drug lever; for animals trained on anxiogenic – suppression of responding on drug lever
Pavlovian (defensive) conditioning	Conditioned emotional response (CER); fear-potentiated startle (FPS)	Inhibition of freezing or exaggerated startle responses elicited by presentation of a cue previously paired with aversive footshock
Punishment procedures	Four-plates test; Geller-Seifter conflict; passive avoidance; Vogel conflict	Disinhibition of behavior (locomotion, lever-pressing, exploration, licking) suppressed by electric shock or cue previously paired with shock

reduction in aggressive behavior cannot be used as a definitive marker of anxiolytic activity.

Antipredator Behavior

Over the past 20 years, pioneering research on the anti-predator defenses of wild and laboratory rodents has culminated in the Fear/Defense Test Battery (FDTB) and the Anxiety/Defense Test Battery (ADTB). Each battery comprises a number of subtests designed to elicit in a controlled and predictable fashion specific components of the defensive repertoire. The FDTB elicits defensive responses (e.g., avoid, freeze, flee, defensive threat and attack) to explicit, proximal, imminent, and unambiguous threat stimuli, whereas the ADTB elicits defensive responses (hypervigilance and risk assessment) to potential, distal, and ambiguous threats. Anxiolytics (benzodiazepines and buspirone) consistently inhibit defensive threat and attack as well as risk assessment whereas, mimicking the clinical situation, panicolytics acutely enhance but chronically suppress flight responses. In each case, changes in defensive behavior can be differentiated from more general behavioral effects.

Consummatory Behavior

Alongside anti-aggressive activity, an enhancement of food (and fluid) intake was one of the earliest behavioral effects observed with benzodiazepines. Initially reported in rats and dogs, such effects have since been documented in species as diverse as pigeons and humans. Although hyponeophagia (an inhibition of novelty-suppressed food intake) is still used in some laboratories as a test of

anxiolytic-like activity, the fact that anxiolytics increase the consumption of familiar foods in sated animals tested in their home cages would suggest a direct stimulatory effect on appetite. Indeed, there exists a huge anxiety-independent literature on the effects of benzodiazepines and related GABA_A receptor compounds on appetite; interestingly, 5-HT_{1A} receptor agonists and partial agonists (e.g., buspirone) also potently stimulate food intake. Although some of these concerns can be addressed by contrasting treatment effects on food intake in novel and familiar surroundings, inhibition of the hyponeophagia response as a pure and simple index of anxiolytic-like activity is fraught with interpretative difficulties – a situation made worse by the fact that hyperphagia is also seen in response to antipsychotics and, in particular, atypical antipsychotics such as clozapine and olanzapine.

Exploratory Behavior

Tests of this type originated with the development of the open field test in the 1930s. Now including behaviorally very much more sophisticated procedures such as the elevated plus-maze, its derivatives (such as the elevated zero-maze) and the light/dark exploration paradigm, these tests are based on the natural tendency of rodents to avoid open and/or brightly lit environments. Placed directly into the test apparatus (i.e., forced exposure), the animal can choose to spend its time in relative safety (near the walls of the open field, in the closed arms of the plus-maze, or the dark compartment of the light/dark apparatus). Alternatively, it may explore potentially more dangerous areas of the apparatus (center of the open field, open arms of the plus-maze, light compartment of

the light/dark apparatus). Anxiolytics of many types (except buspirone and antidepressants) reduce avoidance of the danger areas in a behaviorally selective manner. As clear evidence of bidirectional sensitivity, many anxiogenics produce the opposite behavioral signature of enhanced avoidance. The more recent adoption of behavioral (ethological), as well as conventional spatio-temporal, measures has not only enhanced test sensitivity but, ethically, has also facilitated the detection of behavioral selectivity without recourse to separate control tests. Little wonder then that exploration-based paradigms are currently the most widely used (if not necessarily the most popular) of all animal tests of anxiety, for example, some 3000 papers on the plus-maze been published in less than 25 years.

Social Behavior

Although several variants exist, by far the most common version of this procedure is the rat social interaction test developed in the late 1970s. It is based on the observation that levels of active social interaction between pairs of male rats vary as a function of familiarity with the test partner and lighting levels in the test arena. Social interaction is lowest in the high light-unfamiliar test condition and, independent of effects on locomotor activity, anxiolytics disinhibit social behavior under such aversive test conditions. In contrast, anxiogenics inhibit the higher levels of social interaction obtained under less aversive (low light-familiar) test conditions. An alternative test of social interaction revolves around mother–infant interaction, has been used with mice, rats, and guinea pigs, and is based on the observation that young pups emit ultrasonic distress vocalizations (USVs) when separated from their mother/nest/littermates. Somewhat exceptionally among the multiple animal tests for anxiety, these USVs are suppressed not only by all classes of anxiolytic, but also by certain antidepressants. However, as separation-USVs are proximately caused by the drop in body temperature that accompanies removal from the nest and contact with cohabitants, controls for potential treatment effects on core body temperature *per se* are essential.

Somatic Stress Responses

Physical stressors (e.g., restraint or electric shock) and/or psychological stressors (e.g., social defeat) are widely known to elevate blood pressure, heart rate, body temperature, and plasma corticosterone levels. Although such effects are sensitive to anxiolytics of various classes, they are also reduced by other psychotropic drugs and cannot, by themselves, be used as reliable indicators of anxiety. The one probable exception is stress-induced hyperthermia, a test developed in mice and which appears to show good sensitivity both to conventional and novel

anxiolytics. However, since intrinsic hypothermic (as opposed to anxiolytic) effects could account for any reduction in stress-induced hyperthermia, controls for treatment-induced changes in core body temperature are once again obligatory.

Tests of Conditioned Behavior

Given its potency in eliciting defensive reactions, it is unsurprising that electric shock has figured so prominently in traditional procedures used to study learned fear and anxiety in laboratory rodents (**Table 3**). However, the precise reaction observed (e.g., flinch, startle, jump, or run) will depend upon specific features of the test situation, including shock parameters and size of the test apparatus. Indeed, the categorization of animal tests for anxiety into those involving either response suppression or response emission nicely reflects the basic nature of behavioral defense, that is, passive (e.g., freezing) versus active (e.g., flight or startle).

Aversive Brain Stimulation

Electrical or chemical stimulation of dorsal aspects of the periaqueductal gray matter (dPAG) of the midbrain elicits abrupt escape/flight reactions in rats and intense fear reactions in humans, both accompanied by strong autonomic activation. Unsurprisingly, therefore, strong parallels have been drawn between the effects of dPAG stimulation in rats and the symptoms of panic attack in humans. Pharmacologically, dPAG-induced flight is inhibited by panicolytic agents (e.g., SSRIs) and exacerbated by panicogenic agents (e.g., caffeine and yohimbine). However, it is curious that the inhibitory effects of antipanic drugs on flight are seen with acute administration, whereas, clinically, these agents are effective only after chronic treatment. In fact, acute SSRI treatment is frequently reported to intensify the symptoms of panic in patients. Furthermore, some panicogenic drugs actually inhibit flight (e.g., mCPP), while others (e.g., CCK-4) have little/no apparent effect. Nevertheless, as very few animal tests for anxiety purport to specifically address panic disorder, it would be foolish to exclude dPAG stimulation as a potentially useful procedure. Indeed, this test has very successfully been employed in delineating the midbrain neurochemistry and neural circuitry of defense.

Conditioned Taste Aversion

Rats are biologically predisposed (prepared) to more readily make certain associations than others. The earliest example of this biologically adaptive learning

phenomenon is referred to as conditioned taste aversion (CTA) whereby, on the basis of a single pairing, rats learn to avoid a novel taste (conditioned stimulus, CS) that has been followed by feelings of nausea (unconditioned stimulus, UCS). Numerous studies have shown that CTA can be blocked by a wide range of anxiolytics but not by non-anxiolytics. It has consequently been argued that CTA not only represents a more naturalistic version of traditional approach/avoid conflict (see below) but, since taste aversions are also common in humans, may also be a useful tool in translational research. However, there are some important constraints on this test. For example, a very wide range of drugs (paradoxically, including anxiolytics themselves) will support CTA when paired with novel flavors, begging the question as to exactly what is driving the learned response. Furthermore, as already noted, anxiolytics are renowned for their ability to increase fluid as well as food consumption. Therefore, in single-bottle tests, it could simply be the case that a suppression of CTA reflects a general dipsogenic (not anxiolytic) action of the drug. Although this difficulty can be circumvented using a two-bottle preference task (i.e., paired flavor vs. unpaired flavor), the effects of anxiolytics are not so clear-cut in this version of the test. Thus, despite strong claims for face, predictive, and construct validity, it would seem unwise to use CTA alone as a definitive screening test for anxiolytic-like activity.

Defensive Burying

Another rodent behavior that can be considered a biologically prepared form of learning is conditioned defensive burying, that is, the apparently natural tendency of rats, following initial contact with an aversive object, to bury that object using cage bedding or similar materials. Although the formal version of this test has been developed using a shock prod as the aversive object, identical behavior has been reported in response to sources of aversive air blasts, light flashes, and noxious odors. As for CTA, a single learning trial is sufficient for the emergence of the burying response. A large volume of empirical evidence indicates that conditioned defensive burying behavior in rats is rather selectively suppressed by anxiolytic agents, an action that cannot be alternatively explained in terms of motor impairment or analgesia. Understandably, ceiling effects render this test (and several other conditioned behavior tests) relatively unsuited to the study of anxiogenic manipulations, that is, it lacks bidirectional sensitivity. Overall, the defensive burying test is arguably more useful for research on the neural mechanisms of fear/anxiety than as a primary screen for anxiolytic drug action.

Drug Discrimination

Unlike other tests in this review, drug discrimination is not a test for anxiety *per se* but can legitimately be considered a test for the subjective effects of anxiolytic-like drugs. It rests on the fact that rats can be trained to discriminate the subjective (cue) effects of a training drug from those of placebo. This is typically achieved in a two-lever operant chamber where responding on one lever will only produce reward when the animal has been treated with drug while responding on the other lever will yield reward only under placebo. If rats have been trained to discriminate a chlordiazepoxide (i.e., Librium[®]) cue, then it would be expected that they would respond on the drug lever when tested with compounds producing the same subjective cue as the training drug, that is, varying degrees of cue generalization would be observed depending upon how closely the test drug resembled the training drug. In contrast, if rats have been trained to discriminate an anxiogenic cue (e.g., pentylenetetrazol, PTZ), then it would be expected that responding on the drug lever would be suppressed by an anxiolytic test drug, that is, antagonism of the PTZ cue. In both cases, behaviorally nonselective activity can be determined via monitoring treatment effects on responses on the placebo lever. Both sets of effect (i.e., generalization and antagonism) have been widely reported in the literature, but are largely limited to within-class comparisons (e.g., GABA_A receptor-related drugs). Nevertheless, recent research has confirmed the value of drug discrimination in differentiating compounds within a class, for example, drugs with selective actions on particular protein subunits (e.g., $\alpha 1$ vs. $\alpha 2/3/5$) of the GABA_A receptor complex. This is a significant development in view of genetic and pharmacological evidence for the involvement of $\alpha 1$ -subunits in the sedative effects of benzodiazepines and the $\alpha 2/3$ subunits in their anxiolytic actions.

Pavlovian (Defensive) Conditioning

An early version of this type of test was developed in the late 1930s from Pavlov's original research on defensive conditioning in dogs, and is generally known as the conditioned emotional response (CER) test. Sometimes also referred to as conditioned suppression, it is a simple form of associative learning in which rats are presented with an unavoidable electric shock (UCS) that is reliably preceded by a auditory or visual cue (CS). The subsequent presentation of the CS alone during a food-reinforced operant task suppresses lever pressing and this suppression is the CER. Despite continuing popularity with a number of research groups, the test is renowned for inconsistency. Other more recent versions of the test omit the operant component, relying instead on cue- or context-induced defensive freezing. Due to the relatively

unambiguous fear stimulus and response, cue- or context-induced freezing has been used with considerable success over the past two decades in delineating the neural and cellular mechanisms of fear learning and memory in laboratory rats. One particular variant of CER has, however, proven to be very useful both as a screening tool and as a means for exploring the neural basis of emotion. This test is widely known as fear-potentiated startle (FPS) and is based on the potentiation of the noise-induced startle reflex by a CS (light) that has previously been paired with aversive footshock. FPS, but not basal startle, is reliably blocked by conventional anxiolytic drugs and by buspirone but, like so many other tests, is relatively insensitive to antidepressants.

Punishment Procedures

These tests have in common the suppression of ongoing behavior by punishment. Passive avoidance is based on footshock-induced suppression of exploratory behavior but, due to the 24h interval between training and testing, is more useful in learning and memory research than as test for anxiety. The four-plate test involves the suppression of locomotor activity by electric footshock as subjects move from one quadrant of an metal-floored arena to another. Although several classes of anxiolytic are effective in increasing punished crossings, the test is still being validated as a screening test for anxiolytic-like activity. The more commonly employed Vogel conflict test uses water-deprived animals and is based upon the suppression of drinking by electric shock delivered via the spout of the water bottle. The Vogel test responds well to a broad range of anxiolytics and, with some modification of shock parameters and baselines, to anxiogenics. For obvious reasons, it is imperative to control for possible treatment effects on pain sensitivity. However, by far the most behaviorally and technically sophisticated of all punishment procedures is the ‘Geller–Seifter conflict test.’ Unlike the three other tests above, Geller conflict requires extensive training of the experimental animals prior to drug testing. This training involves food-deprived animals learning that lever pressing in the absence of a tone produces food reward (unpunished; CS⁻), whereas lever-pressing in the presence of a tone produces food reward plus electric footshock (punished; CS⁺). Trained to criterion, rats naturally suppress responding during CS⁺ periods. With the now almost inevitable exceptions of buspirone and antidepressants, anxiolytics release punished responding while a wide range of psychostimulants and analgesics are ineffective. However, as with any procedure based on food deprivation, electric shock and extensive training protocols, it is essential to control for possible treatment effects on primary motivation (in this case hunger and pain) and/or learning and memory processes. Furthermore, there is

very little evidence that animals well-trained in this protocol actually display any behavioral or physiological signs of fear/anxiety during CS⁺ presentation. Along with the extensive training involved, concerns such as these are undoubtedly responsible for the current unpopularity of Geller–Seifter conflict both as a screening test and a simulation.

Animal Tests for Anxiety: Relative Merits?

Aggressive behavior, comummatory behavior and certain somatic stress responses have quite limited value as animal tests for anxiety. Although conditioned taste aversion and drug discrimination procedures would also appear to have few merits in this specific context, such tests are not completely irrelevant to the understanding of anxiety and its treatment. For instance, major differences in the interoceptive cues provided by benzodiazepines and 5-HT_{1A} receptor partial agonists help to inform our understanding of patient noncompliance when switched from diazepam to buspirone. Nevertheless, such tests are demonstrably less relevant than others as tests for anxiety. On present analysis, the procedures that fare best in this regard are the unconditioned tests involving antipredator, exploratory and social behavior, and the conditioned tests based on aversive brain stimulation, defensive burying, CER, and punishment.

There is little to choose among the three most preferred categories of unconditioned test. All have equivalent face and predictive validity, and each involves comparable time and effort in data collection/analysis. Nevertheless, it is worth noting that, of all of these tests for anxiety, the elevated plus-maze and social interaction tests have been by far the most thoroughly validated (pharmacologically, physiologically, and behaviorally). Although the four categories of conditioned test are also reasonably equivalent in terms of face and predictive validity, several require extensive training and/or surgical preparation of the animals (e.g., FPS, Geller conflict, defensive burying, and aversive brain stimulation) and, as such, would not normally be considered frontline screening tests. In contrast, CER and Vogel conflict are much more user-friendly.

Traditional comparisons between tests of conditioned and unconditioned fear/anxiety behavior hold that the former permit much greater experimenter control over behavioral baselines and, through within-subject designs, the use of fewer animals. On the downside, and as already noted, they normally require considerable time for the training of subjects, necessitate food or water deprivation and/or use electric shock. Extensive control tests are therefore needed to negate the possibility that treatment effects on the measure of interest are merely secondary to alterations primary motivation (hunger, thirst, and pain) and/or learning and memory processes. By comparison,

Table 4 Some of variables affecting rodent performance in the elevated plus-maze and other tests of exploratory behavior

Species, strain, age, gender, and estrus
Housing conditions and light cycle
Prior handling and injection experience
Prior stress
Prior test experience (same or different test)
Adaptation to test laboratory
Time of testing and lighting level
Presence of experimenter in test room
Maze construction (e.g., opaque/transparent walls, open arm ledges)
Method of scoring (e.g., live, manual/automated, videotape/DVD)
Measures scored: conventional; ethological
Definition and validation of measures

Modified with permission from Rodgers RJ (1997) Animal models of 'anxiety': Where next? *Behavioural Pharmacology* 8: 477–496 and Carobrez AP and Bertoglio LJ (2005) Ethological and temporal analyses of anxiety-like behavior: The elevated plus-maze model 20 years on. *Neuroscience and Biobehavioral Reviews* 29: 1193–1205.

tests involving unconditioned behavior generally have a higher degree of ecological validity, are much less susceptible to confounds arising from interference with learning/memory, hunger/thirst, or nociception, and allow for the truly comprehensive 'behavioral profiling' of experimental interventions (i.e., a multivariate as opposed to univariate approach). On the debit side of the balance sheet, however, these procedures are notoriously more susceptible to variable baselines arising from a greater sensitivity to factors associated with the experimental animals, holding conditions and/or test procedures (**Table 4**).

In short, all tests for anxiety have advantages and disadvantages and, as such, no single procedure is better than any other as a screening tool or a simulation. The current domination of the literature by unconditioned tests (such as the plus-maze) undoubtedly owes more to practical than to theoretical considerations, that is, simplicity, economy, rapidity, and bidirectionality coupled with the absence of extensive training, food/water deprivation, and/or pain. The conclusion that no one test is objectively superior to any other should convince of the need for a broad-based multitest strategy incorporating both conditioned and unconditioned procedures. However, given the often profound influence of prior test experience on behavioral baselines and anxiolytic pharmacology, the advised multitest strategy should ideally not take the form of sequential testing of the same animals in a test battery. This advice is most apposite for those using animal behavior tests in drug discovery programs.

to their therapeutic benefits, these drugs had unwanted effects as well as a limited therapeutic spectrum. This realization in turn stimulated the search for novel molecular targets of relevance to anxiety and its treatment. In recent years, however, many authors (and CEOs of pharmaceutical companies) have commented ruefully upon the dearth of truly novel psychotherapeutic drugs to have emerged since the psychopharmacology revolution of the 1960s. Indeed, buspirone is the only really 'new mechanism' anxiolytic to have been marketed as such since the discovery of the benzodiazepines. Although many factors are at play, serious inadequacies in preclinical screening tests is chief among the suspected culprits for such lack of progress. The argument runs that were these tests actually 'fit for purpose' then many more novel anxiolytics would by now have made it from the laboratory, through clinical trials, and onto the market. This is not to say that preclinical tests have failed to identify potentially useful targets/agents but rather that these compounds have frequently failed to convince in human trials while (at least at the time of writing) none has gained regulatory approval. This profile indicates that, as used, existing animal tests for anxiety are prone to false positives. Unfortunately, as implied by their failure to detect the anxiolytic potential of buspirone and to display sensitivity to first- or second-generation antidepressants, these tests are also prone to false negatives. This particular form of 'bidirectionality' really does appear to be a most serious indictment of current methods.

Herein lies something of a paradox, in that the obvious shortcomings of animal tests as screening tools stand in marked contrast to their successes as simulations in helping to illuminate the basic neurobiology of emotion. Thus, over precisely the same timeframe (past 25 years), there has been truly astonishing progress in our

Animal Tests versus Animal Models

The introduction of benzodiazepines almost 50 years ago revolutionized the treatment of anxiety disorders. However, it gradually became apparent that, in addition

understanding of the neural circuitry of fear and anxiety as well as the diverse gene products (precursors, enzymes, transmitters, modulators, hormones, receptors, transporters, second messengers, etc.) via which such mechanisms function. This difference in pure versus applied progress emphasizes the substantial conceptual and practical differences between ‘animal tests’ on the one hand and ‘animal models’ on the other. Namely, the vast majority of currently available animal tests for anxiety are based upon quite normal behavioral responses to threat and not (at least not usually or indeed knowingly) upon some pathology or abnormality of these highly adaptive defense mechanisms. Our present understanding is of the former and not necessarily the latter, a situation that has arisen quite logically as a consequence of researching the perfectly normal defensive reactions of normal animals to various threats. However, clinical anxiety disorders are characterized as an exaggeration of normal reactions and/or their display in inappropriate circumstances (contexts). Thus, in anxiety patients, there may well be nothing fundamentally awry with the basic response systems (effector mechanisms) but rather with the upstream mechanisms of perception and appraisal, that is, those mechanisms responsible for the detection and evaluation of stimulus input and triggering the appropriate defense response. Referring to the benzodiazepine gold standard in test validation, the late Richard Lister remarked that “pharmacological validity alone does not make a test a model of anxiety” (1991, p.323). Despite extensive repetition over the past quarter century, we have yet to fully appreciate the implications of this insightful remark – tests for normal fear reactions are not models of fear psychopathology.

For many years, psychological research on anxiety and mood disorders has emphasized the importance of cognitive biases, for example, the tendency of anxiety patients to interpret even neutral stimuli as threatening/potentially threatening. A considerable body of literature now suggests that these cognitive biases operate below the level of conscious awareness and have their origins in genetic predisposition, epigenetics, or adverse life experience. In view of major recent advances in our understanding of gene–environment interactions, it will not be too long before the cognitive biases typical of, for example, generalized anxiety disorder are linked to the early adverse experiences of individuals with a specific version (polymorphism) of this or that gene. These fresh insights into etiology, which are already emerging in the literature (e.g., the importance of serotonin transporter (5-HTT) polymorphisms in coping with stress), should help create the necessary mindset change in those currently using animal screening tests. In essence, the problem with our existing animal tests is not so much with the tests themselves as it is with how they are used. If real

progress is to be made, this crucial point must be fully taken on board by those managing drug discovery programs.

Toward Viable Animal Models of Anxiety Disorder

Elsewhere in biomedical research, the term ‘model’ is used with reference to the induction in animals of a condition/state closely resembling a specific human disorder, for example, hypertension, stroke, and epilepsy. What is therefore required in anxiety research is a means (or several means) of ‘creating’ emotional reactivity outside the normal range that is, hyperanxiety profiles. Such profiles, whether due to genetic, environmental, or interactive factors, could then legitimately be referred to as animal models of abnormal anxiety. In terms of genetic models of high anxiety, there are numerous potentially useful rat lines (Maudsley reactive reactive and nonreactive; Roman high and low avoidance; Flinders sensitive and insensitive; high anxiety HAB and low anxiety LAB) and inbred mouse strains (high anxiety BALB/c and DBA/2 vs. low anxiety C57BL/6J). Furthermore, the vast majority of genetically engineered mice that have been phenotyped for anxiety-like behavior have been found to display high anxiety phenotypes relative to wild-type controls (e.g., 5-HT_{1A} and CRF2 receptor null mutants). On the other hand, considerable evidence has accumulated concerning enhanced adult levels of anxiety in animals that have experienced early-life maternal separation/neglect or, alternatively, some form of physical/ psychological trauma in adolescence or early adulthood. Unsurprisingly, perhaps, some genetic strains are already known to be more sensitive (susceptible) than others to such negative life experiences.

In essence, therefore, the model of anxiety disorder is the ‘susceptible’ animal, while the test for anxiety is essentially the means via which the anxiety-relevant response is elicited and quantified. Defined in this manner, models are clearly theory driven and, with their stronger etiological basis, have considerable merit in the context of contemporary translational research. These tools will be all the more convincing (certainly as models of trait as opposed to state anxiety) if they can be shown to display abnormally intense reactions to a range of (but perhaps not all) threatening stimuli/situations. This specific wording is not just insurance against the occasional awkward finding, but rather an awareness that the awkward finding (the exception) itself may provide much-needed clues as to the model’s relevance for a specific human anxiety disorder.

Table 5 Cardinal symptoms/endophenotypes of human anxiety disorders, possible animal analogues/homologs, and relevant animal tests

<i>Human symptom/endophenotype</i>	<i>Animal analog/homolog</i>	<i>Animal test</i>
Avoidance of potentially dangerous environments (generalized anxiety disorder)	Increased avoidance of exposed, well-lit areas	Exploration-based tests (e.g., open field; plus-maze; light/dark exploration)
Anxiety provoked by social situations (social phobia)	Low social interaction with unfamiliar nonaggressive conspecific	Rat social interaction test
Sudden and intense fear, leading to avoidance (panic attack)	Increased flight from predator	Rat or mouse fear defense test battery
Anxiety provoked by specific feared object (specific phobia)	Rapidly acquired avoidance of novel stimulus associated with pain or discomfort	Conditioned taste aversion (CTA)
Re-experiencing traumatic event leading to enhanced arousal and avoidance (posttraumatic stress disorder)	Increased freezing to fear-conditioned cue or context	Conditioned emotional response (CER)
Flashbacks of traumatic events (posttraumatic stress disorder)	Impairment in extinction of fear memory	CER extinction paradigm
Distress caused by separation from object of attachment (separation anxiety)	Ultrasonic vocalizations (USVs)	Maternal separation-induced distress USV in pups
Cognitive bias to weak/ambiguous threat cues	Increased fear conditioning to partial threat cue	Cue variation in CER
Heightened startle response in unfamiliar settings	Basal and potentiated startle	Fear-potentiated startle (FPS)

Models, Tests, and Endophenotypes

If, as strongly suspected, specific human anxiety disorders reflect dysfunction in different defensive subsystems, it follows that the validity and reliability of our animal tests will depend rather critically upon test selection and, in particular, the precise nature of the associated defensive reaction/s (see **Table 1**). As of now, those working in preclinical research are unanimous in accepting the sheer impracticality (never mind illogicality) of attempting to develop rodent tests that will feature all symptoms (i.e., the entire ‘syndrome’) of a particular human mental disorder. Mirroring pioneering animal research in the area of depression, which has concentrated upon tests of one or two cardinal features of the disorder (e.g., anhedonia, behavioral despair), several authors have more recently argued for adoption of a similar endophenotype-based approach to animal studies on anxiety. As originally conceived by Gottesman and Shields in the 1970s, an endophenotype is an internal phenotype (e.g., neuroanatomical, neurophysiological, biochemical, perceptual, cognitive, motivational, and/or affective) that is itself not obvious to the naked eye but which is manifest in certain response tendencies or biases.

Table 5 (with due deference to John Cryan and Andrew Holmes) exemplifies some cardinal features/endophenotypes of human anxiety disorders and suggests which animal defensive behaviors and tests may be most relevant to these endophenotypes. Combining this much more realistic approach to phenotyping with an understanding that

the model is the (genetically, epigenetically, and/or environmentally) altered animal while the test is a device to elicit and measure behavior comes close to a much-needed and long overdue paradigm shift in the preclinical pharmacology of anxiety. In view of emerging ideas concerning the close relationship between anxiety disorders and major depressive disorder, such an approach to animal modeling may help explain some long-standing conundrums. Not least the question as to why animal tests for normal anxiety, while exquisitely sensitive to benzodiazepines (and a very large number of other pharmacological and genetic manipulations) are so recalcitrant when it comes to 5-HT_{1A} receptor partial agonists and SSRIs.

Glossary

Attention-deficit hyperactivity disorder (ADHD) – A developmental, behavioral disorder which comprises three main symptoms: inattention, hyperactivity, and impulsiveness. The basis for clinical diagnosis is typically guided by the fourth edition of the *Diagnostic and statistical manual of mental disorders* (DSM-IV) or the *International statistical classification of diseases and related health problems – 10th revision* (ICD-10). Although estimates vary, ADHD is thought to affect 3–5% of children under age seven. ADHD is less prevalent, in adulthood.

Covert attention – Refers to the ability to focus and cognitively process information of a particular perceptual feature and/or a particular spatial location without directing or orienting the sense organs to the source. It can be contrasted with overt attention in which the sense organs are reoriented. Covert and overt attention may be either reflexive or voluntary.

Divided attention – Refers to the ability to process and/or perform multiple perceptual and/or cognitive operations simultaneously.

Selective attention (also referred to as focused attention) – Refers to the ability to focus cognitive processing resources on a subset of available sensory and/or cognitive information, to the exclusion of other, potentially competing information.

Stop-signal reaction time (SSRT) – The principal measure of impulsivity in the stop-signal reaction time task which assesses the ability to cancel or stop a prepotent response already initiated and being executed. SSRT is defined as the latency to successfully stop, or complete the cancellation of, an ongoing response. As there is no clearly observable behavioral endpoint for the response inhibition process, SSRT cannot be measured directly and must be inferred or estimated from SSRT task data. In 1984, Logan and Cohen proposed a quantitative method for computing SSRT based on a horse race model in which it is assumed that constant-duration ‘stop’ and ‘go’ processes compete independently to determine the outcome of a given trial on the SSRT task.

Sustained attention (also referred to as vigilance) – Refers to the ability to maintain or continuously monitor perceptual and/or cognitive processing over a period of time. Vigilance may be subtly distinguished from sustained attention and is traditionally defined more

specifically as a state of readiness to detect and respond to unpredictable, rare events.

Temporal discounting (also referred to as delay discounting) – Refers to phenomena in which the effect of reinforcement, or subjective value of the reinforcer, tends to decline as a function of the delay to reinforcer availability. Typical functions used to model discounting behavior are exponential curves – in which the effect of reinforcement or subjective value declines by a fixed amount per unit time – or hyperbolic curves – in which the value of reinforcement or subjective value declines inversely proportional to delay. In hyperbolic discounting models, under certain parameters, a striking reversal in preference is predicted whereby preference shifts from a larger, delayed reinforcer to a smaller, more immediate reinforcer as the choice draws near.

Animal Models of Attention

Varieties of Attention

In a general sense, the term ‘attention’ refers to an enhancement in focus or limiting selection of sensory and/or cognitive processing, in spite of potential competing distractions, over a period of time. However, there is great diversity in opinion over issues such as attentional capacity (e.g., number of items, spatial size, or resolution), timescale (e.g., milliseconds to hours or longer), global and/or domain-specific attentional processing for different types of information (e.g., attending to a particular sensory input dimension Vs. attention during learning or performance output of a motor skill), and whether attention in these different contexts is implemented by distinct or overlapping psychological and neural mechanisms. Indeed, it has long been hypothesized that attention does not represent a single, unitary entity but is rather a concept which encompasses a variety of psychological processes. While many such hypothetical attentional processes have been developed primarily in conceptual terms, recent research is beginning to illuminate potential subdivisions of attentional processes based on neurobiological correlates and mechanisms. However, as yet, no universally accepted definition or taxonomy of attention has been achieved.

Despite the lack of definitional consensus, certain major categories of attention (e.g., selective, divided or sustained attention) have been identified which may represent somewhat independent processes. Moreover, it is clear that such attentional processes encompass and interact importantly with a number of cognitive and behavioral functions including learning and memory, executive control, decision-making, and consciousness. Disturbances in attentional processes are thought to underlie some of the dysfunctional symptoms associated with many neuropsychiatric disorders such as anxiety, depression, schizophrenia, Alzheimer's disease, and attention-deficit hyperactivity disorder (ADHD). Thus, the development and validation of animal models of attention could serve to enhance the characterization of neurobiological mechanisms of normal and disrupted attentional processing, and to facilitate the testing and development of therapeutic interventions. A variety of behavioral paradigms have been proposed to assess certain aspects of attention in nonhuman animals. These paradigms will be surveyed in the context of the broad categories of selective, divided, and sustained attention, with particular emphasis on the procedures most widely used, and which attempt clear, comparative links to attentional tasks in humans.

Experimental Paradigms

Selective attention

1. *Orienting*. The manner in which certain locations or objects are given priority over others epitomizes selectivity in processing of the visual environment, and is typically thought to engage attentional orienting processes. Such spatial selectivity may recruit a shift of the eyes and/or head to place the region of interest onto the foveal visual field (overt orienting), or may alter internal processing resources in the absence of changes in gaze direction (covert orienting). Whether orienting is overt or covert, its control may be further classified as being directed voluntarily (endogenous orienting) or reflexively by external stimuli (exogenous orienting).

A well-established paradigm for measuring visuospatial attention is the cued-target detection (CTD) task first developed for use in human subjects by Posner and colleagues. The main procedure requires that a subject fixate on a central point and produce a speeded motor response upon detection of a stimulus presented briefly within the periphery of the fixated visual field. An 'informative' cue to the location of the imminent target stimulus is typically presented 100–1000 ms preceding the onset of the stimulus and is presented either within the central visual field (endogenous cues – generally thought to promote endogenous orienting) or in the periphery (exogenous cues – generally thought to promote

exogenous orienting). The primary outcome variables of the CTD task are accuracy in visual localization or discrimination, and reaction time (RT) to respond. Cues that correctly predict the location of the target ('valid' cues) typically increase performance accuracy and decrease RT, whereas cues that predict an opposite location ('invalid' cues) decrease accuracy and increase RT – the difference in performance between valid and invalid trials is known as the 'validity effect'. Neutral cues, which precede the target but provide no information about its imminent location, may also decrease RT by generally preparing the subject for the target ('alerting effect') as compared to control trials in which no cue is presented.

The CTD paradigm has been adapted to examine attentional orienting across various species such as primates, pigeons, and rats. In procedural tests of covert orienting, rhesus macaques appear to consistently demonstrate validity effects in their attentional shifts to peripheral target stimuli in response to both exogenous and endogenous cues. However, compared with human subjects, rhesus monkeys typically show faster RTs, smaller validity effects that decline more rapidly, and are considerably less sensitive to changes in the probability of valid cues (in humans, the ratio of presented valid to invalid cued targets influences the magnitude of the validity effect), which may suggest some differences in the cognitive processes used by the two species within the paradigm. Nonetheless, several brain regions have been related to task performance in the primate that correspond well with data from human functional imaging and from brain-damaged individuals: the frontal eye fields and midbrain superior colliculus have been implicated in both overt visual saccades and covert attentional shifts, the lateral pulvinar of the thalamus has been implicated in attentional engagement at a new locus, and the posterior parietal cortex has been implicated in disengagement of attention.

Furthermore, investigations into the psychopharmacology of covert orienting indicates similar effects of certain neurotransmitter systems on task performance between primates and humans. For instance, lesions of the basal forebrain nuclei in monkeys, causing 20–70% reductions in choline acetyltransferase (ChAT) activity within several cortical areas, slows RTs to invalidly cued targets (with only moderate slowing of RTs to validly cued targets). This pattern of results is similar to that seen when rhesus monkey or human subjects are systemically administered the muscarinic antagonist, scopolamine (exhibiting slowed RTs for both valid and invalid cues while not affecting RTs in no-cue trials), or in patients with Alzheimer's dementia who have reduced cholinergic innervation of the cerebral cortices. These results may reflect impaired disengagement of attention from an invalidly cued location. Conversely, systemic administration of the cholinergic agonist, nicotine, in monkeys or

humans tends to speed RTs following invalid cues as compared to valid cues, resulting in a reduced validity effect. Manipulations of acetylcholine (ACh) do not greatly affect the alerting effect. The opposite pattern of results for validity and alerting effects appears to hold for norepinephrine (NE) or dopamine (DA). Low, nonsedative doses of clonidine or guanfacine, alpha-2 receptor agonists which act to reduce NE release, significantly reduce the alerting effect by selectively increasing RTs on double, neutral-cue trials relative to no-cue trials in both primates and humans. Antagonists of alpha-2 adrenoceptors, such as yohimbine or idazoxan, block these reductions in the alerting effect caused by clonidine. The D2 receptor antagonist, droperidol, also reduces the alerting effect in primates but appears to do so by selectively increasing RTs on no cue trials, with little to no effect on double, neutral cue trials. Taken together, converging results from both humans and primates strongly suggest a dissociation between CTD performance based on neurotransmitter function: the cholinergic system influences selective attentional orienting in space, but not alerting, while catecholamines alter alerting but not orienting.

Attempts to model orienting attention in the rat include: a two-choice lever task in which rats (located centrally within a central food well at the start of each trial) press the appropriate lever in response to brief visual targets located above them, preceded by an informative peripheral visual or auditory cue; and a task in nine-hole boxes in which rats withdraw their nose from a central hole and nose poke into an adjacent hole in response to a brief visual target, preceded by a informative peripheral visual cue. There are differences in performance between the rodent and human paradigms: in rats, cues appear to exert effects on target detection for a longer period than in primates or humans, and cues do not change their effect on target detection as a function of the probability of cue validity as observed in human subjects. Furthermore, rats are afoveate and their eye movements are neither monitored nor controlled, which complicate interpretations based on covert attention. However, studies using both rodent CTD task versions have demonstrated validity and alerting effects on response accuracy and RT, where the lever-based task in particular has included several parametric controls such as target salience, probability of target location, inclusion of neutral cue and no cue trials, and varying the probability of cue validity. Such controls suggest that task performance cannot simply be explained by nonattentive mechanisms such as stimulus additivity or response preparation, and thus reinforce explanations based on shifts of selective attention. Moreover, bilateral infusions of a selective cholinergic immunotoxin, 192 IgG-saporin, into the substantia innominata of rats, which causes substantial loss of cholinergic input to the cortex, results in decreased accuracy and RTs to an

invalidly cued target (but not on valid or no cue trials, e.g., not an alerting effect) compared with controls. Pharmacological manipulations within the rat CTD task are relatively few and are difficult to reconcile with data from humans: systemic injections of nicotine or haloperidol produce no significant changes in accuracy or latency, while scopolamine and clonidine reduce both response accuracy and increase RT.

2. Stimulus features and associative learning In addition to paradigms in which cues are presented prior to stimuli in order to attract or orient attention, there are paradigms in which attention is summoned or captured by the properties of stimuli themselves (e.g., brightness, shape, etc.) and their relation to outcome contingencies. Two prominent examples of such paradigms are latent inhibition and intradimensional/extradimensional (ID/ED) set-shifting.

Latent inhibition (LI) refers to the observation that nonreinforced presentations of a particular stimulus renders that stimulus less effective, as compared with a novel one, to subsequent associative conditioning. A typical LI procedure in animals includes three phases: a first phase in which an animal learns, or spontaneously performs, behaviors with a relatively high rate of occurrence (e.g., exploratory locomotion or lever pressing on a VI schedule for food or water) – it is during this first phase in which the to-be-conditioned stimulus (CS, e.g., tone or light) can be repeatedly pre-exposed; a second phase in which a Pavlovian conditioning procedure is employed in which the CS is paired with an unconditioned stimulus (US, e.g., shock); and a third phase in which the animal is re-exposed to the conditions of the first phase and, whilst the animal is behaving, the CS is presented. The extent of CS-US conditioning is assessed by the impact of CS presentation on ongoing behavior in the third phase. The typical LI effect is that animals pre-exposed to the CS tend to show reduced conditioning as compared to those not pre-exposed. Disruptions in LI are thus observed as exhibiting an enhancement in conditioning effects, which is convenient toward ruling out several types of nonspecific deficits in performance.

LI has been observed across a wide variety of behavioral paradigms and in many different species. One major proposed interpretation of LI is that it results from a stimulus-specific decline of attention as a function of repeated irrelevant CS pre-exposure, which reduces the subsequent associability of that CS. Based on such an interpretation, LI has been proposed as a model for attentional dysfunction in schizophrenia, that is, disruptions in LI represent a deficit in the ability to selectively screen out irrelevant stimuli (cf., to the pre-exposed CS). Patients with schizophrenia show disruptions in LI, which tend to be ameliorated by treatment with D2 dopamine receptor antagonists (e.g., neuroleptics). Correspondingly, dopamine receptor agonists that produce psychotic-like effects in humans produce

disruptions in LI in animals, which can be counteracted by administration of neuroleptics (which, in rats, also produce an increase in LI performance) at clinically relevant doses. It should be noted, however, that there is considerable theoretical debate over the attentional interpretation of LI, and it has proven difficult to distinguish this from other associative or learning explanations. Further research is needed to attribute LI more definitively with processes of selective attention.

The ID/ED set-shifting task is based on the premise that control over selective attention is required to optimize performance when different stimulus dimensions are specifically reinforced. In a typical ID/ED set-shifting task, a subject is presented with a series of compound stimuli comprised of several dimensions and is trained to discriminate between attributes which vary along one stimulus dimension (e.g., color or shape). It is believed that an attentional set is formed, rather than simple responding to alterations in different attribute reward contingencies, which can be illuminated by the subject's performance when confronted with discriminations involving novel compound stimuli. If the subject learns more readily to discriminate attributes within a previously reinforced dimension (ID shift) when that dimension remains reinforced as compared to discriminating attributes along a new dimension when a different stimulus dimension is reinforced (ED shift), it is concluded that the subject is selectively attending to the relevant stimulus dimension.

Variants of the ID/ED set-shifting task have been devised for primates, pigeons and rodents. In terms of translation, the ED shift is a main component of the Wisconsin Card Sorting Test, which has proven sensitive (ED shift disruptions) for patients with frontal lobe dysfunction as well as patients with psychiatric conditions such as autism, obsessive-compulsive disorder and schizophrenia. Correspondingly, it has been demonstrated that attentional set shifts require the dorsolateral prefrontal cortex of monkeys and the medial frontal cortex in rats. ED shifting appears to be differentially sensitive to selective lesions of cholinergic and dopaminergic projections to the prefrontal cortex in the marmoset. In rats, noradrenergic (NA), but not cholinergic, deafferentation produces attentional set-shifting impairments while leaving the ability to ignore irrelevant stimuli intact, suggesting that the attentional deficit results from an overly focused attentional state that retards learning when a new stimulus dimension becomes reinforced.

3. Prepulse inhibition. A widely-used model of preattentive or automatic processing is prepulse inhibition (PPI) of the acoustic startle response. The acoustic startle response is a widespread, reflexive muscular contraction in reaction to a sudden, loud auditory stimulus. PPI refers to the phenomenon in which a weaker (nonstartling) prestimulus (prepulse), presented 30–200 ms prior to a

startling stimulus, reduces the magnitude of the startle response. The prepulse is usually acoustic, but visual or tactile stimuli are also effective. Decreases in prepulse inhibition are typically ascribed to abnormalities in sensorimotor gating, interpreted as an inability to filter out unnecessary information. PPI may thus represent an automatic mechanism of selective attention which regulates reflexive responsiveness and may be most closely akin to concepts of alerting attention or motor readiness.

PPI has been observed in numerous species ranging from mice to humans. Reductions in PPI have been noted in patients suffering from psychiatric disorders such as schizophrenia or Alzheimer's disease, and in people subject to brain injury or surgical manipulation. Due to its ease of implementation, precision in the control of task parameters, and robustness and reliability of the response, PPI is a useful paradigm for probing the neurobiology and genetics of gating deficits in these disorders.

There is an extensive literature examining the neural and pharmacological bases of PPI. One obvious mediating factor is sensory threshold (animals that cannot detect the prepulse will not exhibit PPI). Beyond sensory threshold, both the acoustic startle reflex and PPI appear to be mediated by inputs to brainstem nuclei: particularly the ventral cochlear nucleus and nucleus reticularis pontis caudalis. The fact that PPI remains intact after acute trans-collicular decerebration in the rat suggests that the expression of acoustic PPI does not require the forebrain. However, PPI has also been observed to be modulated by various brain structures such as the hippocampus, ventral striatum, and medial prefrontal cortex (mPFC) across many different species. Moreover, infusions of D1/D2 dopamine receptor agonists such as apomorphine tend to disrupt PPI, and these disruptions can be remediated by a number of antipsychotic agents to an extent significantly correlated with their clinical potency.

Divided attention

It is generally assumed that organisms are limited both in their ability to monitor a number of simultaneous sensory inputs, as well as in their ability to perform concurrent responses (e.g., dual-task performance). Thus, the concept of divided attention suggests that rapid switches in attention between input or output channels are necessary to effectively deal with multiple, simultaneous demands. In humans, neuro-imaging studies of divided attention of bimodal sensory information have implicated recruitment of the middle-dorsolateral prefrontal cortex. These activations are distinct from those required for selective attention toward only one of the presented sensory inputs, which is achieved primarily via modulation of the sensory cortices. There have been several paradigms devised to measure divided attention in experimental animals. In one task, Robbins and colleagues devised a method analogous to a paradigm developed for human subjects where

rats were required to monitor and discriminate between two simultaneous, laterally presented, visual stimuli and respond specifically to the stimulus which terminates first. By manipulating the difference in the termination times, a minimum switching time could be inferred. Systemic administration of d-amphetamine produced a dose-dependent reduction in choice accuracy, which was blocked by depletion of dopamine in the nucleus accumbens. In another task, rats were trained to respond on one of two levers under a random ratio schedule of food reinforcement – the correct lever was redetermined before each response and was signaled by a light. Systemic d-amphetamine increased the proportion of responses made on the correct lever at low and intermediate doses, but reduced the proportion at a higher 3.2 mg kg^{-1} dose. A third protocol demanded that rats make a temporal discrimination of stimuli presented either alone or together. Rats with lesions of the frontal cortex (FC) or nucleus basalis magnocellularis (NBM) were able to time each stimulus when it was presented alone, but not when they were presented together. FC or NBM lesioned rats appeared to only time the intruding stimulus whilst ignoring the other, suggestive of an impairment in divided attention. Rats with lesions of the fimbria-fornix (FF) or medial septum (MS) performed the dual stimulus task normally, but exhibited a general failure to remember the duration of a stimulus, suggesting a failure of working memory. In the cross-modal divided attention task, rats are initially trained in consecutive operant auditory and visual conditional discrimination tasks. This is followed by trials comprising a sequence of stimuli from auditory and visual modalities as well as from different stimulus properties (flashing/pulsing or constantly turned on). Although response accuracy remained unchanged in the bimodal condition, response latencies were generally longer in comparison to unimodal trials suggestive of an increased switching cost. Both, the muscarinic receptor antagonist scopolamine and the benzodiazepine receptor agonist chlordiazepoxide (CDP), increased the response latencies, with scopolamine eliciting greater latency increases in the bimodal condition.

Sustained attention

In a general sense, sustained attention refers to the ability or capacity to maintain attention over some specified period of time and is a fundamental component of cognitive capacity in humans and other animals. Since the work of Mackworth in the late 1950s, the highly related concept of vigilance has been operationally defined, based on human task performance, as a state of readiness to detect and respond to unpredictable and rare events under conditions of relatively low arousal. Vigilance is thus quite difficult to sustain for prolonged intervals and typically results in decreased accuracy of signal detection and

increased latencies to respond over time. Performance on sustained attention or vigilance tasks appear to vary systematically in response to relevant parametric manipulations, which are believed to influence attentional capacity or load, including signal intensity (brightness or duration), trial rate, signal predictability in type or location, and demands on working memory. Two general classes of paradigms have been proposed as models of sustained attention: continuous performance tasks and tests of vigilance.

1. *Continuous performance.* Rosvold and colleagues first devised a task for human subjects in which decisions were continuously required in the detection of a target item. For instance, individuals were asked to press a key whenever they saw a target stimulus X. Many variations of the task have been developed, such as including one or more distractors (e.g., nontarget stimuli) or conditional rules (e.g., respond only to X if preceded by the stimulus A). A further variant was developed in which subjects had to continually monitor five distinct locations in order to detect a target stimulus. Carli and colleagues later developed the five-choice serial reaction time task (5-CSRTT) as a rodent analog of such human continuous performance tests of sustained attention.

On the 5-CSRTT, a large number (100 or more) of discrete consecutive trials are presented. Each trial is initiated when the subjects nose poke into a rear panel magazine tray. Subjects are then required to turn and wait during a short (e.g., 5 s) inter-trial interval (ITI) while scanning a horizontal array of five apertures on the front panel for the presence of a brief light stimulus. There are four possible response outcomes for each trial. Correct responses are recorded when animals nose poke in the aperture having the same spatial location as the brief visual stimulus, and earn food reinforcement delivered to the rear panel magazine tray. The next trial begins immediately upon food collection. Incorrect responses are recorded when subjects nose poke into a different spatial location as the brief light stimulus and are followed by a 5 s timeout period. Omissions are recorded if the animal does not nose poke into any of the front panel apertures within a short (e.g., 5 s) limited hold period after onset of the brief visual stimulus, and are followed by a 5 s timeout period. Premature responses are recorded if subjects respond during the ITI, prior to the presentation of the brief visual stimulus, and are also followed by a 5 s timeout period. For incorrect, omitted, and premature trials, the next trial begins when subjects nose poke into a rear panel magazine tray after the timeout period has elapsed.

A valuable feature of the 5-CSRTT is that it provides several relatively independent measures of attentional performance, including accuracy of target detection (defined as the ratio of correct to the total number of correct and incorrect responses), response speed as

well as response inhibition (a putative measure of impulsivity – see below). Furthermore, the task parameters can be manipulated in order to further evaluate and specify the characteristics of attentional performance within the 5-CSRTT. The stimulus duration or luminance can be altered to vary task difficulty (or attentional load) and to test for changes in sensory threshold. The ITI or the event rate can be altered or made variable such that animals can no longer rely on internal timing to control orientation and thus have to maintain readiness on a continuous basis. Distracting stimuli, such as bursts of white noise, can be used to concurrently assess selective attention. Motivational factors may be captured by examining food collection latencies; however, it should be noted that one common problem with continuous performance tasks in experimental animals is that, owing to the large number of trials, ingestion of rewards may lead to satiety over the course of a session.

In the rat, lesion and pharmacological studies have implicated a variety of brain regions and neurotransmitter systems on attentional performance in the 5-CSRTT. For example, rats given large excitotoxic lesions of the mPFC exhibit substantial reductions in response accuracy and increases in response latency compared with sham-lesioned controls. More discrete excitotoxic lesions show that this effect on discrimination accuracy, particularly following variable ITI and noise burst challenges, may be restricted to damage of the anterodorsal mPFC. Similar decrements on response accuracy and lengthening of response latencies are observed following lesions of the dorsomedial striatum and are consistent with the observed connectivity between anterodorsal mPFC and dorsomedial striatum. The importance of this functional circuitry is further strengthened by the observation that asymmetrical, disconnection preparations (in which a lesion to the mPFC in one hemisphere is combined with a lesion to the medial striatum in the other hemisphere), produce effects similar to that of the bilateral lesions. These results are also consistent with the hypothesis that several components of 5-CSRTT performance are mediated by somewhat distinct corticostriatal circuits.

Ascending cholinergic (ACh) and monoaminergic (NA, DA, and 5-HT) systems appear to contribute to both distinct and overlapping aspects of attentional performance on the 5-CSRTT. Excitotoxic lesions of the NBM in rats, or lesions produced by the selective cholinergic immunotoxin 192 IgG-saporin, generally produce impairments in discrimination accuracy, particularly during the increased attentional demand imposed by shortened stimulus durations or the concurrent presentation of auditory distractors. Similarly, decreases in response accuracy and increases in response latency are observed following intra-NBM doses of the GABA agonist, muscimol, at doses sufficient to produce reductions in cholinergic activity. Infusions of 192 IgG-saporin

directly into the ventromedial PFC impair 5-CSRTT performance accuracy, specifically under high event rates. And intra-mPFC infusions of the muscarinic receptor antagonist, scopolamine, induce significant deficits in response accuracy. These results are compatible with the hypothesis that cholinergic afferents in the mPFC serve to optimize attentional resources, particularly under conditions of increased attentional demand or load. Destruction of the ascending noradrenergic projections to the FC by infusions of 6-hydroxydopamine (6-OHDA) into the dorsal noradrenergic ascending bundle also impair attentional accuracy, but only following variable ITI challenge or in the presence of white noise distraction.

Based on these and similar findings, the ACh and NA systems, although functionally distinct, appear to contribute to overlapping operational processes relevant to visual attention, presumably in a manner serving to maintain discriminative selectivity in the face of interference. Less is known of the role of the prefrontal DA systems in the 5-CSRTT, but combined depletion of NA and DA from the mPFC has been observed to result in attentional impairments, specifically during a variable short ITI contingency. Manipulations of 5-HT systems have generally been observed to affect impulsivity more than attentional processes and are described below.

2. Vigilance. Early attempts to model vigilance in experimental animals typically employed a discrete trial procedure in which a signal (e.g., light) had to be detected above a background stimulus and a unitary response performed. These early models relied heavily on signal detection theory, which helped provide a quantitative basis for dissociating discriminative sensitivity for the signal from other factors such as response bias. However, such procedures are often subject to interpretative and computational issues regarding signal detection and response bias and, subsequently, two-response discrete trial tasks (e.g., one response for reporting signal detection, and a separate response for reporting no signal detected) were developed to help obviate these difficulties. In one version of a two-response task, rats were required to respond to the presentation of brief visual signals by pressing one lever and a second lever in the absence of a signal in order to receive reward. The face validity of the task was assessed through manipulation of signal intensity, background noise (flashing chamber houselight), event rate, and signal asynchrony, parameters which are known to alter performance in human vigilance tasks. Predictable performance decrements were observed as the signal length was decreased (fewer correct detections), as background noise increased (decreased discrimination between signal and nonsignal events as well as a vigilance decrement over blocks of trials observed for shortest signals) and as the event rate increased (vigilance decrement over blocks of trials). However, no reliable effects were observed by increasing signal asynchrony.

Within this two-lever task, basal forebrain depletions of ACh via 192 IgG saporin lesions of the NBM in rats led to a persistent decrease in the ability to detect signals (while leaving the ability to correctly reject nonsignals unaffected). By contrast, 6-OHDA lesions of the dorsal noradrenergic ascending bundle produced no consistent effects. Administration of the benzodiazepine receptor (BZR) agonist CDP resulted in a decrement in discriminability between signal and nonsignal events, which was exclusively due to an increase in the number of misses. The BZR partial inverse agonist RU 33965 (0.1, 0.5 mg kg⁻¹) impaired the vigilance performance in a dose-dependent manner, whereas BZR ligands with weak or selective inverse agonist properties (e.g., ZK 93426; beta-CCtB) did not affect the vigilance performance. Amphetamine administration also impaired the vigilance performance, but these impairments may have been due to effects unrelated to attentional mechanisms, such as increased perseveration and/or 'lever switching.'

Although two-response procedures provide the most sophisticated assessment of vigilance to date, they have been criticized on the basis that alerting or arousal mechanisms cannot be completely accounted for, and because there is often a lack of interaction of treatment effects across trial blocks, as is typically observed in humans.

Animal Models of Impulsivity

Varieties of Impulsivity

There are currently a variety of definitions and uses of the term 'impulsivity' within cognitive and behavioral neuroscience, none of which are universally accepted. This definitional multiplicity is generally believed to result from heterogeneity in the timescale, context, population, or category of behavior within which impulsivity is ascribed. In other words, impulsivity is likely not a unitary construct but rather a concept incorporating a range of phenomena spanning several dimensions – from immediate, ongoing actions to more enduring personality traits; from adaptive or functional behaviors to those considered as maladaptive or dysfunctional; and from 'normal' acts of impulsiveness to symptoms of certain psychiatric or pathological conditions. Within such dimensions, definitions of impulsivity also commonly encompass several, seemingly distinct, classes of behaviors – such as actions elicited with less consideration of future consequences; acts reflective of a deficit in the ability to withhold, inhibit, or stop; or decisions reflective of increased risk-taking. Moreover, both within and between such classes of impulsive behaviors, individual actions likely recruit distinct or overlapping sets of psychological processes – such as attention, motor control, switching, timing, arousal, or sensitivity to reward or punishment – processes which themselves may

be multifaceted and have distinct or overlapping neurobiological implementations.

Despite the difficulties in achieving a precise definition of impulsivity, in the clinical setting, measures of impulsivity continue to play a prominent role both as correlates and diagnostic symptoms of a variety of psychopathological conditions including ADHD, conduct disorder, borderline personality disorder, and addiction. Given its various definitions, it is not surprising that there are a diverse methods by which impulsivity can also be measured. Many clinical approaches assess impulsivity by introspection and use of self-report questionnaires. Scale design and principal-component analyses within and between questionnaire test items suggest that these scales are assessing multiple, independent dimensions. While useful as correlative tools, self-report scales are primarily subjective and are designed to measure longer lasting personality characteristics – the majority have little focus on the dynamics of ongoing impulsive behaviors or the influence of relevant situational variables. To this aim, a number of paradigms have been developed to more objectively quantify behaviors which are thought to reflect impulsivity. The extent to which such behavioral indices are related to the rating scale assessments of impulsivity is the subject of ongoing research. However, behavioral paradigms provide useful clinical correlates in their own right and have the added advantages of being amenable to the tools of neurobiological analysis and enabling the development of analogous paradigms for testing in humans and nonhuman animals. The next section will summarize some of the expanding research efforts aimed at investigating impulsivity in animals.

Experimental Paradigms

Behavioral paradigms designed to measure impulsivity in animals have traditionally been divided into two broad categories: paradigms that assess some form of behavioral inhibition of a motor response (i.e., impulsive action), which are typically inclusive of actions that are premature, mistimed, or difficult to suppress or control; and those that assess altered decision-making processes (i.e., impulsive choice), which are typically inclusive of actions that are initiated without accounting for, or in spite of, other possible options or outcomes. The most common tasks designed to measure behavioral inhibition in animals are the go/no-go task, the stop-signal reaction time (SSRT) task, the 5-CSRTT as well as other delayed response tasks (e.g., differential reinforcement of low rate of responding (DRL) task).

Impulsive action

1. *Go/No-go tasks.* In a typical go/no-go paradigm, a subject is reinforced to make a particular response (e.g.,

approaching/touching a stimulus or pressing a lever) when signaled by a sensory cue (the 'go' signal – typically visual, auditory, or olfactory). This reinforced response is often made prepotent by the presentation of a number of such 'go' trials. However, on a subset of 'no go' trials, in order to receive reinforcement the subject must inhibit this prepotent response when a distinct, 'no-go' signal is presented prior to, or concurrently with, the 'go' signal. Higher impulsivity in the go/no-go task is typically defined by a reduced ability to withhold responding on 'no-go' trials relative to accuracy of performance on 'go' trials.

Brain-imaging studies investigating the neural basis of human go/no-go task performance have generally observed bilateral activations within the inferior frontal cortex (IFC), anterior cingulate cortex (ACC), supplementary motor area, dorsolateral PFC, and inferior parietal cortex. In rats, the situation is somewhat less clear. While early results indicated significantly impaired go/no-go performance on an odor discrimination task following aspiration lesions of the orbitofrontal cortex (OFC), later studies inducing bilateral OFC lesions with the excitotoxin, N-methyl-D-aspartate (NMDA) found no impairments in acquisition or performance of go/no-go responding. Similarly, no consistent effects have been observed following NMDA lesions of the prelimbic and infralimbic areas of the mPFC. However, ibotenic lesions of the ACC in the rat disrupt the acquisition of a go/no-go task requiring behavioral temporal sequencing, but do not affect more traditional go/no-go responding when selection processes were based on a tone/light conditional rule that does not require temporal patterning. Of the ascending neurotransmitter systems, 5-HT has been most heavily implicated in go/no-go performance in both humans and rats. In rats, 5-hydroxytryptamine (5-HT) depletion following intra-cerebroventricular (ICV) infusions of 5,7-DHT (5,7-dihydroxytryptamine) profoundly and selectively disrupts the acquisition of go/no-go task performance. Similar results are observed following para-chloroamphetamine administration, which also produces a profound and selective loss of 5-HT in the brain.

2. *SSRT tasks.* The SSRT paradigm follows a similar logic to the go/no-go task with the exception that, in the subset of 'no-go' trials, the 'no-go' signal (or 'stop' signal) is presented some time after the presentation of the 'go' signal. Therefore, while the go/no-go task is thought to measure inhibition of a motor response before the response has been initiated (e.g., action restraint or withholding), the SSRT task is thought to measure inhibition of a motor response which has already been initiated (i.e., action cancellation or stopping). The primary outcome variable of the SSRT task is SSRT, which is an estimate of the latency of a subject to successfully cancel or stop the prepotent 'go' response. As the endpoint of withholding a response cannot be observed directly, SSRT is typically

estimated within the theoretical framework of the 'race' model, a model which assumes that 'go' and 'stop' processes proceed independently from one another. Higher impulsivity in the SSRT task is defined by an increase in SSRT.

Brain imaging studies in humans have implicated many of the same brain regions as the go/no-go task. However, further work has suggested that IFC, and particularly the right IFC, is critical to inhibition on the SSRT task, while other activated structures are better correlated with other task-related processes such as maintaining the go response or error monitoring. Patients with lesion damage to the FC display a strong correlation between lesion size within the right IFC and increased SSRT. There is no such correlation with lesion size and SSRT for other neighboring regions within the right hemisphere or anywhere in the left hemisphere. At the moment it is unclear whether there is a region homologous to the IFC in the rat. Neurotoxic lesions of several subregions of the PFC have been reported to have no effect on SSRT measures – to date, only lesions of the OFC have produced increases in SSRT. Unlike the go/no-go task performance, SSRT does not appear to be reliably altered by manipulations of 5-HT in humans or rats. Neither acute tryptophan depletion (which reduces brain 5-HT levels) nor acute administration of the 5-HT reuptake inhibitor, citalopram, has any significant effect on SSRT in humans. Moreover, global (ICV) 5,7-DHT lesions have no effect on any SSRT task parameters in rats and 5-HT transporter knockout mice show no impairments in SSRT. Recent work has demonstrated that acute administration of the NE reuptake inhibitor, atomoxetine, can improve SSRT in both healthy human subjects as well as in normal rats, suggestive of a potential role of catecholamines in action cancellation forms of behavioral inhibition.

3. *Delayed response tasks.* In both the go/no-go and SSRT paradigms, a separate and explicit signal is used to indicate a subset of trials requiring behavioral inhibition. The absence of an operant response on such trials is typically reinforced. By contrast, on the 5-CSRTT and other forms of delayed response tasks, the absence or delay of responding on any given trial results in a loss and/or delay of reinforcement (e.g., all trials are similar to prepotent 'go' trials). In other words, in typical delayed response tasks, there are no trials with an explicit signal to inhibit responding, nor any immediate feedback that a trial has been successfully inhibited.

As described above, the 5-CSRTT consists of a number of discrete consecutive trials in which subjects are required to wait (e.g., restrain or withhold responding) during a fixed or variable inter-trial interval (ITI) while scanning a horizontal array of five apertures, and to nose poke in the spatial location of a brief visual stimulus in order to earn reinforcement. Nose pokes during the ITI,

prior to the presentation of the visual stimulus, are classified as premature responses. Higher impulsivity is defined as increase in the number of premature responses.

Of many brain regions examined, neurotoxic lesions of the postgenual ACC (Cg1) and infralimbic cortex (IL), as well as local NMDA receptor antagonism in the IL, stand out with respect to the magnitude of the increased impulsivity observed on the 5-CSRTT in the rat. While central depletion of ACh and NE produces effects mainly on 5-CSRTT performance accuracy (described above), a long-lasting increase in impulsive responding (along with a transient increase in accuracy) is observed on the 5-CSRTT following global (ICV) 5-HT depletion produced by infusions of 5,7-DHT into the dorsal raphe nucleus (which mainly innervates the neocortex and striatum). Psychostimulants, which exert marked increases in DA neurotransmission, generally increase impulsivity on the 5-CSRTT task and, in the case of acute amphetamine administration, can be reversed by selective DA depletion in the nucleus accumbens. Overall, these results are consistent with studies using delayed response tasks in humans which heavily implicate both fronto-striatal circuitry and the ascending serotonergic and dopaminergic neurotransmitter systems in the regulation of impulsive behavior.

On a DRL schedule of reinforcement, the subject is required to space operant responses by a specified time interval to obtain reinforcement. Impulsivity is generally attributed to a greater number of responses made before the interval has elapsed and/or lower levels of efficiency (reward per response ratio). On a fixed consecutive number (FCN) schedule, the subject is required to perform a minimum number of responses on one operandum before a response on a second operandum will deliver reinforcement. A reduction in the number of consecutive responses made on the first operandum before responding on the second is typically interpreted as increased impulsivity. On a variant of this task – the paced FCN – the two levers are withdrawn from the chamber each time the rat responds. The paced FCN schedule helps to control for the potential confounding effects of alterations in general levels of activity. A key methodological distinction between the 5-CSRTT and standard DRL and FCN schedules is that in the 5-CSRTT the end of the waiting period (i.e., the time after which an operant response will be reinforced) is explicitly signaled.

While less is known regarding the neural substrates of behavior on DRL and FCN schedules, the effects of psychopharmacological agents shows remarkable overlap with the 5-CSRTT. For example, destruction of the ascending serotonergic systems using 5,7-DHT impairs DRL performance, similar to the effects of selective lesions to the median raphe nucleus. Experiments examining specific destruction of 5-HT neurons in the dorsal raphe suggested that, while processes of temporal

discrimination remained intact, behavioral ‘switching’ mechanisms may be dysregulated following 5-HT loss. Moreover, akin to the 5-CSRTT, administration of psychostimulants such as amphetamine cause increases in impulsivity in both the DRL and FCN procedures.

Impulsive choice

Another category of procedures used to assess impulsivity relates to decision-making or impulsive choice. Impulsive choice is typically measured in the delay discounting paradigm where impulsivity is defined by a greater tendency to value or choose smaller, more immediate reinforcers over larger, more delayed reinforcers – even where it is economically advantageous to value or choose the latter. This tendency to devalue delayed reinforcers appears highly consistent across species, exemplified by characteristic hyperbolic discounting curves for reinforcer as a function of increasing delay. While this obviously implies that delay discounting has adaptive value in natural environments, it is also clear that when the tendency to show preference for immediate reinforcers over more lucrative delayed reinforcers is exaggerated, it may lead to maladaptive behavior. Another variant of impulsive choice procedure includes probability or risk discounting (i.e., a tendency to choose larger, but less probable rewards over smaller more certain rewards despite smaller economic value); however, less work has been performed using this paradigm in experimental animals.

As an example, in one recent rodent version of the delay discounting procedure, rats were first trained to initiate trials (upon activation of a light cue) at regularly spaced intervals to gain access to one of two levers, and to press the extended lever to receive a food pellet reward. Subsequently, rats initiate a series of free-choice trials in which both levers are extended. Rats choose between pressing one lever that always results in the immediate delivery of a single food pellet and pressing another lever that always results in four pellets, but only after a delay that is increased progressively across blocks of trials in each session. Impulsivity, or impulsive choice, in this paradigm is commonly attributed to subjects who show a greater choice of the lever giving the smaller, more immediate reward at some or all of the increased delays on the lever giving the larger reward.

Higher levels of impulsive choice have been documented in individual suffering from disorders such as addiction and ADHD. Further, human brain imaging studies of subjects performing impulsive choice tasks involving primary (e.g., juice) or secondary (e.g., money) rewards have shown that lateral prefrontal and intraparietal cortical regions are activated independently of the delay – which are proposed to participate in ‘rationally’ evaluating the relative value of immediate and delayed rewards, while limbic regions including the ventral striatum and medial OFC are preferentially activated by

relatively immediate rewards – which are proposed to promote choice of imminent rewards without consideration of delayed alternatives. In rats, the implication of prefrontal cortical regions is less clear. Neither mPFC lesions (including both prelimbic and infralimbic regions) nor perigenual ACC lesions appear to influence impulsive choice behavior. While some studies have observed increases in impulsive choice following neurotoxic lesions of the OFC, others have observed decreases in impulsive choice. It should be noted, however, that large mPFC lesions (including prelimbic, infralimbic, Cg1, and Cg2) as well as more selective ACC lesions do appear to affect choice between smaller rewards obtained with low-effort (no ramp) and larger, high-effort alternatives (steep ramp to climb) by reducing preference for the high-effort option. Thus, the ACC may be involved in promoting the selection of effortful, rather than delayed, alternatives. Subcortical brain regions have been more strongly implicated in delay discounting in the rat. Excitotoxic lesions of the nucleus accumbens, hippocampus, and basolateral amygdala all result in increased impulsive choice, while lesions of the subthalamic nucleus tend to decrease impulsive choice.

Forebrain 5-HT depletion has generally been observed to elicit higher levels of impulsivity across a variety of impulsive choice paradigms in the rat, typically by steepening the discounting function. In humans, lowering 5-HT levels via dietary tryptophan depletion, which decreases levels of 5-HT metabolites in cerebrospinal fluid (an indirect indicator of brain 5-HT levels) has not been observed to increase impulsive choice. Psychostimulants such as amphetamine or methylphenidate, which potentiate DA neurotransmission and are widely used in the treatment of ADHD, produce mixed effects on impulsive choice behavior in the rat. Some studies have found that they promote choice of delayed reinforcers while others have observed the opposite effect. One factor that may explain some of these discrepant effects is the presence of cues or signals present during the delay to the large reward alternative, however, these discrepancies require further clarification. While little work has investigated the role of NE in delay discounting, it has recently been observed that acute administration of the NE reuptake inhibitor, atomoxetine (a nonstimulant medication also used in the treatment of ADHD) can decrease impulsive choice in the rat.

Summary

A number of paradigms and procedures have been developed to assess attention and impulsivity in experimental animals. Many of these tasks are automated and highly sophisticated and are readily scalable to analogous paradigms in humans, including selected patient groups. As such, they provide tangible models of core cognitive and behavioral processes relevant to neuropsychiatric disorders, which are amenable to investigative neurobiological research. The continued development of tasks to measure attention and impulsivity in animals is inevitable as research continues to refine the taxonomy of attention and impulse control in humans.

Glossary

Conditioned response (CR) – A response elicited by a conditioned stimulus.

Conditioned stimulus (CS) – In Pavlovian conditioning, a conditioned stimulus (CS; e.g., a tone) comes to elicit a conditioned response (e.g., salivation) by being paired with an unconditioned stimulus (US; e.g., food). The term ‘conditional’ is sometimes used in place of ‘conditioned.’

CS-US interval – In Pavlovian conditioning, the time between the onset of the CS and the onset of the US.

Extinction – In Pavlovian conditioning, the presentation of the CS without the US that it was previously paired with.

Intertrial interval (ITI) – In Pavlovian conditioning, the time between trials, where a trial is one pairing of the CS with the US.

Unconditioned response (UR) – A natural response elicited by a stimulus in the absence of conditioning.

Unconditioned stimulus (US) – In Pavlovian conditioning, a US (e.g., food) elicits an unconditioned response (e.g., salivation) regardless of the experience or learning history of the subject. Pairings of a neutral stimulus (e.g., a tone) with US (e.g., food) may convert the neutral stimulus into a CS that elicits a conditioned response (e.g., salivation). The term ‘unconditional’ is sometimes used in place of ‘unconditioned.’

can come to do so, given the appropriate conditions. In particular, a previously neutral stimulus such as a sound can come to elicit a CR such as salivation if it has been established as a valid and reliable signal for a US such as food.

It should be noted that some authors use the terms ‘conditional’ and ‘unconditional’ in place of ‘conditioned’ and ‘unconditioned,’ respectively, when referring to the stimuli used in Pavlovian conditioning procedures. One pairing of a CS with a US is called a ‘trial.’ An experimental session generally consists of multiple trials. The time between trials is called the ‘intertrial interval’ (ITI). The time between the onset of the CS and the onset of the US is called the ‘CS-US interval.’

Four possible temporal arrangements of a CS and US are represented by delay, trace, simultaneous, and backward conditioning procedures. In delay conditioning, the CS is presented first and then, while the CS is still present, the US is delivered. The essential features of delay conditioning are that the CS precedes the US and that the two stimuli partially overlap in time. In trace conditioning, the CS also precedes the US, but they do not overlap each other. There is a period of time between the offset of the CS and the onset of the US where neither stimulus is present. This period is called the ‘trace interval.’ Pavlov called this procedure trace conditioning because it was assumed that the aftereffect of the CS (i.e., the CS trace), rather than this CS directly, was associated with the US. Both delay and trace conditioning procedures reliably produce conditioned responding and are the most commonly used temporal arrangements of CS and US. In simultaneous conditioning, the CS and US perfectly overlap. The two stimuli commence as well as terminate at the same time. Simultaneous conditioning is not considered to be as effective as delayed or trace conditioning procedures. In backward conditioning, the US is presented before the CS. Pavlov originally reported that backward conditioning was entirely ineffective, although more recent research has found that learning can be generated with backward conditioning in certain preparations.

Introduction and Basic Terminology

In Pavlovian conditioning (also known as classical or respondent conditioning), a conditioned stimulus (CS) comes to elicit a conditioned response (CR) by being paired with an unconditioned stimulus (US). For example, Ivan Pavlov found that a sound (the ticking of a metronome) that was repeatedly presented several seconds before the delivery of food was capable of eliciting salivation in dogs. In this case, the metronome was the CS, the food was the US, and salivation was the CR.

The US is a stimulus that elicits an unconditioned response (UR) regardless of the learning history of the subject. For example, salivation in response to food being placed in the mouth is an unlearned, innate response. In contrast, sounds do not normally elicit salivation, but they

Pavlovian versus Operant Conditioning

The distinguishing feature between Pavlovian and operant (instrumental) procedures lies in the nature of the relationship between the presentation of stimuli and the subject’s behavior. In Pavlovian conditioning, the CS and

US are presented independently of the behavior of the subject. For example, the sounding of the metronome was followed by food regardless of what the dog was doing. The salivation CR was elicited by the CS, but did not affect the presentation of the CS or US. In contrast, in operant conditioning, the presentation (or removal) of the reinforcer depends on the subject's behavior. For example, a food reinforcer might be presented if a rat presses a lever. The food is not presented otherwise and therefore its presentation is dependent on the lever-press response of the rat. Although a simplification, the following heuristic may be useful in highlighting this essential difference between the two paradigms: in Pavlovian conditioning, a stimulus (e.g., a sound) produces a response (e.g., salivation); in operant conditioning, a response (e.g., a lever-press) produces a stimulus (e.g., food).

Major Procedures Used Today

Eyeblink Conditioning

In the eyeblink conditioning preparation, the US is a puff of air delivered to the eye or a brief electric shock applied to an area near the eye. The UR elicited by this US is an eyeblink. A stimulus, such as a tone or a light, can be converted into a CS by being repeatedly paired with the air puff or shock. Such a CS will come to elicit an eyeblink CR. A special feature of the eyeblink conditioning preparation is the shortness of duration of the optimal CS-US interval. Research has shown that conditioned responding is best generated by intervals of 200–400 ms, with less conditioned responding occurring when shorter or longer CS-US intervals are used. Several hundred trials may be necessary to firmly establish the CR.

Eyeblink conditioning has most often been studied in rabbits, although humans have also served as subjects. In addition to eyelids, rabbits have a nictitating membrane, which is located below the eyelid and serves a very similar function to the eyelid (it has been called a 'third eyelid'). Closure of the nictitating membrane has often been the CR directly measured in studies with rabbits. Thus, the CR in studies with rabbits is often referred to as the 'nictitating membrane response.'

Fear Conditioning

Rats are commonly used as subjects in the conditioned fear preparation. A stimulus, such as a tone or light, is presented and paired with a brief electric shock that is applied to the metal grid floor of the chamber. This footshock US elicits a UR that may consist of an initial jump or startle reaction, occasionally accompanied by a vocalization, followed by a longer period of immobility. A CS that has been paired with footshock elicits a CR that has been referred to as 'freezing.' This freezing response is

characterized by the absence of all movement except that required for breathing. The CS in conditioned fear experiments typically lasts from several seconds to several minutes in duration. The CR can be acquired after relatively few trials. In the simplest version of the conditioned fear procedure, the freezing CR is measured directly by observing and scoring video recordings or through the use of movement-analyzing video software.

Conditioned suppression is a frequently used procedure that involves the indirect measurement of conditioned fear. This technique has also been referred to as the 'conditioned emotional response,' or CER, procedure. Subjects are first trained to make an operant response such as lever-pressing for food. Once a stable baseline of operant performance (e.g., a regular pattern of lever pressing) is established, classical conditioning is conducted where a CS such as a tone is paired with the footshock US. After several CS-US pairings, the CS comes to suppress performance of the operant behavior.

Autoshaping/Sign-Tracking

One of the most commonly used procedures today in the study of Pavlovian conditioning is autoshaping, which is also known as 'sign-tracking.' The autoshaping response typically involves approaching and contacting a CS that has been paired with an appetitive US. In the standard autoshaping procedure with pigeons, the CS is the brief (e.g., 8 s) illumination of a keylight which terminates with delivery of a food US. After a relatively small number of CS-US pairings (usually <100), the CS comes to elicit a pecking CR. Pigeons peck the keylight CS at high rates even though the food US is delivered regardless of their behavior. Remarkably, pigeons continue to peck the keylight CS, although at a reduced rate, even when it is arranged so that pecking leads to the omission of the food US on that trial. This modification of the standard autoshaping procedure is called the 'negative automaintenance' or 'omission' procedure. Autoshaping is also frequently studied with rats as subjects. In the standard rat version of the procedure, insertion of a retractable lever (typically for 10–15 s) is the CS. Upon retraction of the lever, a food pellet US is delivered. The CR soon elicited by the CS is vigorous touching, biting, gnawing, and licking behavior directed at the lever CS. Similarly to pigeons, rats will persist in contacting the CS, although at a reduced rate, even when doing so cancels delivery of the food US.

It has been argued that the term autoshaping is a misnomer since it implies that that operant behaviors or procedures (such as shaping) are involved. The original investigators that coined this term described the procedure as a more efficient and standardized alternative to operant shaping as a method for training pigeons to acquire the keypeck response. However, a procedure is

a Pavlovian one if the CS and US are presented independently of the subject's behavior. Furthermore, results from negative automaintenance studies (described above) suggest that the autoshaping response is a Pavlovian CR rather than an operant behavior since the autoshaping response appears and persists even when it has never been reinforced. The term sign-tracking has been suggested as an alternative to autoshaping since it is an accurate description of the phenomenon and it does not have the operant connotations. Despite these advantages, autoshaping has remained the more commonly used term.

The identities of the CS and US determine the form of the autoshaping CR and whether or not autoshaping occurs at all. Auditory stimuli or diffuse visual stimuli do not generate the robust autoshaping behavior that is produced by keylight CSs in pigeons or by retractable lever CSs in rats. While food has been the most commonly used US in autoshaping studies, CSs paired with other appetitive stimuli have also been shown to elicit approach and, sometimes, contact responses. For example, a keylight CS paired with a water US elicits a drinking- or slurping-like CR that is directed at the key-light in pigeons. In rats, a lever CS paired with reinforcing intracranial stimulation (ICS) elicits approach and contact behavior directed toward the lever. Recently, there have been reports of approach elicited by CSs paired with drugs of abuse, such as cocaine or alcohol in rats, although such autoshaping behavior appears to be less robust than that elicited by CSs paired with food.

Orienting responses, such as looking at a CS that has been paired with food, are similar to autoshaping responses in that both include the observation and tracking of a stimulus that is predictive of a US. However, in autoshaping, the subject moves toward and, usually, physically contacts the CS (sometimes biting or grabbing it), whereas mere orientation does not involve the forward locomotion and tactile interaction with the CS that characterize autoshaping.

Magazine Entry/Goal-Tracking

'Magazine entry' (sometimes called head entry) is a frequently used procedure to study Pavlovian conditioning in rats. A briefly presented (e.g., 30 s) tone or light CS is paired response-independently with a food pellet US. After several such pairings, the rat begins to anticipate delivery of the food pellet during the CS and puts its head into the receptacle (sometimes referred to as a 'magazine') or aperture where the food pellet is soon presented. The number of times that the rat checks for the food pellet during the CS can be measured by counting the number of times that a photobeam projected across the food aperture is broken. This behavior has been called 'goal-tracking' to contrast it with sign-tracking (see above). In goal-tracking, the approach CR elicited by the CS is

directed toward the site of US delivery. In sign-tracking, the approach CR elicited by the CS is directed at the CS itself (the sign). Characteristics of the conditioning procedure (e.g., whether the CS is auditory or visual) determine whether goal-tracking or sign-tracking occurs.

Conditioned Taste Aversion

In conditioned taste aversion learning, a novel taste CS, such as saccharin-flavored water, is paired with an aversive US, such as the injection of an emetic drug. In a commonly used version of the procedure, thirsty rats are allowed to drink a saccharin solution for several minutes prior to injecting them with lithium chloride. With as little as one saccharin CS–lithium US pairing, rats learn to avoid drinking the CS solution in the future. A special feature of conditioned taste aversion learning is that the CS–US association can be learned with very long CS–US intervals (e.g., up to 24 h). In addition to using lithium chloride as the US, conditioned taste aversions have been demonstrated in rats when the US was an injection of a drug of abuse, such as cocaine or morphine.

Extinction and Related Phenomena

If, after having established a CS–US association, the CS is no longer paired with the US, the CS will gradually cease to elicit the CR. For example, Pavlov noted that when a metronome that had previously been paired with food and that had elicited salivation was presented alone for several trials, it took progressively longer for salivation to be elicited and the amount of salivation elicited grew progressively smaller. The procedure where CS–US pairings are discontinued and the CS is presented alone is called 'extinction.' The weakening of the CR resulting from such a procedure has also been referred to as extinction.

Pavlov performed much research on extinction and discovered many of its properties. He noted that a CR that had been thoroughly extinguished would reappear if the CS were presented again after a period of time during which it was not presented. For example, a visual CS that had come to elicit salivation by being paired with a food US was repeatedly presented by itself (extinction) until it no longer elicited salivation. A 2-h period was allowed to pass during which time no stimuli were presented. When the visual CS was then presented, the dog began salivating again. Pavlov called this phenomenon 'spontaneous recovery.' Pavlov also observed that presentation of some extraneous stimulus, such as a loud sound, could cause a CS that was previously subjected to extinction, and that had ceased to elicit the CR, to begin to elicit the CR again. He called this phenomenon 'disinhibition.'

Much recent research has investigated other situations where behavior reappears after it had been eliminated through extinction. In reinstatement, presentation of the US alone leads to the reappearance of the CR when the CS is subsequently presented by itself. For example, a tone previously paired with shock might be subjected to extinction during multiple sessions so that it no longer elicits a freezing CR. If the shock is then presented by itself a number of times, the tone will once again elicit the freezing CR if the tone is subsequently presented. In rapid reacquisition studies, the CS that had been subjected to extinction is again paired with the US. Thus, this is similar to the reinstatement procedure except that the US is not presented alone, but is paired with the CS. The typical result is that the CR appears much sooner than during initial conditioning and much sooner as compared to a control group receiving CS-US pairings for the first time.

In context renewal, pairings of the CS and US occur during the first phase in one context and then, in a second phase that is conducted in a different context, the CS is subjected to extinction until it no longer elicits the CR. When the CS is presented by itself in the original context it again elicits the CR. For example, rats might experience pairings of a tone with footshock in an experimental chamber that has black-and-white striped walls, a low level of illumination, and a eucalyptus-scented ambient odor. By being paired with shock, the tone CS comes to elicit a freezing CR. Then, extinction is conducted and the tone is presented by itself over the course of several sessions conducted in a different experimental chamber that has solid white walls, a high level of illumination, and a vinegar-scented ambient odor. Even if the tone no longer elicited any conditioned freezing by the end of the extinction treatment conducted in the different context, it will again produce a robust freezing CR if it is presented to the subjects in the original training chamber. This is the context renewal effect.

The five phenomena just described involving a reappearance of the CR after extinction – spontaneous recovery, disinhibition, reinstatement, rapid reacquisition, and context renewal – all indicate that extinction does not lead to the loss of, or unlearning of, the CS-US association. Rather, such findings suggest, in accordance with Pavlov's ideas as well as more recent accounts, that extinction involves a type of inhibitory learning that acts to suppress expression of the CR while leaving the original CS-US association intact. Much current research has been concerned with investigating the mechanisms involved in extinction learning.

Inhibitory Pavlovian Processes

A CS that has been paired with a US and comes to elicit a CR because of this association is said to have excitatory

properties and is called an 'excitor.' A stimulus that signals the absence of a US and comes to control a behavioral tendency opposite that of an excitor is called a 'conditioned inhibitor.' For example, a tone that signals that food will not be presented and thereby comes to suppress salivation is a conditioned inhibitor.

There are a number of ways to create inhibitory stimuli. In the most commonly used conditioned inhibition procedure, originally described by Pavlov, one stimulus (denoted A) is first established as an excitor by being paired with the US. Trials where stimulus A is paired with the US are called A+ trials. On other trials that are intermixed with A+ trials, another stimulus (called B) is presented simultaneously with stimulus A and the US is omitted. On these AB- trials, stimulus B signals the absence of the US. The CR eventually stops being elicited on these AB- trials, while it remains intact on A+ trials. This method of creating inhibition has been called the 'A+/AB- conditioned inhibition procedure.'

Another method of establishing an inhibitory stimulus is through the use of differential conditioning, or what Pavlov referred to as the 'method of contrast.' Two types of trials are presented in an intermixed fashion: A+ trials, where one stimulus (e.g., a tone) is paired with the US; and B- trials, where another stimulus (e.g., a light) is presented alone. Stimulus A becomes an excitatory CS that elicits the CR and stimulus B becomes an inhibitor capable of suppressing the CR.

Pavlov called the instances of inhibitory learning described above 'internal inhibition' to contrast it from external inhibition. In external inhibition, the suppression of the CR is not due to inhibitory associative learning, but rather is due to the disruptive or distracting effect of some extraneous stimulus on CR performance. For example, an unexpected loud noise coincidentally occurring at about the same time that a CS for food is presented might temporarily suppress the salivation response, but this suppression is not due to the type of learning that is involved in conditioned inhibition.

Two major methods used for measuring conditioned inhibition are the summation test and the retardation-of-acquisition test. In the summation test, the putative inhibitor is presented simultaneously with an excitor for the first time (not the same excitor that was used to create the inhibitor). Evidence for conditioned inhibition is provided if the presence of the putative inhibitor leads to a reduction in the amount of conditioned responding normally elicited by the excitor when it is presented alone. In retardation of acquisition, the putative inhibitor is paired with the US and the rate of acquisition of the CR is measured. Evidence of conditioned inhibition is provided if the rate of excitatory conditioning of the putative inhibitor is slower than that of a novel or neutral stimulus that was not previously established as a signal for the absence of the US.

Control Procedures Used in Pavlovian Conditioning

In studies of Pavlovian conditioning, control conditions are often included to determine whether a CS-US association has been formed and to rule out potential alternative explanations of changes in behavior. A number of procedures have been used for this purpose.

CS-Only Control

In the simplest procedure, the experimental group receives pairings of the CS and US, while the control group receives only presentations of the CS. This control procedure is often used in conditioned taste aversion and conditioned fear studies. For example, an experimental group may receive access to saccharin (the CS) that is followed by an injection of lithium chloride (the US), while a control group receives access to saccharin that is followed by an injection of saline (or other inert substance). Changes in saccharin drinking over successive trials are then measured and a conditioned taste aversion is assumed to have been produced if saccharin drinking in the experimental group is reduced relative to that observed in the CS-only control group.

A CS-only group is not an ideal control procedure, although it may be the only one that is practical or feasible in some situations. The problem is that nonassociative effects of the US are not controlled for because a CS-only group does not experience the US. This is a critical shortcoming in situations where simple exposure to the US might affect the subject's reaction to the CS in a way that makes it appear as though a CS-US association has been learned when, in fact, such an association has not been learned. For example, an intense electric shock might cause subjects to freeze in response to any subsequently presented unfamiliar stimulus. If an experimental group receiving tone-shock pairings quickly happened to freeze in response to the tone (or any other stimulus), while a CS-only control group did not freeze in response to the tone, it might be erroneously concluded that subjects in the experimental group have extremely rapidly learned a tone-shock association. To address such potential pseudoconditioning effects, control procedures that involve presentation of both the CS and the US are necessary.

Explicitly Unpaired Control

In the explicitly unpaired procedure, both the CS and US are presented, but never together. The US is presented during the ITI. For example, in a rat autoshaping experiment, the experimental group might receive trials

consisting of a 15-s lever insertion CS that is followed immediately by a food pellet US, with ITIs lasting a mean of 90 s. An explicitly unpaired control group might receive the same number of presentations of both the lever and the food pellet, but with a food pellet presented at a varying time points during each ITI that is no more than 20 s before or after presentation of the lever CS.

A concern with the explicitly unpaired control procedure is that it may produce inhibitory conditioning. That is, a stimulus that is never paired with the US is a signal for the absence of the US. If such a stimulus acquires inhibitory properties, it may come to produce a level of CR performance that is below the true baseline, control level that would be elicited by a neutral CS. Therefore, comparing the response elicited by a CS that has been paired with the US with that elicited by a stimulus subjected to explicitly unpaired treatment may lead to overestimates of how much learning was produced by CS-US pairings.

Truly Random Control

In the truly random control procedure developed by Robert Rescorla, the CS and the US are both presented as frequently as in the experimental condition, but they are presented independently with respect to each other. To use the rat autoshaping example described above, a truly random control group might receive presentations of the 15-s lever CS with a mean ITI of 90 s. Deliveries of the food pellet US would be programmed to occur at varying intervals that also have a mean of 90 s. However, the schedules controlling the varying intervals at which each stimulus is presented would operate independently. This would mean that the lever and the food pellet would occasionally be presented together by chance, in contrast to the explicitly unpaired procedure where they would never be presented together.

Because in the truly random control procedure the likelihood of the US occurring during the CS is the same as the likelihood of the US occurring during the absence of the CS, there is no contingency between the CS and US. Therefore, the CS should become a true control stimulus, without either excitatory or inhibitory properties.

Contiguity, Contingency, and Predictive Value

Temporal Contiguity

Pavlov believed that the most essential factor for the learning of a classically conditioned response was the temporal contiguity of the CS and US. This was based on his observation that a CR readily developed when the CS preceded and overlapped with the US, but not when

this temporal relation was absent. More recent work has shown that temporal contiguity between the CS and US plays an important role, but that such contiguity is not sufficient for associative learning and that the effects of CS-US temporal relations vary depending on the specific conditioning preparation that is used.

Contingency

Research by Rescorla demonstrated that contingency between the CS and US is necessary for the learning of Pavlovian associations. Contingency refers to the degree to which presentation of the US depends on the prior presentation of the CS. If the US is more likely to occur when the CS has been presented than when the CS has not been presented, then there is a positive contingency between the CS and US. This arrangement produces excitatory conditioning as evidenced by the CS's elicitation of CRs. If the US occurs following presentation of the CS just as frequently as it occurs when the CS has not been presented, then there is no contingency between the CS and US. This zero contingency does not produce learning of an association between the CS and US. If the US occurs less frequently when the CS is presented than when the CS is not presented, then there is a negative contingency between the CS and US. This type of contingency may lead to inhibitory conditioning.

Predictive Value

In experiments by Leon Kamin, a noise stimulus was paired with a shock US in a first phase. Subjects learned this noise-US association and the noise came to elicit a conditioned fear response. Then, in a second phase, the noise was presented simultaneously with a light and this noise + light compound stimulus was paired with the shock US. Even after many pairings of the noise + light compound with shock, the light did not elicit any conditioned fear when it was presented by itself despite the facts that (1) the light was always paired with the shock US, and (2) the light elicited a strong conditioned fear response in a control group that did not experience the phase 1 training where the noise alone was paired with shock.

This phenomenon is known as 'blocking' because the conditioning history of the noise prevented, or blocked, learning about the light. Blocking has been explained in terms of CS information value or predictiveness. When the light was presented simultaneously with the noise in phase 2 of the experiment described above, it did not provide any new information relevant to the occurrence of the shock US. This is because the shock was already fully predicted by the noise.

Blocking and related findings indicate that an essential condition for the formation of CS-US associations is that the CS must provide nonredundant information relevant to the occurrence of the US. If the outcome that follows a stimulus is already fully predicted and expected, then no learning about that stimulus results because it provides no valuable predictive information. If the outcome that follows a stimulus was not yet fully predicted, then learning about that stimulus occurs. That is, associative learning is a function of the discrepancy between the outcome that the CS predicts and the outcome that actually occurs (i.e., the US). The idea that this discrepancy, or prediction error, drives learning is the basis of error-correction theories of Pavlovian conditioning, such as the influential Rescorla-Wagner model.

Allocentric – An other-centered spatial frame of reference, which is independent of the organism's current viewpoint or location.

AMPAR – The α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPA). AMPARs are ionotropic ligand-gated receptors for glutamate that mediate fast synaptic transmission in the central nervous system and are essential for the maintenance and expression of long-term potentiation (LTP). AMPARs are composed of four subunits, previously known as GluR-A to GluR-D or alternatively as GluR1 to GluR4, but now known as GluA1-4. In this article, we use the nomenclature of the original cited studies (i.e., GluR-A).

Egocentric – A self-centered spatial frame of reference, which is dependent on the organism's current viewpoint or location.

GluR-A – A subunit of the AMPAR, which has been selectively knocked out in GluR-A^{-/-} mice. These mice are deficient in certain aspects of LTP.

Long-term potentiation (LTP) – An experimental model of the type of synaptic plasticity that may provide the neural substrate for learning and memory. In practice, LTP refers to a long-lasting increase in synaptic efficacy that follows stimulation of a chemical synapse.

Spatial reference memory – A form of hippocampal-dependent, long-term memory which involves the formation of associations between particular spatial locations and specific outcomes, such as associating one arm of a maze with food reward or associating the location of a fixed platform with escape from an aversive environment. GluR-A^{-/-} mice are not impaired in spatial reference memory tasks.

Spatial working memory – A form of hippocampal-dependent, short-term memory, which requires the ability to distinguish between the relative familiarity of previously encountered spatial locations. GluR-A^{-/-} mice are impaired in spatial working memory tasks.

Introduction

The ability to learn and remember spatial locations, and to associate them with other stimuli, is essential for adaptive behavior. Birds need to remember nesting sites or where they have cached food; rodents need to learn about

their surroundings to locate provisions and avoid predators; humans need to navigate complex environments, such as cities. A network of brain regions is involved in spatial learning and memory, including the hippocampus, dorsal striatum, and the entorhinal, retrosplenial, prefrontal, and parietal cortices. Different types of spatial representation may recruit different components of this network. For example, some spatial tasks can be solved purely on the basis of egocentric (self-centered) information (e.g., vestibular, proprioceptive, or sensory cues) that will change every time the animal moves. In contrast, other spatial tasks require encoding of the relationship between salient features of the environment to create an allocentric (other-centered) representation that is independent of the animal's current location. Such a representation has been termed a 'cognitive map.' This article concentrates on animal studies of allocentric spatial learning and describes some of the dominant models that have been used to investigate spatial learning and memory, with particular focus on studies of the hippocampus and related brain structures in rodents.

The Hippocampus and Allocentric Spatial Learning

Evidence from a variety of sources suggests that the human hippocampus plays an important role in spatial memory. Human patients with hippocampal pathology, whether as a result of surgery, ischemic brain damage, or as a consequence of clinical conditions such as Alzheimer's disease, have problems with spatial orientation and get lost even in surroundings with which they have considerable experience. Moreover, normal, healthy individuals exhibit activation of brain areas in the hippocampal formation during functional neuroimaging, when performing navigational tasks in virtual reality environments. Interestingly, in structural magnetic resonance imaging (MRI) studies, London taxi drivers with many years experience of navigating around a busy city were found to possess larger hippocampi than age-matched controls. Spatial information is likely to provide an important contextual cue for retrieving other memories, and thus it has been widely suggested to be a key component of human episodic memory.

In rodents, hippocampal lesions impair allocentric but not egocentric spatial memory. There has been considerable debate as to what constitutes an allocentric spatial cue or

what makes a behavioral task spatial in nature (it certainly should not be defined on the basis of sensitivity to hippocampal lesions). It is generally considered that spatial cues are complex, multimodal representations of the environment, comprising information from different sensory modalities, and diffuse in nature. O'Keefe and Nadel proposed two distinct systems to guide spatial learning and memory. The first of these, the taxon system, utilizes egocentric cues and specific behavioral responses to specific landmarks or stimuli (e.g., always turn right, always approach stimulus X, always avoid stimulus Y, etc.) to allow for route-based navigation. The second system, the locale system, underlies allocentric spatial encoding and the formation of a cognitive map of the environment. The locale system provides the mechanism for solving the conflict that arises when it is not always the correct thing to do to approach stimulus X or avoid stimulus Y. In such situations, by using current position and/or heading direction, the correct response can be selected for efficient navigation to occur. O'Keefe and Nadel proposed that the locale system is hippocampal dependent with place cells as its basic functional units (see below).

Electrophysiological Correlates of Spatial Processing

Place Cells in the Hippocampus

Although scientists had studied rats in mazes since the early twentieth century, it was not until the 1970s that spatial processing was linked to a specific neural substrate. The breakthrough came when O'Keefe and colleagues found cells in the hippocampi of behaving rats that selectively increased their firing rate only when the rat occupied a well-defined region of the environment, the place field, and rarely fired outside the place field. Logically, these cells were named place cells. (NB: It is important to note that the firing rate of hippocampal neurons has also been shown to correlate with nonspatial stimuli in other experimental situations.)

In open-field arenas, place cells are nondirectional in that they will fire irrespective of the direction from which the animal enters the place field (see **Figure 1(a)**). This suggests that place cells are not dependent on specific sensory input such as the local view of the animal. Subsequent studies found that place fields can be altered in predictable ways by manipulating the spatial environment. For example, rotating salient cues around the testing arena causes the place fields to rotate accordingly. Further, when several cues are present, removing one or two cues typically does not abolish the place field. These results argue that place cells depend on the configuration of distal (extramaze) cues rather than specific local (intra-maze) cues, and as such place cells exist within an allocentric frame of reference.

However, on linear tracks or mazes, many place cells only fire when the animal enters the place field from a particular direction, demonstrating that the egocentric local view can influence place-cell activity. Moreover, place cells do not require visual input at all as they develop normally in rats that are blind from birth and can remain stable in sighted rats when tested in the dark. Thus, in addition to extramaze visual cues, it is likely that rodents can use local olfactory, auditory, and somatosensory cues as well as vestibular, proprioceptive, and other motor signals to help maintain a representation of their current location within the environment.

Movement is particularly important for place cells as they tend only to fire when the animal moves through the place field and not when it is immobile within the place field. More specifically, the firing rates of place cells are modulated by spatial location only in the presence of theta activity, the regular 5–12 Hz oscillation in hippocampal electroencephalogram (EEG) that occurs during voluntary behaviors such as walking, running, and swimming. Within a given place field, a place cell will fire in bursts at different phases of theta. When entering the place field, the place cell fires at the late phase of theta and as the animal traverses the place field, the firing bursts occur at progressively earlier stages in the theta cycle, so-called phase precession.

Although there is no obvious topographical organization of place cells, recent investigations have shown that the spatial resolution of place cells differs systematically along the longitudinal (septo-temporal) axis of the hippocampus. Place field size progressively increases (i.e., spatial resolution decreases) from the septal (dorsal) to the temporal (ventral) pole of the rat hippocampus, suggesting that the environment is mapped simultaneously at many different spatial resolutions.

Of course, knowing your current location (information potentially provided by hippocampal place cells) is necessary, but not sufficient, for successful navigation. The cognitive map proposed by O'Keefe and Nadel requires not only information about individual places but also information about the direction and distance between places. Evidence for cells that can provide this directional and distance information came from the discovery of head direction (HD) cells in the dorsal presubiculum (and anterior thalamus) and grid cells in the entorhinal cortex, respectively.

Head Direction Cells in the Presubiculum

HD cells, first reported by Ranck and colleagues, signal a single preferred head direction, irrespective of body orientation or current position; whether the animal is moving or stationary (see **Figure 1(c)**). HD cells appear to be controlled by distal sensory input and, like place cells, realign to the rotation of salient environmental cues.

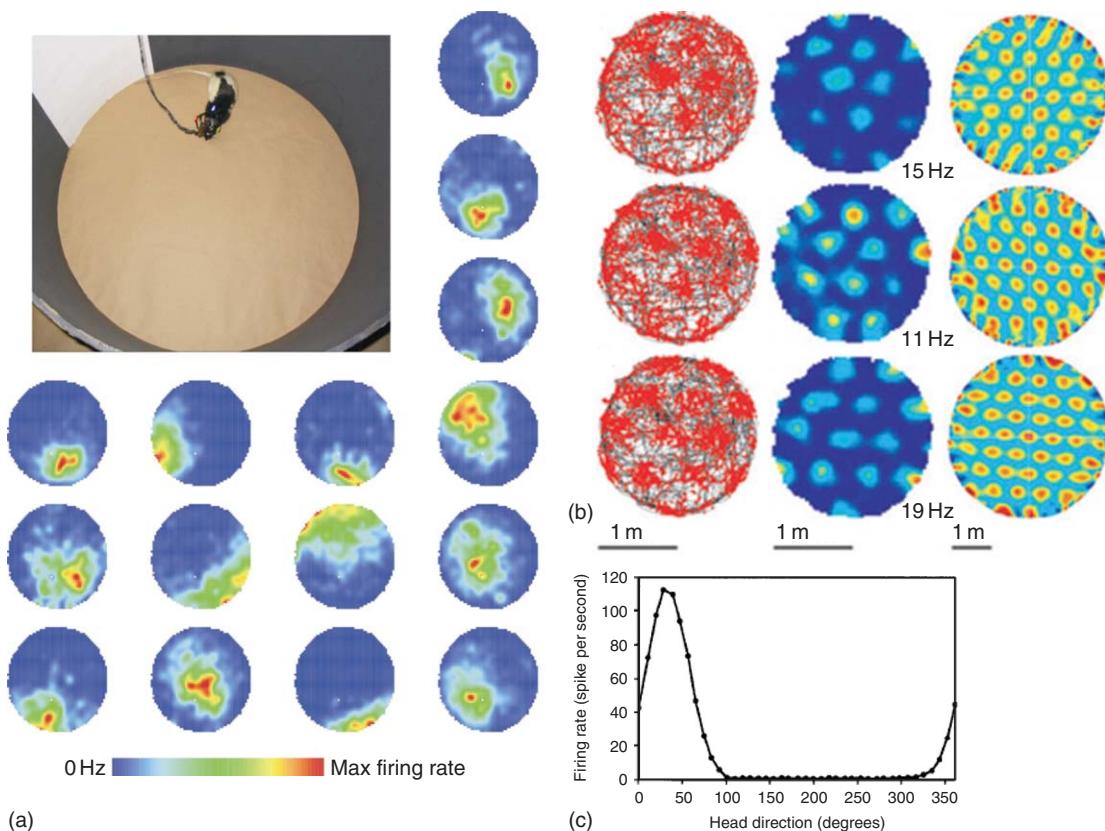

Figure 1 Place cells, grid cells, and head direction cells. (a) Place cells in the hippocampus. Place fields recorded from the hippocampus of a freely moving rat. The picture shows a rat implanted with 16 tetrodes in the hippocampus foraging for food pellets in a circular open-field (75 cm diameter). The 15 density plots represent the firing rate of 15 pyramidal cells at different locations within the open-field. The cells fired only when the rat was at a specific location in the open-field. (b) Grid cells in the entorhinal cortex. Firing fields of three simultaneously recorded cells from layer II of the dorsal medial entorhinal cortex during a 30 min session in a large circular enclosure. Left column, trajectory of the rat (black) with superimposed spike locations (red). Middle column, color-coded rate map with the peak rate indicated. Red is maximum, dark blue is zero. Right column, spatial autocorrelation for each rate map. The color scale is from blue ($r = -1$) through green ($r = 0$) to red ($r = 1$). (c) Head direction cell in the postsubiculum. The plot shows firing rate against head direction for one cell in the postsubiculum. The firing rate is above a background rate of 0 spikes per second for a $\sim 90^\circ$ range of head directions centered on 27° . (a) Unpublished data from Kevin Allen, used with permission. (b) Adapted with permission from Hafting T, Fyhn M, Molden S, Moser M-B, and Moser EI (2005) Microstructure of a spatial map in entorhinal cortex. *Nature* 436: 801–806. (c) Adapted with permission from Müller RU, Ranck JB, Jr, and Taube JS (1996) Head direction cells: Properties and functional significance. *Current Opinion in Neurobiology* 6: 196–206.

Importantly, even when the environmental cues controlling HD cells are disrupted, the angular distance between any two HD cells remains constant. This constancy provides a fixed frame of directional reference for the animal.

Grid Cells in the Entorhinal Cortex

It is likely that HD cells exert their influence on hippocampal place cells via grid cells in the medial entorhinal cortex (MEC), which were first reported by the Moser group in 2005. Unlike hippocampal place cells, which fire in only one part of a given environment, grid cells fire at several regularly spaced locations, with marked inhibition of firing outside of these locations. Thus, a map of peak firing rates resembles a hexagonal lattice (see Figure 1(b)). The distance between grid-cell firing locations depends on

the depth of the recording site on the dorsal–ventral axis of the MEC. Cells recorded from the dorsal MEC have a short distance between firing locations and thus code distance on a fine scale. The distance between firing locations progressively increases from dorsal to ventral MEC, and this change in scale maps onto the increase in place field size along the dorsal–ventral axis of the hippocampus. Thus, grid cells could provide the distance metric by which space is coded.

In summary, detailed electrophysiological investigations in the last 40 years have laid the foundations for subsequent neurobiology theories of spatial learning and memory. However, electrophysiological experiments are correlational by nature – they can tell us that a cell responds under certain circumstances but they cannot tell us that this response is necessary for the

accompanying behavior. Thus, to demonstrate that a particular anatomical structure or neurobiological feature is necessary for a particular behavior, researchers use interference methods. Chief among these techniques are selective brain lesions, pharmacological interventions, and genetic manipulations. Critically, these techniques must be combined with the appropriate behavioral paradigms.

The Morris Watermaze Task

Perhaps the most influential behavioral paradigm demonstrating hippocampal-dependent spatial learning and memory is the watermaze task, devised by Morris in the early 1980s. In this task, rodents have to locate a hidden escape platform submerged just beneath the surface of the water in a large cylindrical tank (e.g., ~2 m diameter for rats). The water is made cloudy by adding milk or non-toxic paint to ensure that the animal cannot see the submerged platform. Therefore, the animal must use the extramaze cues around the room to form an allocentric representation of the environment, including the platform location.

In the standard reference memory version of the task, the animal is trained to the same fixed platform location over several days. Platform locations should be counterbalanced between experimental groups to counteract unconditioned preferences for particular areas of the pool (e.g., half of the animals in the control and experimental groups might be trained to a platform in the

northwest quadrant, while the remaining animals are trained to a southeast quadrant location). Although the platform remains in the same position throughout training, crucially, the starting position changes on each trial to prevent the use of egocentric strategies (e.g., body turn). During acquisition, subjects are given a time limit to find the platform (e.g., 120 s) and those that fail can be guided or placed on the platform by the experimenter. The subject is then allowed to remain on the platform for a short period (e.g., 30 s). Learning is assessed by measuring the amount of time or, preferably, the swimming path length taken to find the platform over successive trials. Importantly, spatial memory of the platform location is then also assessed specifically using a probe trial (transfer test) in which the platform is removed from the pool and the subject allowed to swim freely for a set time (e.g., 60 s). Subjects that remember the platform location spend more time searching in the appropriate part of the pool. Accurate measurement of time, distance, and swim speed can be made using a ceiling-mounted camera and specialized tracking software. Control tasks can be used to ensure that impaired performance is not due to sensorimotor or motivational deficits. For example, rats can be made to swim to a visible platform or a highly salient cue can be used as a beacon to indicate the platform location.

Hippocampal lesions made before training dramatically impair both the acquisition stage of the watermaze task and performance in the transfer test (Figure 2). Hippocampal lesions made after training also impair retrieval; with a flat gradient of retrograde amnesia observed in rats lesioned up to 3 months after the initial

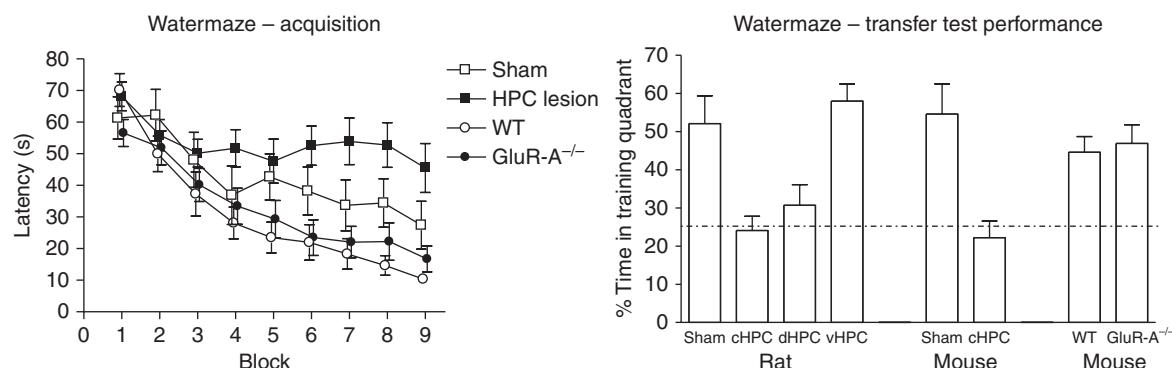

Figure 2 Watermaze. *Watermaze acquisition:* Complete and dorsal hippocampal lesions but not GluR-A deletion impair transfer test performance following training on the standard, fixed location, hidden escape platform, (spatial reference memory) version of the Morris watermaze task. *Transfer test performance:* Mean percent time in the training quadrant (\pm SEM) during a probe trial in which the platform is removed from the pool and the rats allowed to swim freely. Left: Performance of sham, complete (cHPC), dorsal (dHPC), and ventral (vHPC) lesioned rats. Center: Performance of sham and complete (cHPC) hippocampal lesioned mice. Right: Performance of wild-type and GluR-A-knockout mice. Broken line equates to chance performance (25%). *Transfer test performance:* (Left) Reproduced with permission from Bannerman DM, Yee BK, Good MA, et al. (1999). learning. Hippocampal-lesioned animals are not impaired when a visible platform is used, arguing against a sensorimotor or motivational explanation of the deficit.

More recent work has shown that tissue at the septal end of the hippocampus (dorsal hippocampus in rodents) is more important for watermaze spatial learning than tissue at the temporal end (ventral hippocampus; **Figure 2**, right panel). Moser and colleagues found that the severity of the watermaze impairment was proportional to the degree of dorsal hippocampal damage and that relatively small volumes of dorsal tissue (25–30%) could support water maze acquisition and retrieval. This finding is consistent with the higher spatial resolution exhibited by dorsal hippocampal place cells and dorsal MEC grid cells. However, ventral hippocampal lesions made after training can impair subsequent retrieval and, under certain training regimes, the ventral hippocampus does appear able to support spatial learning in the standard reference memory task. Thus, it is important not to exclude the ventral subregion from a role in spatial processing altogether.

Studies of lesioned animals can inform as to whether a particular brain region is necessary for a particular task but they offer little insight into the physiological or molecular mechanisms that underlie normal memory function. Importantly, experiments using pharmacological manipulations or transgenic mouse studies, in which specific neurobiological mechanisms can be targeted, have revealed dissociations between different types of spatial memory that were not evident on the basis of lesion studies.

Hippocampal Long-Term Potentiation and the Spatial Learning Hypothesis

Donald Hebb suggested that memories are stored as changes in the strength of the synaptic connections between neurons. The subsequent discovery that high-frequency stimulation of an input pathway (e.g., the perforant pathway from the entorhinal cortex to the dentate gyrus) can produce long-lasting changes in synaptic efficacy has led to long-term potentiation (LTP) becoming the dominant experimental model of the cellular mechanisms of learning. It has been widely suggested that LTP-like events in the hippocampus might underlie allocentric, hippocampus-dependent spatial learning abilities. The induction of LTP is dependent on the activation of N-methyl-D-aspartate receptors (NMDARs). Its subsequent maintenance and expression are thought to involve changes in α -amino-3-hydroxy-5-methyl-4-isoxazolopropionate receptor (AMPAR) number and function in the postsynaptic neuron. Thus, the 'hippocampal LTP/spatial learning hypothesis' can be tested by interfering with these receptors and assessing the consequences on spatial learning.

Experiments by Morris and colleagues confirmed that blocking NMDARs, by infusing the NMDAR antagonist 2-amino-5-phosphopentanoate (AP5) into the cerebral ventricles, impaired reference memory acquisition in the watermaze at concentrations that also blocked LTP *in vivo*. However, subsequent experiments showed that rats treated with AP5 were in fact capable of forming an association between a spatial location and the platform, and of navigating to that location, if they had received watermaze pretraining prior to testing with the drug.

Genetic Manipulations of NMDA and AMPA Receptors

The hippocampal LTP/spatial learning hypothesis has also been tested in numerous studies of genetically modified mice in which key proteins required for either the induction or expression of LTP are deleted, altered, or overexpressed. For example, mice lacking the GluR-A (also known as GluR1 or GluA1) subunit of the AMPA receptor (GluR-A^{-/-} mice) are particularly deficient in the early component of LTP in the Schaffer collateral pathway (CA3 → CA1) yet they show normal acquisition and retention in the standard reference memory watermaze task. However, they are profoundly impaired on tests of spatial working memory. The concept of distinct working memory and reference memory systems was first proposed by Honig and developed by Olton and colleagues, primarily on the basis of studies using the radial arm maze (see below). It is important to note that the term working memory has been used by different researchers to reflect different processes. For example, researchers working with primates use working memory to refer to a short-term, online system supported by frontal lobe structures. In the present context, however, we use the term to refer to a flexible short-term memory system in which conditional, trial-specific information is used to select between response options that are variably correct or incorrect, and which is dependent on the hippocampal formation.

Simultaneous Dissociation of Spatial Reference and Working Memory

Spatial reference and working memory can be assessed simultaneously in the same animals using a radial maze. The radial maze consists of a number of arms (commonly 6, 8, or 12) radiating out from a central area like spokes on a wheel. The aim of the task for the animal is to collect hidden food rewards located at the ends of the arms by using the distal extramaze cues around the laboratory. Because the food rewards are not replaced, the animal has to adopt a win-shift strategy and remember which arms it has already visited. This provides a test of spatial working memory. By baiting only certain arms but always

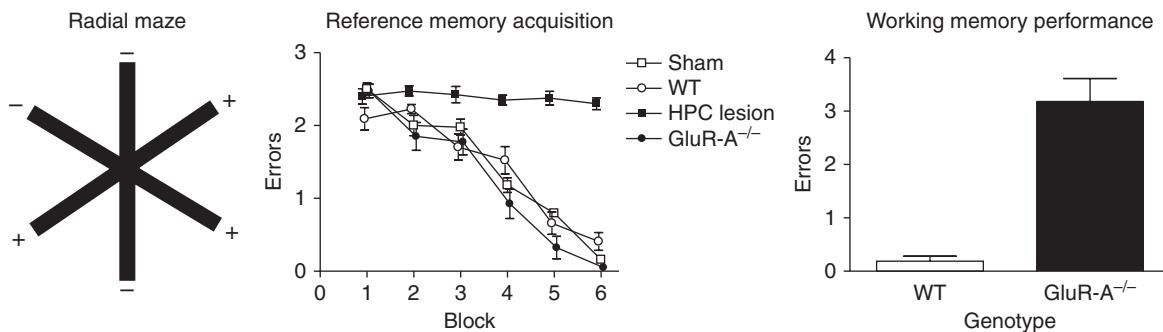

Figure 3 Radial arm maze. Hippocampal lesions but not GluR-A deletion impair acquisition of the spatial reference memory component of the radial maze task. *Left:* Mice were trained to discriminate between three baited arms (+) and three nonbaited arms (−) of a six-arm radial maze. Doors prevented mice re-entering arms they had already visited on that particular trial (i.e., the doors prevented working memory errors) during this stage of the experiment. *Middle:* Mean number of reference memory errors per trial (\pm SEM) during six blocks of training (four trials per block). Sham lesioned (white squares), wild-type (WT: white circles), and GluR-A-knockout mice (GluR-A^{-/-}: black circles) all acquired the task at an equivalent rate. Hippocampal lesioned mice (HPC: black squares) were completely unable to learn which arms were baited and which arms were not baited. *Right:* GluR-A deletion impairs spatial working memory performance on the six arm radial maze task. Mice were still rewarded in the same three arms of the maze and not rewarded in the three nonbaited arms, but now they were allowed to re-enter arms as often as they liked, and rewards were not replaced within a trial. Mean number of working memory errors per trial (\pm SEM) for wild-type (white bar) and GluR-A-knockout mice (GluR-A^{-/-}: black bar). Reproduced with permission from Schmitt WB, Deacon RM, Seuberg PH, Rawlins JN, and Bannerman DM (2003) A within-subjects, within-task demonstration of intact spatial reference memory and impaired spatial working memory in glutamate receptor-A deficient mice. *Journal of Neuroscience* 23: 3953–3959.

baiting the same arms, spatial reference memory can be assessed simultaneously (Figure 3, left panel).

For example, mice can be first trained to discriminate between three baited and three never-baited arms on a six-arm maze. Once an arm has been chosen, a door prevents access to that arm for all subsequent choices during the rest of that trial. This prevents the animals from making working memory errors during the reference memory acquisition phase. This is important because working memory errors made during initial training can interfere with reference memory acquisition. Reference memory errors (maximum of 3) are scored when an animal enters a never-baited arm. This measure provides a pure test of spatial reference memory acquisition and rats or mice with hippocampal lesions are impaired on this stage of the task. GluR-A^{-/-} mice successfully acquire the 3/6 spatial reference memory task, making progressively fewer errors as training proceeds, and they are perfectly able to associate a particular arm with reward (Figure 3, middle panel).

Once at a high level of performance, the working memory component of the task is now introduced. The same three rewarded arms are baited as before but now the mice are allowed free access to all arms on each choice and thus can re-enter arms that have previously been visited on that trial. As the rewards are not replaced within a trial, efficient performance relies on a win-shift strategy. Under these circumstances, GluR-A^{-/-} mice continue to make few reference memory errors (they rarely visit the never-baited arms) but they make significantly more spatial working memory errors than their

wild-type counterparts (Figure 3, right panel). In other words, GluR-A^{-/-} mice learn which arms are never baited but cannot remember which arms they have recently visited. This radial maze procedure is important because it clearly dissociates working memory and reference memory spatial processes within the same animals and the same trials, with the same sensorimotor and motivational demands, and using the same spatial cues to guide performance.

T-Maze Alternation

Spatial working memory can also be assessed on a simple T-maze using a discrete trial, rewarded-alternation procedure. In this task, each trial has two runs. In the sample run, one of the goal arms is blocked off, forcing the animal to enter a particular goal arm (e.g., the left arm), whereupon it receives a reward. Prior to the subsequent choice run, the block is removed and the animal is then given a free choice of either arm. If the animal re-enters the previously visited arm, it receives no reward; if it enters the alternate arm (e.g., the right arm), it does receive a reward (see Figure 4, top panel). Thus, accurate performance depends on remembering which arm was visited most recently during the sample run in order to guide appropriate responding in the choice run, with the correct spatial response varying from one trial to the next. The amount of time between the sample and choice runs can be varied to increase/decrease the working memory demands. Rewarded alternation cannot be solved by a fixed association between reward and location because

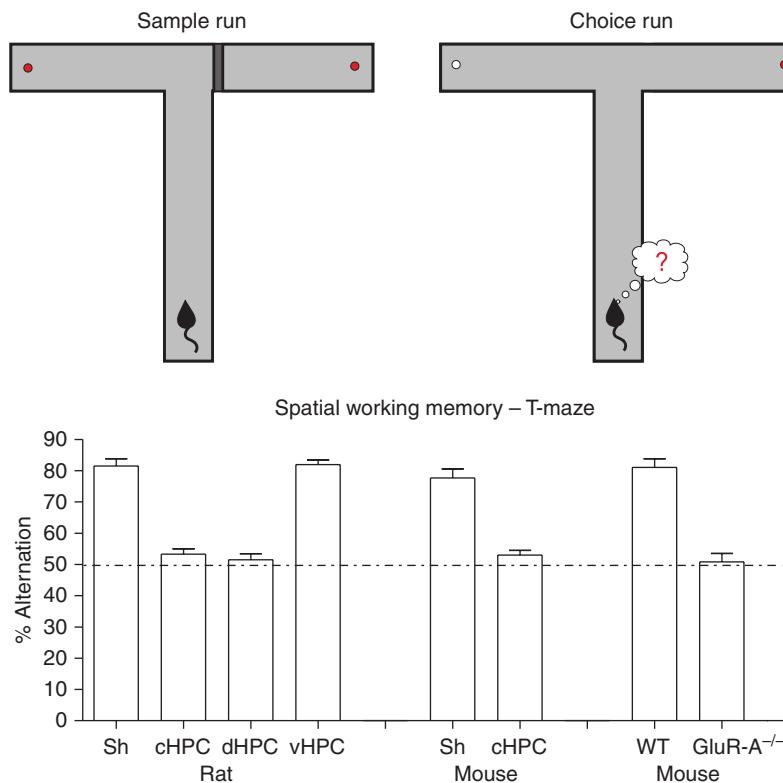

Figure 4 T-maze rewarded alternation. Hippocampal lesions and GluR-A deletion both impair spatial working memory performance during non-matching to place testing (rewarded alternation) on the elevated T-maze. *Top:* During a sample run (*left*) mice are forced into either the left or right goal arm, according to a pseudorandom sequence, and receive a milk reward. During the choice run (*right*) the animals are required to go to the opposite (previously unvisited) goal arm for a second milk reward. Many trials are run over a period of time with the identity of the arm visited on the sample run varying pseudo-randomly. *Bottom:* Mean percentage of trials on which the mouse alternated successfully (\pm SEM). *Left:* Performance of sham, complete (cHPC), dorsal (dHPC), and ventral (vHPC) lesioned rats., *Center left:* Performance of sham and complete (cHPC) hippocampal lesioned mice (unpublished), *Center right:* Performance of wild-type and GluR-A-knockout mice. (*Left*) Reproduced with permission from Bannerman DM, Deacon RM, Offen S, et al. (2002) Double dissociation of function within the hippocampus: Spatial memory and hyponeophagia. *Behavioral Neuroscience* 116: 884–901. (*Center left*) unpublished. (*Center right*) Reproduced with permission from Reisel D, Bannerman DM, Schmitt WB, et al. (2002) Spatial memory dissociations in mice lacking GluR1. *Nature Neuroscience* 5: 868–873.

both arms are rewarded to an equal extent over the many trials of a session. Further, by pseudo-randomizing the allocation of the sample runs to the left and right arms, a continuous alternation strategy is insufficient for optimal performance. Rodents with hippocampal lesions display chance levels of performance on this task. GluR-A^{-/-} mice are also impaired, and also perform at chance levels (see Figure 4, bottom panel), despite their perfectly normal spatial reference memory performance on tasks like the watermaze. Rewarded alternation is also profoundly sensitive to direct infusion of AP5 into the dorsal hippocampus.

Rodents have a natural tendency to alternate their choice of goal arm on the T-maze, in much the same way as they demonstrate win-shift behavior on the radial-maze spatial working memory task. Therefore, they often demonstrate high levels of alternation immediately (typically $>80\%$). In fact, animals do not need to be appetitively rewarded to show this behavior; and in this

case it is called ‘spontaneous alternation.’ This likely reflects short-term habituation to the more familiar arm that was experienced on the most recent sample trial. This can be illustrated with a one-trial spatial novelty preference test.

Spontaneous Spatial Novelty Preference

Conceptually, this task is equivalent to a single trial of spontaneous alternation. In the first stage, the rat or mouse is exposed to two arms of a Y-maze for 5 min. These two arms are designated the start arm and the familiar arm. The novel arm is blocked off during this initial exposure (see Figure 5, top left panel). The animal is then removed from the maze for 1 min and the door to the novel arm is opened. The animal is then placed back into the start arm and allowed to explore all three arms for two minutes (see Figure 5, top right panel). Normal rats and wild-type mice will spend more time in the novel arm

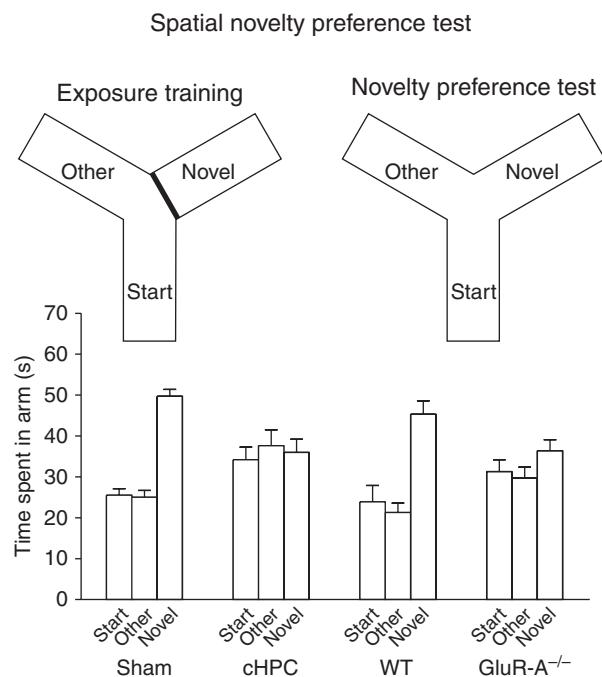

Figure 5 Spatial novelty preference. Hippocampal lesions and GluR-A deletion both impair performance on a spatial novelty preference test. Sham and wild-type (WT) mice exhibit a preference for a previously unexposed (Novel) arm of a Y-maze over two familiar arms to which they have previously been exposed (Start and Other). GluR-A knockout mice and hippocampal lesioned mice do not show a significant preference for the novel arm. Reproduced with permission from Sanderson DJ, Gray A, Simon A, et al. (2007) Deletion of glutamate receptor-A (GluR-A) AMPA receptor subunits impairs one-trial spatial memory. *Behavioral Neuroscience* 121: 559–569.

than the familiar during this test phase, reflecting their habituation to the recently experienced familiar arm(s). Hippocampal lesioned mice show no preference. Similarly, GluR-A^{-/-} mice are also impaired in this task, showing no preference for novel over familiar arms (see **Figure 5**, bottom panel), despite their normal spatial memory performance in the watermaze.

The preference that normal animals show for the novel arm during the spontaneous spatial novelty preference task likely reflects their short-term habituation to the two familiar arms during the initial exposure phase. Similarly, during win-shift behaviors on appetitive maze tasks, normal animals choose relatively more novel over more familiar arms. In contrast, spatial reference memory performance reflects the ability to form associations between spatial locations and outcomes (e.g., an escape platform or food reward). Thus, the impaired spatial working memory observed in GluR-A^{-/-} mice on the radial maze and during T-maze rewarded alternation reflects the fact that GluR-A mediates short-term habituation to recently visited spatial locations, based on a nonassociative memory for the relative familiarity of that

recently visited place. Associative, long-term spatial memory, as typified by performance on reference memory tasks, is GluR-A independent. This division of spatial memory processes into short-term, nonassociative and long-term, associative mechanisms is, in principle, similar to the dual-process memory models that have been proposed for nonspatial stimuli. Thus, although spatial and nonspatial information processing may, to some extent, be subserved by different brain regions, the same basic learning rules and models may apply.

Conclusions

In summary, converging evidence argues that the hippocampal formation is critical for allocentric spatial learning and memory. More recent evidence suggests that separate, dissociable mechanisms may underlie spatial working memory (short-term, nonassociative) and spatial reference memory (long-term, associative). The latter is unimpaired in GluR-A^{-/-} mice. In contrast, performance on spatial working memory tasks, which relies on short-term memory processes, is GluR-A-dependent and could reflect a rapidly induced, short-lasting component of synaptic plasticity; although the direction of the plasticity change (increase or decrease) remains to be established.

Future Directions

Over the last 40 years, great progress has been made in characterizing the anatomical and cellular substrates of spatial learning and memory. However, the repertoire of spatial behaviors in mammals is vast and complex and we are a long way from a complete account. For example, we know little about how different brain areas communicate to facilitate spatial navigation. Moreover, it remains to be determined whether allocentric spatial information is processed within a specialised network or whether spatial information processing is just one manifestation of a more general cognitive process that also applies to certain aspects of nonspatial processing. Answering these questions will pose some of the major challenges for behavioral neuroscientists in the twenty-first century.

Glossary

Aging – A process that accumulates physiological, psychological, and social changes in an organism over time.

Alzheimer's Disease – A neurodegenerative disorder named after the German psychiatrist, Alois Alzheimer, who first described the hallmarks of the brain symptoms associated with progressive dementia.

Animal model – Animal preparation used to mimic and study a normal or pathological human condition.

Construct validity – A validation approach designed to determine the degree to which an animal model incorporates relationships across multiple levels (molecular, cellular, systems, and functional) of analysis as proposed by theory.

Dementia – Dementia describes an advanced state of declining cognitive functions due to neurodegeneration.

Mild Cognitive Impairment (MCI) – A syndrome characterized by cognitive impairments that are greater than expected for an individual's age and education level but that does not interfere in everyday activities. MCI is widely considered a precursor state of Alzheimer's disease.

descending a stairway), which may reflect limitations in attentional capacities.

Research on the neuronal mechanisms mediating such age-related decline in cognitive capacity in humans is largely limited to neuroimaging. This research demonstrated that older adults engage different and often more – including more bilateral – brain regions, and often exhibit greater activity in key brain regions in order to match the cognitive performance of younger adults. These findings corroborate cognitive analyses suggesting that age-related change in cognitive capacity is not merely due to a loss of function, but that older brains process information qualitatively differently.

Such expansion of brain systems recruited by the aging brain has been suggested to reflect the additional cognitive operations, or efforts, that are required to perform a cognitive task. Greater demands on top-down control of cognitive operations, perhaps associated with a more effective suppression of competing operations, require more processing resources and thus the participation of more regions across the two hemispheres. A more pessimistic, competing hypothesis suggests that additional activity of brain regions reflects the relative inability to suppress competing cognitive activity and the de-specialization or de-differentiation of neuronal systems. Perhaps both hypotheses are correct and refer to different stages of decline, with the latter one predicting a more severe loss in cognitive capacity. This view is also supported by evidence showing that patients with Alzheimer's disease may initially activate brain regions similar to healthy subjects but then fail to deactivate these regions later during the performance of the task.

The evidence obtained from research on the cognitive functions and capacity of aged but nondemented humans – a focus of this article – provides understanding of the cognitive mechanisms and variables that need to be modeled in animals for research on underlying neuronal mechanisms. Attentional impairments, particularly resource limitations – whether resulting from impaired top-down mechanisms and inadequate suppression of competing cognitive activity or true decline in processing capacity – are key cognitive mechanisms that would need to be reproduced in animal models. Tasks for various aspects of attentional functions and capacities have been developed and validated for use in laboratory rodents. Therefore, this component of animal models can be readily implemented.

Cognitive Targets and the Nature of Models

Cognitive performance of aging, nondemented human beings is characterized by slower processing speeds, de-automation of the performance of habits, well-practiced skills and cognitive operations, and reduced attentional capacities, particularly with respect to the ability to divide attentional resources between competing tasks and to switch between tasks ('resource-reduction hypothesis'). These impairments are not restricted to situations that require coping with multiple demands explicitly for cognitive operations. For example, the age-related increase in the incidence of falling and the severity of fall-related consequences have been suggested to be due in part to the more effortful processing required by older people to perform complex movements (such as

In contrast, the literature on age-related cognitive decline in humans provides little guidance for selecting specific neuronal alterations that would be hypothesized to mediate the age-related cognitive decline discussed above. Although there is a substantial amount of data that describes a wide range of morphological and neurochemical changes in the aging brain, evidence that would directly relate such changes to specific aspects and mechanisms of cognitive decline is scarce. This situation causes a major challenge for the validation of animal models. How is one to validate an animal model when the human evidence on cognitive aging does not provide neurobiological benchmark data to directly validate the model? However, this situation is not that different from the challenges of modeling most neuropsychiatric disorders. In the absence of evidence obtained directly from the modeled condition, evidence about the basic neuronal mechanisms that mediate the cognitive functions of interest, and the theories that summarize and conceptualize this basic evidence, may be employed to validate a model.

While such an approach may, at first glance, appear disappointing relative to the modeling of ‘hard facts,’ it represents a productive scientific perspective. First, an animal that reproduces only a neuronal mechanism *per se* does not constitute a model; likewise, a cognitive task is not a model (it is a task). An animal model consists of a model of brain–behavior relationships that reproduces both neuronal and cognitive mechanisms and demonstrates precise relationships between the two levels of analysis (see **Figure 1**).

This view implies that an animal model always represents a theory of the condition to be modeled, and as such, the model itself is subject of research on basic brain–behavior relationships. This is called construct validation; it is the most useful aspect of validity and thus deserves more consideration.

Construct Validity and Other Modeling Issues

The literature examining the validity of animal models is littered with classification schemes, but rarely addresses the perennial question: which model should I choose to model age-related cognitive decline? Should I use senescent rats for my research? Or should I create a lesion of a brain system to produce impairments, or somehow produce abnormal amyloid accumulation, or tangles, or what? Construct validity suggests that these are the wrong questions to ask. The correct question would be: How can we test the cognitive functions of interest in animals? What do we know about the neuronal systems that mediate the cognitive functions of interest? How can we employ the (scarce) information about age-related changes in relevant neuronal systems to produce decline in this neuronal system and thereby cognitive decline? Stated simply, we will use existing biopsychological theories to build a model and then study the relationship between manipulations of key neuronal systems and cognitive decline. Such an approach entails the obvious risk

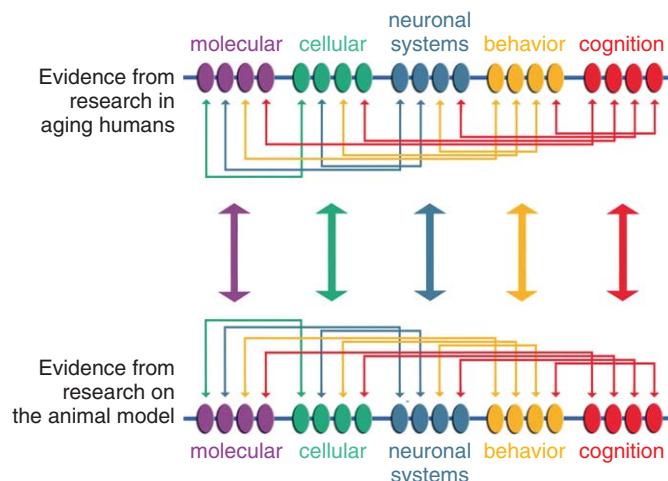

Figure 1 Research using animal models of age-related cognitive decline as well as research in aged human beings test theories about causal and correlational relationships between changes in molecular and cellular mechanisms, impairments in the regulation or integrity of brain systems, and cognitive decline. The main levels of analysis (molecular, cellular, neuronal systems, behavior, and cognition) ideally are presented in research on animal models (bottom) and in research in aged human beings (top). Each research domain establishes relationships between evidence from these levels of analyses (horizontal connections) and, importantly, informs the other domain about such potential relationships. The collective hypotheses concerning the neuronal mechanisms of cognitive decline constitute a theory. The construct validity of an animal model reflects the degree to which relationships between cognitive and neurosystems or cellular changes determined in the model map onto corresponding relationships predicted by theory on cognitive aging and/or are demonstrated in research involving aging human beings (vertical connections; the figure was modified from Sarter M (2006) Preclinical research into cognition enhancers. *Trends in Pharmacological Sciences* 27: 602–608).

that the relationships studied in the model and the new theories created based on the model do not apply to the modeled condition. However, as the model is being investigated, it will evolve in part by integrating new insights from research in humans. Conversely, as cognitive neuroscience research in humans is increasingly informed by results from research using animal models, such cross-fertilization can be particularly fruitful for the process of construct validation.

To reiterate, a model represents a bundle of theories about the brain–behavior relationships underlying the condition to be modeled, and as such it needs to evolve based on bidirectional interactions with human research. This is the essence of construct validation and it is illustrated in **Figure 1**.

Reverse Modeling

Construct validation is an open and ongoing research process that benefits not just the model but that also inspires research on the target condition. For example, evidence suggesting abnormal regulation in the cortical cholinergic input system as a major source for age-related decline in attentional capacity may sponsor efforts to generate measures of the dynamic regulation of cholinergic neurotransmission in humans. Such reverse modeling of hypothesis-driven research (the model dictates research in the condition that is to be modeled) has become more common in recent years and is driven in part by the rigor of tasks developed for the test of cognitive functions in animals. Such tasks have been increasingly adopted for parallel research in humans, thereby fostering interdisciplinary research approaches.

Reverse modeling is further motivated by the unavailability of measures of the dynamic characteristics of neuronal dysregulation in humans. Evidence concerning such dysregulation forms the basis for hypotheses that are testable in humans. For example, postmortem measures of enzymes associated with acetylcholine (ACh) synthesis or metabolism inform about the residual number of cholinergic neurons or terminals, but are not capable of revealing abnormalities in the timing, rise time, or clearance of the phasic cholinergic signals that mediate key aspects of attention. However, research in animals indicates that impaired orchestration of cholinergic signals, at the scale of seconds, may contribute to attentional decline in aging. Obviously, current imaging methods cannot detect such changes; however, studies on the effects of agonists at nicotinic ACh receptors have been shown in animals to modify the cholinergic transients that mediate attentional performance and thus these data can be employed to test hypotheses that predict precise attentional effects of such agonists in the human, including the aging human. Moreover, since brain systems activated by attentional performance have been well characterized in recent years, these hypotheses can be

expanded to predict, for example, drug-induced modulation of mediolateral prefrontal activity in situations that require shifts in attention.

Face Validity

Face validity refers to the degree to which the model, in strictly phenomenological terms, corresponds with overt features of the target. Face validity is a seductive criterion but it is of limited usefulness. Conducting research using old rats, looking overweight and featuring a ruffled coat, and exploring a maze significantly less efficiently than a young animal, seems intuitively attractive and certainly benefits from an enormous amount of face validity – both with respect to the condition of the animal and the overt performance in the maze task. Hypothesis-generating research often depends on, and is informed by, experimental approaches that are justified by face validity. In that respect, aged animals represent a highly valuable resource. However, the deduction of specific brain–behavior relationships from such approaches is a challenge. First, changes in maze patrolling behavior have been shown to result from variations in numerous cognitive and noncognitive variables, including sensorimotor, motor, and motivational variables, rendering the substantiation of changes in terms of impaired learning or memory to be an unexpectedly complicated subject. Second, the exact neuronal condition modeled by an aged animal, and therefore the neuronal basis underlying the behavioral/cognitive change, is difficult to determine. For example, it is not clear whether the brains of laboratory rats reach a sufficiently high age to spontaneously reproduce some of the changes that are considered key to the human-brain aging. The activity of choline acetyltransferase (ChAT) in the cortex of aging humans suggests a continuous thinning of cholinergic presynaptic terminals after the age of 40 (this will be discussed later in more detail). Aged rats, however, even very old ones, show only limited changes in this neuronal system and, indeed, these neurons remain able to release ACh even following strong challenges. Conversely, spontaneously aged rats exhibit numerous physiological, sensory (including retinal degeneration), and endocrinological abnormalities. The frequently used Fisher-344 rat is particularly prone to extensive age-related pathology.

Using spontaneously aged animals, the determination of the neurobiological mechanisms that are responsible for defined changes in behavioral/cognitive performance is extremely challenging. Depending on the biological variable of interest, correlations between chronological and biological aging in rats may not map onto such correlations in humans. The alternative approach examining the cognitive consequences of hypothesis-driven manipulation that influences the brains of young rats to exhibit defined features of the aged human brain affords

experimental control and the ability to generate conclusions about specific brain–behavior relationships. Collectively, face validity-based approaches assist in exploratory research, but as the field progresses and hypotheses begin to describe increasingly specific brain–behavior relationships, they are neither necessary nor sufficient for testing such hypotheses.

Predictive Validity

Predictive validity typically refers to the prediction of treatment effects in human subjects on the basis of treatment effects in animals. In this context, this issue concerns specifically the prediction of attenuation of cognitive decline, more generally, of cognitive enhancement by pharmacological treatments. Several analyses of the available evidence indicate that traditional animal models of cognitive decline failed spectacularly. These models typically combined the use of off-the-shelf or fast-and-dirty behavioral tests with unknown validity in terms of measuring the learning and memory (e.g., object-recognition tests, avoidance tasks), and/or the use of testing procedures that violate such validity, with the use of spontaneously aged animals or animals exhibiting behavioral/cognitive impairments produced by manipulations such as lesions or pharmacological (cholinergic) receptor blockade. These approaches produced an enormous number of false-positive results. The fact that these conventional approaches have remained popular represents a huge concern, in part as clinical trials on the effects of drugs in cognitively impaired subjects continue to be initiated on the basis of evidence from animal models that has been shown extensively to not predict clinical efficacy.

Mismatch between Neurobiological and Cognitive Targets and Task Validity

The rapid accumulation of evidence concerning the neurobiological markers, events, and mechanisms that are altered during nonpathological aging and the dementias (see below for a brief review) has formed the basis for the generation of a considerable number of animal models that reproduce aspects of these neurobiological abnormalities. Efforts to characterize the cognitive status of these animals and, more rarely, cognitive decline frequently utilized tasks that assess cognitive functions that are either unrelated to the neuronal system of interest or of unknown relevance for specifically revealing the cognitive impact of the neurobiological abnormality of interest. The literature provides a classic case to illustrate this issue. Several publications reported the absence of effects of forebrain cholinergic lesions on spatial learning and memory. Such a negative result is predicted by present

theory of cholinergic function, particularly in view of the limited demands on attentional stimulus processing involved in spatial learning and memory of standard maze tasks. Despite this evidence, research has continued to explore the effects of age, and the interactions between the effects of manipulations of the cholinergic system and age on spatial performance. As expected, results were negative and formed the basis for rejection of the general hypothesis that the cholinergic changes contribute in any way to age-related cognitive decline.

This example stresses the importance of a detailed justification of the selection of the behavioral or cognitive function employed to determine the consequences of a particular neuronal manipulation or process (Figure 1). In the absence of such justification, the search for age-related cognitive decline amounts to little more than an indiscriminate hunt for putative effects.

The justification for selecting a task – or of the focus on the test of a particular cognitive function – is necessarily associated with the demonstration that the selected test, indeed, measures this function. The literature has addressed the wide-ranging, serious concerns about the validity of popular behavioral tests and related testing procedures. These concerns about validity focused on traditional learning and memory tasks, such as avoidance tasks, as well as maze tasks and maze-testing procedures. Furthermore, the object-recognition task has recently gained popularity and been claimed to measure declarative memories. The popularity of the object-recognition task appears to be based largely on face validity. However, there is little proof that animals indeed recall discrete and declarative information, in terms of “I have seen this particular object before.” Furthermore, certain testing procedures, such as the presence of a putative drug treatment during massed acquisition sessions, as well as the test session introduced potential confounds associated with the state of the animal while repeatedly exploring the familiar object. The most sophisticated reproduction of a particular age-related neuronal process or event in an animal forms a useful model only in conjunction with the valid assessment of a behavioral or cognitive function that is conceptualized to be affected by this particular neuronal process or event.

Longitudinal versus Cross-Sectional Studies and Confounds Based on Neuro-Stagnation

The modeling of age-related cognitive decline benefits enormously from longitudinal approaches. Compared with cross-sectional designs, longitudinal experiments tracking age-related brain changes offer substantial experimental power due, in part, to the statistical advantage of with-in subject analyses and have the potential to

reveal the dynamic effects of aging on brain–behavior relationships. For example, we demonstrated that limited thinning of the cortical cholinergic input system does not affect rats' performance of a sustained-attention task until the animals reached about two-thirds of their maximal life span. In other words, animals' performance remained comparable to control animals until they reached the equivalent of about 65 years of human age. The exact interactions between this pre-condition and the aging process remain unknown; however, models that address the age-related emergence of attentional impairments perhaps are key to understanding how aging reveals the vulnerability of compromised or inadequately developed neuronal systems.

Such longitudinal models also offer the opportunity to control for the impact of lifelong cognitive activity on (pathological) aging. When conducting cross-sectional studies, aged animals typically have spent over 2 years without practicing any cognitive skills, experiencing adequate social interaction, and, in most cases, are housed in conditions that fail to stimulate cognitive activity prior to their first exposure to cognitive testing. Thus, it is likely that the results of cognitive training and testing at a relatively old age are robustly confounded by the negative neuroplasticity – or better, neuro-stagnation – that is a result of having been reared under socially and cognitively deprived conditions. It is not implausible that such housing conditions cause major behavioral and cognitive abnormalities, including abnormal responses to the presence of conspecifics, being handled, being exposed to new environments, and so forth. As a result, one has to be concerned that the cognitive decline observed in spontaneously aged animals in cross-sectional studies reflects interactions between detrimental housing conditions and the aging process, rather than aging *per se*. This concern may also apply to studies that tested spontaneously aged rats that were screened for robust behavioral and cognitive impairments. It would seem of interest to address the mechanisms that render subgroups of animals more vulnerable to the interactions between the aging process and extended periods spent in socially and cognitively impoverished housing conditions.

The persistent cognitive testing that characterizes longitudinal studies provides a more informative approach for studying cognitive decline when compared with cross-sectional studies. Based, in part, on the scarcity of longitudinal studies in humans as well as in animal models of cognitive decline, evidence concerning extremely fundamental questions, such as whether persistent cognitive practice and associated activation of key brain systems accelerates or in fact delays the consequences of pathological vulnerability.

Neurobiological Targets

Aging in the Absence of Dementia

Longitudinal and cross-sectional morphometric studies indicated that gray and white matter volumes shrink with age, that there are signs of dendritic regression and a widespread decrease in synaptic density primarily in telencephalic regions. Major loss of neurons is not considered to represent a general age-related event in the brains of nondemented patients. The morphological evidence is conflicting and inconclusive, reflecting the limited significance of chronological age as a predictor of neuronal (and cognitive) decline.

The neurochemical evidence likewise has not formed the basis for a general concept of the neuronal basis of age-related cognitive decline. However, considering the key role of the cortical cholinergic input system in the mediation of attentional processes and capacities, early dysregulation and subsequent disintegration of this system has long been hypothesized to contribute to cognitive decline. Immunohistochemical and neurochemical studies indicated a decrease in choline acetyltransferase (ChAT) activity in hippocampal regions, as well as in the temporal lobe of aged subjects, eventually reaching levels similar to those in subjects with Alzheimer's disease. These decreases in ChAT activity reflect loss of cholinergic terminals and perhaps neurons, or at least the loss of cholinergic markers in neurons that show age-related morphological alterations that index their increased vulnerability.

Similar to findings in aged humans, spontaneously aged animals were reported to exhibit morphological alterations in the basal forebrain, primarily neuronal shrinkage. However, robust ChAT loss was not found in aged rodents and measurements of ACh release using *in vivo* microdialysis did not suggest robust changes in basal release or in the capacity of this system to respond to challenges. Thus, with respect to this key neuronal system, the brains of spontaneously aged rats do not appear to age sufficiently. Corresponding with this evidence, the attentional performance of spontaneously aged rats remains stable until a very old age when more general behavioral decline interferes with basic task performance. Thus, as already mentioned in our discussion about the use of spontaneously aged animals (above), and at least with respect to cholinergic systems and attentional capacities, spontaneously aged rats do not appear to represent a useful animal model. Consequently, attempts to model the declining cholinergic system in humans and the associated decline in attentional capacity requires additional, hypothesis-based manipulations in rats in order to reproduce the vulnerability and functional decline of this neuronal system during aging. Such hypotheses concern, for example, developmental abnormalities in the trophic

factor support of cholinergic neurons, the particularly detrimental effects of aggregations of amyloid-beta ($A\beta$)-peptide for cholinergic neurotransmission, or the exquisite vulnerability of the cholinergic system to ischemic events and microvascular disorder.

Despite a considerable literature describing age-related changes obtained at all levels of analysis (from human blood flow and metabolic markers to markers of mitochondrial mechanisms), this evidence provides little guidance for focusing on one over the other neuronal symptom for modeling purposes. This situation has often been cited as a justification for conducting exploratory studies using spontaneously aged animals (discussed above). However, to reiterate, this situation also reflects the limited heuristic power of chronological age as a main independent variable. It may be more useful to study hypothesis-driven changes in neuronal systems in animals that either spontaneously, or as a result of an experimental manipulation, exhibit cognitive decline during the aging process.

Mild Cognitive Impairment

Mild cognitive impairment (MCI) is a psychometrically determined diagnosis of cognitive impairments in subjects older than 50 years of age. The cognitive capacity of these subjects typically is one standard deviation below the mean for the age group and affects between 15% and 35% of the general population. Several studies indicated that MCI represents a precursor of Alzheimer's disease, as the majority of subjects develop dementia within a decade. Research on MCI and animal models of this intermediary stage may generate particularly useful, fundamental insights into the dynamic processes of pathological brain aging and cognitive decline.

As we repeatedly focused on the role of cholinergic systems in the mediation of attentional performance and age-related decline in attentional capacities, it is worth noting that evidence indicates that basal forebrain (BF) cholinergic neurons are not normally regulated in MCI. The number of cholinergic neurons expressing TrkA receptors, a high-affinity receptor for nerve growth factor (NGF), is markedly decreased in MCI patients compared to normal age-matched noncognitively impaired subjects. NGF-mediated signaling via TrkA receptor is crucial for the development, maturation, and function of cholinergic neurons. Despite the absence of cholinergic cell loss in MCI, the number of TrkA-positive neurons in the BF of subjects with MCI was found to be as low as in patients with Alzheimer's disease. Furthermore, TrkA receptor downregulation correlated with cognitive decline in MCI subjects.

The critical role of TrkA receptors for the maintenance of the aging cholinergic system is substantiated by the finding that, in mice lacking this receptor, cholinergic

neurons do not fully mature and begin to atrophy during the early weeks of postnatal life. Furthermore, in mice with segmental trisomy of chromosome 16, which models aspects of Down's syndrome, decreases in BF TrkA immunoreactivity predict behavioral and cognitive impairments. Collectively, these studies suggest that loss of TrkA receptors disrupt maturation of cholinergic neurons and eventually lead to degeneration of these neurons and cognitive impairments.

The mechanisms that lead to the suppression of TrkA-mediated NGF signaling, and the ontogenetic regulation of this defect have remained completely unclear. However, the evidence collectively suggests that an animal that reproduces early disruption of TrkA suppression and that exhibits age-related decline in cholinergic signaling and associated attentional performance may be an extremely useful model. Such a model may also assist in revealing the developmental nature of the mechanisms that evoke age-related cognitive decline, including the age-related mechanisms that interact with such a pre-existing condition to evoke such decline.

Alzheimer's Disease

Plaques and tangles

Substantial evidence suggests that cerebral deposition of amyloid precursor protein (APP) product, $A\beta$ -peptide, plays a critical role in the pathogenesis of Alzheimer's disease. $A\beta$ is suggested to be an early pathological biomarker for Alzheimer's disease and associated cognitive and behavioral deficits. Genetic linkage studies suggested the involvement of a genetic mutation in APP gene on chromosome 21 in familial Alzheimer's disease. Approximately 20 pathological mutations in APP have been identified. Mutations in APP do not account for all cases of familial Alzheimer's disease. A large number of genetic linkage studies have identified mutations in Presenilin 1 on chromosome 14 and Presenilin 2 on chromosome 1. Presenilins are associated with the formation of active site of γ -secretase complex that is involved in the production of $A\beta$. Finally, a variant of a gene coding for protein involved in $A\beta$ clearance, that is, the presence of apolipoprotein E (ApoE) $\varepsilon 4$ allele, represents a risk factor for nonfamilial (or sporadic) Alzheimer's disease. It also needs to be noted that there is substantial evidence linking abnormal APP processing with cholinergic decline, including the regulation of the high-affinity choline transporter, the capacity of which is critical for ACh synthesis.

Transgenic mice overexpressing APP, such as TgAPP22 mice, exhibit amyloid plaques and deficits in standard laboratory tasks for the measurement of learning and memory. Likewise, mice overexpressing Presenilin-2(PS2) reproduce essential neuropathological features. More recent strategies led to the development of

double/triple transgenic mice to mimic the multiple neuropathological markers of Alzheimer's disease, including double transgenic mice that co-express human PS1 and APP, or triple transgenic mice harboring a PS1_{M146V}, APP_{Swe}, and tau_{P301L} transgenes. These latter mutants also exhibit cholinergic deficits and cognitive impairments.

Clearly, these molecular advances offer a rich set of neurobiological targets for the development of animal models. It is unexpected, therefore, that research using these animals has rarely demonstrated a precise relationship between the degree, density, or amount of neuropathological product and specific aspects of cognitive decline. As we discussed above, such relationships are key to a productive use of these models, including for predicting the efficacy of potential treatments. The widely held assumption that reproducing the neuropathological markers alone represents a complete animal model, and that reducing, for example, A β levels or plaque burden *per se* is sufficient to predict improvement of the cognitive status of patients interferes with the important test of the hypothesis that the presence of these markers is causally responsible for the severity of cognitive decline.

Cerebrovascular disorder

Cerebrovascular pathology is now increasingly recognized as a causative factor for all dementias, including Alzheimer's disease. At least 20% of subjects diagnosed with MCI develop vascular dementia supporting the general notion that acceleration of cognitive decline and its underlying neuropathology involve vascular dysfunction. Decreases in cerebral blood flow as a result of transient ischemic attacks (mini-strokes) are proposed to act as a significant causal factor for the emergence of cognitive decline in Alzheimer's disease. Vascular lesions in cortical associational regions predict the severity of dementia, and Alzheimer's disease has even been conceptualized as a vascular disorder with neurodegenerative consequences.

Forebrain cholinergic neurons innervate and dilate cortical microvessels directly via muscarinic or nicotinic receptors, as well as indirectly via a local cortical nitric oxide transmission. Cholinergic lesions produce decreases in cerebral blood flow. Decreased cholinergic activity impairs cortical perfusion and metabolic activity and thus enhances the risk for ischemic events. Furthermore, as a result of cholinergic cell loss in advanced Alzheimer's disease this predicts a reduced capacity for cerebral microvascular dilation and thus an increased vulnerability for ischemic events. Ischemic events and microvascular disorder have been suggested to trigger the production of excitotoxic and inflammatory mediators that may reduce further cortical cholinergic activity and cholinergic innervation. Moreover, ischemic attacks associated with microvascular disorders may contribute to the accumulation of A β and neurofibrillary tangles. These highly

reciprocal interactions between the consequences of abnormally regulated cholinergic system and impaired cerebrovascular function, perhaps as a result of mini-infarcts occurring at the time of onset of the dementia, may trigger essential pathological cascades.

Given the predominance of models focusing on the aggregation of A β and tau, the modeling of cerebral microvascular disorders, including the demonstration of relationships between the severity of such disorders and age-related cognitive decline, appears to be a pressing research subject. We demonstrated that intracarotid administration of microspheres produces embolism and microvascular disorder and impairments in attentional abilities in rats. It would be important to employ these and other models to study the age-related consequences of mini-infarcts, perhaps in interaction with abnormal protein aggregations and decline in the regulation of key neuronal systems.

Developmental Animal Models of Age-Related Cognitive Decline

Why is it the case that only 15–35% of the aging population develops MCI? Is it really the case that lifelong cognitive activity protects against age-related cognitive decline, or do such correlations in fact reflect self-selection for sustained cognitive activity based on a healthier and thus more efficacious brain early in life?

Although chronological age is a robust predictor for cognitive decline, it appears unlikely that major neuronal events manifest fairly rapidly because human beings reach 50 or 60 years of age, resulting in MCI or even dementia. Rather, it appears likely that age-related decline of brain systems mediating cognitive functions are a result of vulnerabilities that result from neurodevelopmental aberrations, perhaps interacting with later cardiovascular and cerebrovascular, infectious, or immunological mechanisms to trigger age-related cognitive decline. Additionally, head traumas and vascular events are risk factors and as such may interact with developmentally established imperfections in neuronal wiring, synaptic mechanisms, dendritic organization, and so forth to evoke age-related cognitive decline.

These considerations suggest that efforts to model age-related cognitive decline may need to integrate manipulations that cover the entire life span, perhaps beginning prenatally and involving the implementation of multiple risk factors throughout adolescence and adulthood. Perhaps a single event during neurodevelopment is sufficient to produce MCI-like cognitive decline in aged animals, or perhaps a multitude of variables will need to interact over longer periods of time to establish age-related vulnerability. As we stressed above, the scarcity of longitudinal studies combined with models that rarely

focused on the demonstration of specific, selective, and age-related relationships between neuronal and cognitive mechanisms (**Figure 1**) and the indiscriminate use of behavioral tests with limited or unknown validity in terms of measuring a particular cognitive capacity – have collectively contributed to the rather sobering view that despite a sizeable literature there is little evidence to begin addressing the very basic, mechanistic questions about the bases of age-related cognitive decline.

The famous Nun study demonstrated that the density of ideas and the complexity of the grammar in the autobiographies written by the sisters in their early 20s predicted their cognitive status late in life. If pathological aging begins early in life, then the modeling of this condition likewise needs to begin with neuronal manipulations or events that occur early in life.

Glossary

22-kHz vocalization – Ultrasonic calls emitted by rats in dangerous and aversive situations with the peak sound frequency close to 22 kHz (usually 20–25 kHz) and call duration from 100 to 3000 ms. Rats receiving these calls show a number of defensive responses, including freezing, escape, and hiding.

50-kHz vocalizations – Ultrasonic calls emitted by rats in social and appetitive situations with peak sound frequency close to 50 kHz (usually 40–60 kHz) and call duration from 20 to 70 ms. Rats receiving these calls show affiliative responses, including approach and play.

Cholinergic system – Any of the brain systems consisting of neurons synthesizing acetylcholine as the neurotransmitter and releasing it at the terminals of their axons. The tegmental cholinergic system pertains to the group of neurons in the laterodorsal tegmental nucleus, which projects to the forebrain limbic regions.

Mesolimbic dopamine system – A brain subsystem of neurons synthesizing dopamine as the neurotransmitter and releasing it at the terminals of their axons. The mesolimbic dopamine system originates from the ventral tegmental area and projects to the forebrain, and predominantly to the nucleus accumbens.

researchers agree that emotional states enhance the organism's interaction with the environment – by prolonging certain internal states, amplifying experiences, and thus allowing for better evaluation of salient stimuli and situations critical for survival. Emotional states are also critical for anticipatory capabilities, which allow the animal to organize its behavior in light of potential events rather than actual events. Although the evolutionary appearance of emotional states seems to be understandable, the question arises: why do animals express their emotional states and inform other individuals, including their opponents, about their state? One may argue that hiding an organism's emotional state rather than demonstrating it would be a more beneficial solution. Although animals may overtly express their emotional states or show an expressive suppression that masks their inner states, the former phenomenon is overwhelmingly dominating, as emotional expression has a highly adaptive value.

Situations Promoting Emotional Expression

The expression of an internal state might have limited biological value without the presence of other individuals of the same or other species. Conversely, the presence of other individuals has a catalytic effect on the expression of these states. Expression of emotional states was probably an effective tool in promoting, creating, and facilitating social interactions among animals and building and enhancing biologically successful social groups. Thus, the expression of emotional states gained biological significance as a social phenomenon and, as such, is imminently associated with communication among animals. Although not all communicative signals are emotional expressions, the vast majority are. Darwin strongly emphasized the communicative aspect of emotions. It is worth mentioning that both the expressive repertoire of the displaying animal, as well as the effects of that expression on receivers and their receptivity and acuity coevolved and were mutually interdependent.

The phylogenetically oldest situations promoting such a communication would be in reproductive contacts, while raising offspring, and when interacting with predators. Effective expression of internal states is equally adaptive for infants, their mothers caring for them, and during defense against predators (although, in the latter

Charles Darwin, in his book entitled *The Expression of Emotions in Man and Animals*, published in 1872, provided the first modern biological explanation of the expression of affective states in animals and its evolution and homology among species. Although Darwin's ideas and explanations were based on limited observational evidence, new data and facts reinforce and support most of Darwin's hypotheses, which were largely ignored by researchers for almost a century. Darwin was convinced that not only observable expressions of emotions ('expressive movements') but also the underlying brain processes ('states of the mind') were subjected to the evolutionary process. He argued that certain emotional expressions are innate, and formulated one of his principles about the 'direct action of the nervous system,' that is, that the activity of the central nervous system produces and directly regulates mechanisms of these expressions.

Emotional states have evolved in animals over a long period of time as biological adaptations increasing the likelihood of survival and successful reproduction. Most

situation, it is usually the expression of emotional state by adults and expressive suppression by infants.

Expression of emotional states in animals may be classified into interspecific and intraspecific communication. Interspecific communication involves communicating signals directed to the predator or potential predator, while intraspecific communication may be further subdivided into a form of dyadic communication in which only two individuals of the same species communicate with each other, or as a group communication in which one or more organisms express their state to many individuals – usually to the whole social group or colony. Despite some similarities in biological functions of these expressions, the dyadic and group situations differ from each other and the relevant emotional expressions may also differ. For instance, in some forms of defensive or appetitive behavior, the presence and size of the social group have an enhancing effect on emotional expression.

The expression of an emotional state may be autocentric (i.e., serving the immediate individual needs of the displaying animal) or allocentric (i.e., the entire social group may benefit from the display). Autocentric expression of emotions is displayed in situations such as defending against an aggressor, forcing an opponent to retreat, soliciting sexual activity, or begging for food, and occurs mostly in dyadic communications. Allocentric expression of an emotional state may be demonstrated by alarming postures or vocalizations or some cooperative behaviors, generally occurs during group communication, and is usually dependent on the presence of many individuals.

Biological Functions of Emotional Expression

Interspecific communication involves mostly agonistic interactions, such as deception, threat, warning, and intimidating displays directed to the predator or to another, usually larger, animal posing a potential danger. For example, rodents will readily express their emotional state of fear or anxiety toward a cat, dog, or human. Occasionally, interspecific communications can be appetitive in nature, as between a human and a dog or among some household animals of different species who live together with the human.

Biological functions of intraspecific communication could be subdivided into numerous categories, including dyadic and social group interactions. Each function may contain, to a varying extent, an emotive component (emotional expression), that is, information about the emitter's internal emotional state and its valence. These functions include: (1) a locating function that might be the oldest form of communication, in which an individual signals its presence and enables its localization; (2) an identifying

function that allows for individual recognition and facilitates guiding one animal to another; (3) a monitoring function that facilitates watching the environment for potential danger, in which one animal relies on the signals from other animals with regard to relative safety; (4) a conative function, which mobilizes or recruits the recipient(s) to action in a general way or activates their attention; (5) a calming function – which extinguishes unnecessary activation or commotion in a general way; (6) an alarming function that informs about an actual or potential danger and promotes defensive responses; (7) an agonistic function, which has a breaking-contact role and promotes escape, withdrawal, or dispersion; (8) an appeasement function that reduces the possibility of (conspecific) attack; (9) an affiliative function, which signals approach, promotes conspecific contacts, and attracts individuals to each other; (10) a phatic function, which maintains connections among individuals, enhances cohesiveness within the social group, plays a reassuring role as to the close presence of the group members, and/or makes them aware of their mutual presence and proximity; and (11) a hedonic function, which informs about joyful situations and is most frequently (but not exclusively) observed during ludic behavior (playful behavior) of juvenile and adolescent animals. It has been noted that the most frequent signals used in animal communication pertain to negative affect (fear, threat, anxiety, etc.).

Most of these functions serve the entire social group, and emotional expressions of individuals are addressed to other members of that group. Ethological studies of many mammalian species have shown that emotional expression of an individual organism is subjected to the phenomenon of emotion contagion, an adaptive mechanism by which emotional state may be quickly transferred across the social group, with many other members of the social group repeating the emotional expression of the initial signaler and changing their behavior. This phenomenon is particularly clearly observed in recruiting or alarming situations but is not restricted to these situations. Emotion contagion may also have a calming function. In some situations, emotion contagion may lead to an overreaction of the group in a form of panic behavior or outbreak of agonistic interactions.

Forms and Physiological Channels of Emotional Expression

There are a large number of possible forms of emotional expression used by animals, with nearly every sensory modality utilized in this process. Signals can be conveyed by visual, olfactory, gustatory, tactile, acoustic, or even electric discharge displays (in fish). Forms of emotional expression include posturing, expressive movements, production of odors or pheromones, or release of other

chemicals, nonvocal acoustic, or vibrational signaling (sounds produced by friction, beating the ground or water surface, or own chest, as in gorillas), emission of vocalizations (by blowing air through an orifice), or even electrical phenomena (although mammals do not use electric discharges for communication, electroreception has been documented in monotremes). Mammals have the most diversified and versatile forms of emotional expression and communication as compared to any other taxon. Most mammalian species rely on two or more of these physical forms for unambiguous communication, involving a combination of olfactory, visual, tactile, and vocal signals.

Emotions are not expressed by unchanging structural attributes of organisms, such as bright spots of coloration (badges) on the animal's body, although such nonbehavioral signals do serve as intraspecies communication and may acquire, for instance, warning value in some situations. However, emotional expressions can be communicated by a number of physiological channels, which include somatomotor, hormonal, and autonomic responses. Somatomotor responses include expressive whole-body posturing (kinesis) – particularly, position and movements of head, ears, and extremities; active facial expression; and vocal expression (vocalization). Several mammalian species pay particular attention to facial expression, position of eyelids and eyebrows, eye movements, and direction of the gaze, which might be more important than body posture. For example, looking straight into an individual's eyes may have aggressive and intimidating properties (dogs, monkeys, the human, etc.), while gaze directed in another direction may point out a source of danger or object of interest. Autonomic responses involved in the expression of emotional states include changes in breathing pattern, skin coloration, and appearance of the eyes (e.g., size of pupils, drooping eyelids, exophthalmos, etc.); piloerection; tremor; external secretions (salivating, drooling, lacrimation (tearing), sweating, producing odors, etc.); and micturition and defecation. Many autonomic expressions play an important role for animal communication (e.g., piloerection along the arched back of a cat) but a lesser role in human behavior (e.g., bulging blood vessels on a forehead).

Despite the numerous forms of emotional expression, precise communication is limited, particularly as to its quantitative value, except in vocal communication.

Vocal Communication and Emotional Expression

Utilization of vocal signals has numerous advantages over any other forms of communication, and vocal communication is the most widespread, complex, and elaborate

form of emotional expression. Mammals have developed a sophisticated system of sound production by the vocal apparatus (the larynx) and by modulatory and articulatory mechanisms of supralaryngeal sound modification. There are several biological reasons for this development.

Sound has many advantages over any other forms of communication, particularly in emotional communication, which frequently takes place in biologically dangerous situations. Sound can travel over a relatively large distance and its reception is not dependent on daylight. The transmission rate of acoustic signals is practically immediate and signals could be terminated instantly. Sound can also travel in water, in underground tunnels, and in dense vegetation (albeit for a shorter distance). Sound fades away quickly, leaving no permanent trace. Acoustic signals can vary greatly in sound frequency (pitch), signal duration, and loudness. Acoustic signals can also vary immensely in temporal pattern (e.g., frequency-modulation pattern and repetition rate). The combination of all of these parameters offers an unusually diverse freedom for coding signals. Most mammalian species use both changes of acoustic sound parameters as well as temporal patterning in coding their signals. As a result, mammalian vocal signaling and vocal emotional expression represent the richest collection of coded signals with an almost infinitive number of possible outcomes.

Evolution has favored different vocal outcomes and codes, depending on the species – their physiological and anatomical features, the environment of their habitation, and biological and ecological conditions. Although most mammalian species emit sounds within the human hearing range (sonic range of 20 Hz to 20 kHz), some mammals can utilize infrasounds (below 20 Hz, such as elephants, whales, and tigers), or ultrasounds (above 20 kHz, such as bats or rodents). Many species can produce sounds spanning from low frequencies up to the kHz range (humpback whales) or from sonic to ultrasonic frequencies (e.g., juvenile rats). Whales produce the loudest vocalizations among animals because they need to communicate over the longest distances.

Production of vocal sounds (i.e., those produced by the respiratory system) may have many mechanisms. It is believed that primates and whales have attained the highest sophistication of sound production among mammals. Most mammalian vocal sounds are laryngeal in origin, but sounds of toothed whales are produced by a specialized nasal system (phonic lips and nasal sacs), and thus are not homologous with those originating from the laryngeal system of other mammals. The mechanism of laryngeal sound production is also not uniform. Most mammalian species use vibration of vocal folds; however, baleen whales have a modified larynx without vocal folds. Finally, rodents use a stabilized larynx as a whistle without vibration of vocal cords. Vocal folds are used to

narrow the orifice for airflow, and in this way the vibrating air column produces sound that can reach high ultrasonic frequency. It is important to point out that all of these mechanisms of sound production are governed and regulated by complex control mechanisms of the central nervous system.

Neural Substrate for Vocal Emotional Communication

It has been known for more than half a century that the brainstem and limbic system are responsible for the initiation and control of species-specific vocalizations. This system is also a main substrate for the generation and regulation of affective states with concomitant behavioral manifestations, including vocal expression of these states. Despite enormous variability in emitted vocalizations, the neural substrate for their production is well preserved across mammalian species. The main components of the brainstem and limbic system remain very similar with only slight changes across mammalian species, including the human.

The attention of researchers was focused initially on the brain structures involved in the initiation of vocalization and concomitant affective state as a result of early studies with electrical stimulation of various brain regions in awake animals. In 1928, Swiss physiologist Walter R. Hess published the first description of an affective expression induced by electrostimulation of the cat's brain, and then fully mapped the brain system responsible for control of autonomic functions and release of affective manifestations and expressive vocalization. This system for vocal expression included the septal, hypothalamic-preoptic, amygdala, fornix, periaqueductal gray, and other brainstem regions. The highest level of the limbic system from which vocalization could be induced by direct stimulation appeared to be the cingular gyrus, but only in monkeys.

Subsequent studies of emotional expression and affective vocalization suggested a descending hierarchical organization of brain control of this expression. The lower level of the central nervous system in the brainstem (reticular formation, structures of pons and medulla) contained motor nuclei controlling vocalization and respiratory movements. The periaqueductal gray, hypothalamus, and limbic system contributed to motivational/emotional aspect of this expression. Finally, the cingular gyrus, a limbic cortical area, was suggested to be involved in the voluntary initiation of vocal expression.

Direct stimulation of the brain with chemical agents (chemostimulation) and the development of behavioral neuropharmacology in the early 1960s brought new insight into the organization of limbic structures in the regulation of vocal expression of internal states. Several

pharmacological agents (mostly cholinergic, e.g., pilocarpine, tremorine, carbachol, arecoline, eserine, and d-tubocurarine) were reported to have properties of inducing different species-specific vocalizations in the cat following central application. Thus, the central cholinergic system has been implicated in the initiation of species-specific vocalization as an emotional expression.

Comparable responses to cholinergic muscarinic stimulation were discovered in rats, except that these animals emitted ultrasonic vocalizations. Following a thorough mapping of the cat and rat brains for vocal responses induced by intracerebral injection of carbachol, a predominantly muscarinic agent, a similar brain system was identified to that known from studies utilizing electrostimulation. This system, termed the medial cholinoreceptive vocalization strip, extended from the tegmentum and the periaqueductal gray, through the medial hypothalamic-preoptic regions and the bed nucleus of stria terminalis, up to the lateral septum. The main difference between results of electrostimulation and chemostimulation was that, while results of the former studies pointed to the descending system to the brainstem, the latter revealed an ascending system from the tegmentum to the forebrain and identified a specific transmitter, acetylcholine.

In recent years, intracerebral application of dopaminergic agents into the nucleus accumbens induced a different type of species-specific vocalization in the rat and implicated a second neurotransmitter in the initiation of vocalization. It appeared that another ascending tegmental system, the mesolimbic dopamine system, is involved in vocal expression of positive affective states. The laboratory rat became the best-studied mammalian species with regard to the organization of the neurochemical systems regulating emission of vocalization and vocal expression of affective states.

Neurochemical Control of Vocal Communication of Emotions

Rats are highly social animals and have developed a complex system of vocal communication. They use predominantly ultrasonic vocalization as a defensive measure against numerous predators. Adult rats emit two different types of ultrasonic calls, termed 22 kHz calls and 50 kHz calls. It has been observed that 22 kHz vocalizations are mostly associated with aversive situations and retreat behavior, and 50 kHz vocalizations with appetitive situations and approach behavior. It has been suggested that 22 kHz calls evolved as antipredator alarm behavior, while 50 kHz vocalizations are affiliative calls promoting approach and cooperation among conspecifics. As 50 kHz calls were observed to be particularly abundant in juvenile rats during play behavior, it was also suggested that

these calls represent a rodent primordial counterpart of human laughter.

Numerous recent studies strongly suggest that 22 kHz vocalizations are associated with negative states and expression of negative affect, and that 50 kHz vocalizations express positive states and positive affect. These two types of calls have substantially different acoustic structures, guaranteeing an unambiguous recognition of these categories of signals by recipients. In addition, rats can emit only one of these types of calls at a given time and mixed vocalizations are almost never observed. Only in rare situations of behavioral ambiguity may rats emit both types of calls.

Neuropharmacological studies of rats have led to the determination of two neurotransmitter systems responsible for initiation and emission of affective calls. Chemical stimulation of structures along the cholinergic vocalization strip with cholinergic muscarinic agonists invariably induced 22 kHz vocalization. It has been suggested that the ascending cholinergic pathways from the laterodorsal tegmental nucleus to the basal forebrain, medial hypothalamus, and septum that release acetylcholine at their terminations will initiate negative emotional states that may be expressed by 22 kHz alarm vocalization. On the other hand, application of dopaminergic agents (amphetamine, quinpirole, etc.) into the nucleus accumbens, a structure known to be associated with reward, appetitive processes, and anticipation of reward, invariably induced 50 kHz vocalizations. The ascending mesolimbic dopamine system from the ventral tegmental area to the basal forebrain, olfactory tubercle, and nucleus accumbens that releases dopamine at its terminals was suggested to initiate positive emotional state, which may be expressed by 50 kHz affiliative vocalizations. Several neurochemical and cellular studies further suggested that these two ascending systems work in a mutually opposite manner; that is, an increase in activity of one of these systems will cause a decrease in the activity of the other, and vice versa. Thus, acetylcholine and dopamine seem to be specific neurotransmitters in initiating negative or positive states and vocal expression of these states. Such results could not be obtained using intracranial electrical stimulation, which was not specific to any neurotransmitter system and often induced mixed behaviors.

Although the neurochemical control of emotional expression and ultrasonic communication has been studied mostly in rats (and partially in cats), the acetylcholine–dopamine balance between the ascending tegmental systems is most likely common to all mammalian species, including the human. The ascending direction of tegmental projections indicates that these systems are involved in changes of the general and affective states in animals; the descending pathways from the limbic system to the brainstem motor nuclei will then initiate the actual motor acts for vocalization. It is also important to mention that there are several other

neurotransmitters involved in the control of emotional states and vocal expression; however, acetylcholine and dopamine seem to be critical for the initiation of these states as a first and necessary step in emotional expression.

Emotional Communication as an Interactive Process

In agreement with the theory of communication, the expression of emotions is meaningful only in the context of the interaction between a sender and a receiver. The emitted signal has to contain encoded semiotic value (a message); however, it is meaningful only if the receiver can decode the signal and respond to it appropriately. In early ethological studies, such communication was usually understood as a unidirectional process and discussed in terms of costs and benefits to the sender as compared with the receiver. Recent studies indicate that expression of emotional states is a dynamic and interactive process between senders and receivers. For example, in dyadic interactions, vocal signals are produced not only to influence the behavior of the other animal; the sender also continuously responds and adjusts its behavior according to the behavior of the receiver. Affective communication can be interpreted here as an interactive management/assessment process, and not as a unidirectional act of sending information to the receiver. Thus, emotional expression may not only inform other conspecifics about the affective state of the sender, it also probes the affective state and responses of the receivers. This process involves both sending and gaining information from other individuals and may have a feature of continuous dialog probing the state of other companions. As a result, the sender and the receiver make predictions about future behavior and can reach adequate decisions. These observations provide a better understanding of the process of emotional expression and its adaptive value in a social group.

Finally, the question arises as to which part of the brain is responsible for the process of assessment and decision making as to the outcome behavior, including vocal expression of emotions. Although not understood in detail, this process is likely to occur at many levels of the central nervous system, and may involve the acetylcholine–dopamine balance in the ascending tegmental system. Thus, the interaction between acetylcholine and dopamine may take part in the process of decision making and selection of optimal behaviors in the context of emotional communication.

Glossary

Diagnostic and Statistical Manual (DSM-IV) of the American Psychiatric Association

A manual published by the American Psychiatric Association, providing diagnostic criteria for mental disorders. It is used by mental health professionals, researchers, psychiatric drug regulation agencies, health insurance companies, pharmaceutical companies and policymakers to standardize diagnostic classification.

Endophenotype – The term ‘endophenotype,’ in a psychiatric context, was coined by Gottesman and Shields in the early 1970s, where they described it as an internal phenotype that emerges from the pathway between genes and the disease state. Fundamental to the concept is the assumption that the genetic basis of variations of the given endophenotypes between patients and control subjects are fewer than those involved in the manifestation of a complex disorder *per se*. Thus, employing endophenotypic approaches provides a means for identifying the genetic basis of specific clinical phenotypes, in addition to aiding the analysis of the phenotypic consequences of genes being turned on or off.

Intracranial Self Stimulation (ICSS) – Also called brain-stimulation reward, this refers to the phenomenon in which animals will perform an operant task to receive an electrical current delivered through electrodes implanted in certain parts of their brains, such as the lateral hypothalamus.

Long-term potentiation (LTP) – The long-lasting improvement in communication between two neurons that results from stimulating them simultaneously. LTP is widely considered one of the major cellular mechanisms that underlies learning and memory.

laboratory testing. In clinical practice, many tools have been developed and validated to better diagnose depression and the efficacy of treatment strategies in humans. These range from the *Diagnostic and Statistical Manual (DSM-IV)* of the American Psychiatric Association to the various rating scales such as the Hamilton depression scale. Further, clinicians also rely on self-reporting from patients for the diagnosis in depression and it goes without saying that no such tools are available when we shift to animal models. Indeed, many of the human symptoms of depression as described in the DSM-IV (such as recurring thoughts of death or suicide or having excessive thoughts of guilt) are impossible to be modeled in rodents. The question therefore remains impenetrable as to whether we can ever know whether a rodent is depressed. It is clear that evolutionary progression has enabled humans with a much more elaborated cerebral cortex than rodents that facilitates integration of complex psychological concepts also relevant to human depression, such as self-esteem and the ability to perceive the future, that are absent in rodents. Nonetheless, there are also many fundamental physiological and behavioural responses that have been evolutionarily conserved between species, in order to regulate homeostasis. Therefore, largely through inference, we can exploit these latter responses to elucidate phenotypes relevant to emotional behaviors. Moreover, it is becoming clear that increased interaction between clinical and basic sciences is allowing new insights into the generation of tractable, valid, and translational animal models.

An ideal animal model of depression would have identical causative factors, symptomology and treatment modalities to the disease. Despite these hurdles a number of diverse animal models of depression have been widely utilized and many show substantial construct face and predictive validity (i.e., antidepressant administration reverses the behavioral parameters assessed). These animal models are often referred to as tests of antidepressant-like activity given that they have all been validated since the introduction of clinically approved medications. This also renders the predictive validity of the models unclear until a novel acting compound from preclinical testing is successfully applied in man. The distinction between a model and a test is not always made clear and as a result, sometimes a test is called a model. A model comprises both an independent variable, known as the inducing manipulation, and a dependent variable that is a behavioral/neurochemical readout, whereas a test simply

Introduction

Depression is one of the most serious illnesses in today's society. Moreover, it is a heterogeneous disorder with symptoms manifested at the psychological, behavioral, and physiological level and which lacks a clearly defined and specific pathology, thus providing great difficulty in attempting to mimic the disorder in the laboratory. Most attempts have focused on using rats and mice for

comprises the latter variable. As the underlying pathophysiology of mood disorders is poorly understood, this has had a knock-on effect in choosing independent variables. In recent years, the increased clinical experimental evidence has, however, provided the preclinical researchers with more information to design the independent variable and therefore garner more information about the underlying aetiology of mood disorders. This has also been aided by the relatively recent focus on an endophenotype-based approach to study psychiatric disorders.

Animal models of antidepressant-like activity and depression

The Forced Swim Test

The forced swim test (FST) is the most widely used tool for assessing antidepressant activity preclinically. This is a model of antidepressant activity as opposed to depression *per se*. The widespread use of this assay as a model of antidepressant activity is largely a result of its ease of use, reliability across laboratories, and ability to detect a broad spectrum of antidepressant agents. The test is based on the observation that rats, following initial escape-oriented movements, develop an immobile posture when placed in an inescapable cylinder of water. If they are replaced in the testing apparatus 24 h later, they resume this posture quickly. The immobility is thought to reflect either a failure of persistence in escape-directed behavior (i.e. behavioral despair) or the development of passive behavior that disengages the animal from active forms of coping with stressful stimuli. If antidepressant treatments are given between the two exposures, the subjects will actively persist engaging in escape-directed behaviors for longer periods of time than after vehicle treatment. Investigators have been able to distinguish specific behavioral components of active behaviors, namely climbing and swimming behavior which have been able to selectively distinguish noradrenergic (increasing climbing) from serotonergic (increasing swimming) antidepressants. In mice, one exposure is sufficient to generate a stable immobility readout that can be countered by acute pretreatment with antidepressant agents. One major drawback of the FST (as with many antidepressant-sensitive paradigms) is the fact that short-term antidepressant treatments reverse the immobility, whereas in the clinic it can take weeks for the same antidepressants to elevate mood. As with many behavioral models motor performance can also affect behavior in this test and needs to be controlled for by running parallel locomotor activity assays.

The Tail Suspension Test

Since its introduction over 20 years ago, the tail suspension test has become one of the most widely used models for assessing antidepressant-like activity in mice. As is the case with the FST, it is a model of antidepressant activity and not a model of depression as there is no distinction between readout and inducing manipulation. The test is based on the fact that animals subjected to the short-term, inescapable stress of being suspended by their tail, will develop an immobile posture. Various antidepressant medications reverse the immobility and promote the occurrence of escape-related behavior. Although similar in construct to the closely related FST, there are distinct differences between the actions of drugs in both tests and they can offer complimentary information on a drug. Overall, the tail suspension test is a useful test for assessing the behavioral effects of antidepressant compounds and other pharmacological and genetic manipulations relevant to depression.

Olfactory Bulbectomy

The bilateral removal of the olfactory bulbs of a rat (hamsters and mice also have been used) results in a complex constellation of behavioral, neurochemical, neuroendocrine, and neuroimmune alterations, many of which are correlated with changes observed in major depression. To many investigators the bulbectomy model seems to be an obscure test because the rationale for its use as an animal model has been often questioned based on construct and etiological validity arguments. However, this model has one of the best portfolios for the prediction of known antidepressant compounds following repeated administration and is reliable between laboratories. The most consistent behavioral change caused by bulbectomy is a hyperactive response in a novel, brightly lit open field apparatus, which is reversed almost exclusively by chronic, but not acute, antidepressant treatment. Reasons for this time-dependent reversal are not fully understood but have generated much interest of late.

Learned Helplessness

The learned helplessness paradigm is based on the fact that following repeated uncontrollable shocks, animals demonstrate escape deficits that are reversible by antidepressant agents. The behavioral deficits are sensitive to a broad spectrum of antidepressant compounds usually following short-term treatment. The major drawback of the model is that most of the depression-like symptomatology does not persist beyond 2–3 days following cessation of the uncontrollable shock. Controlling for alterations

in pain sensitivity and motor performance must be carried out as they can alter activity in this test.

Chronic Mild Stress

The chronic mild stress (CMS) model consists of exposing rodents to series of mild unpredictable stressors during a prolonged period (usually >2 weeks). This stress regimen induces many long-term behavioral, neurochemical, neuroimmune, and neuroendocrine alterations resembling those dysfunctions observed in depressed patients. Primarily, there have been two major antidepressant-sensitive readouts characterized in the CMS model: (1) CMS depresses the consumption and preference for sucrose solution and (2) CMS decreases brain reward function as assessed using intracranial self-stimulation (ICSS). Both measures are correlated with anhedonia, one of the core symptoms of depression as defined in the DSM-IV. These anhedonia-like behaviors have generally been shown to be reversed by chronic, but not acute, treatment with several classes of antidepressants. Although the paradigm has been described as a model with a high predictive, construct, and etiological validity, it has very poor reliability and CMS-induced effects could not be reproduced in many laboratories.

Other Stress-Based Models

As the chronic mild stress model has fallen out of favor due to the lack of cross-laboratory reliability, other approaches to develop chronic stress-based models of depression have emerged.

Restraint Stress

One of the most consistent findings from neuroimaging studies in depressed patients is that there is a deficit in hippocampus function, whereas the amygdala is hyperactive. Building on these findings Chattarji and colleagues have developed a model of repeated stress in rats and mice, in which both of these findings are recapitulated. Following 10 days of repeated restraint stress there were deficits in hippocampal LTP, and dendritic atrophy and debranching in CA3 pyramidal neurons were observed, whereas there was increased arborization in the amygdala. Further studies with this paradigm may help to shed light on the mechanisms underlying the changes in these two important regions in depression.

Social Defeat Stress

There has been a resurgence of interest in social defeat stress as a model of depression. Behavioral and neurochemical alterations have been assessed following

exposure of mice to social defeat and continuous contact with the aggressor for 10 consecutive days, resulting in a long-lasting social aversion, even to unfamiliar mice. The authors suggest that given that chronic stress can lead to depression in vulnerable humans that this paradigm could represent a model of depression. This hypothesis is given some credence as chronic, but not acute antidepressant, nor anxiolytic (chronic or acute), administration reversed this social aversion.

Models of the Early-Life Stress

Experience of stressful events during childhood has long been thought to contribute to the pathophysiology of emotional disorders, and recent research findings describe how early life trauma and neglect exert a profound and pervasive influence on risk for depression and anxiety disorders. Indeed, it appears that early life trauma may not only increase risk for these disorders in adulthood, but may also precipitate illness onset, increase co-morbidity among disorders, and alter the efficacy of treatments for these conditions. In rats postnatal maternal separation can produce lasting increases in emotional behavior and stressor reactivity together with alterations in neurotransmitter systems implicated in emotionality, including corticotrophin-releasing factor, serotonin, noradrenaline, and glutamate.

Models Based on Drug-Withdrawal-Induced Anhedonia

Reward deficits associated with withdrawal from drugs of abuse can represent an animal model of the symptom of 'diminished interest or pleasure (anhedonia)' with construct, convergent, and predictive validities. Recent studies showed that amphetamine withdrawal is characterized by decreased breaking-points under a progressive ratio schedule for a sucrose solution reinforcer. Under the progressive ratio schedule animals are required to increase their operant responding for a fixed reward until they reach a break point which determines the maximal amount of effort the animals will expend to procure the desired rewarding stimulus, thus the break point provides an objective measure of the subjects motivation. Amphetamine withdrawal is also associated with decrements in anticipatory and motivational measures for sexual reinforcement and elevations in brain reward thresholds in rats. In certain situations, antidepressant compounds have been shown to attenuate the withdrawal-induced reward deficits in ICSS thresholds.

Endophenotype-Style Approaches

The traditional models of depression mainly rely on a small number of final readouts following a lesion or stressor. However, given the lack of novel antidepressants being derived, recent studies have attempted to use a more focused approach to study psychiatric disorders in preclinical laboratories, which attempts to assess only one symptom, or marker, of the disease. This approach aims to utilize characteristic endophenotypes of diseases and model them independently rather than the whole syndrome. Fundamental to this endophenotype-based concept is the assumption that the genetic basis of variations of the given marker between patients and control subjects are fewer than those involved in the manifestation of a complex disorder *per se*. This has the benefit of simplifying a complex disorder, such as depression, into individual behaviors, which are more easily measurable in both patients and laboratory animals. Moreover, this approach is akin to preclinical testing, where only one variable is generally measured. Such endophenotypes of depression that can be easily modeled in animals include psychomotor alterations, hedonic deficit (lowered response to rewarding and pleasurable stimuli), appetite and weight alterations, circadian and sleep disturbances, and cognitive deficits. However, care must be taken when using this approach for concerns of pseudo-specificity may arise, as even those endophenotypes considered as core symptoms in depression can, and usually are, present in other diseases.

Genetic Approaches

There has been an upsurge in the use of mice as models of psychiatric disorders, due to the ability to generate genetically modified mice. Such mice provide insight into receptors where there is a lack of pharmacological agents and have aided discovery of numerous potential targets underlying depression, which may give rise to novel antidepressants. However, care must be taken when using knockout mice, as compensatory changes can occur due to the life-long ablation of a protein and it may in fact be such alterations that result in the behavioral phenotype. More recently, inducible and site-specific knockouts have been generated, which enable the role of proteins to be assessed in adult mice negating the compensatory effects. Similar strategies can also be used to knock-in specific genes, which lead to an overexpression of the protein. The development and refinement of more mice behavioral models has also expanded the strength of genetically modified mice and as such they represent a powerful tool with which to study the role of specific proteins in depression.

However, care must be taken when using knockout mice, as compensatory changes can occur due to the life-long ablation of a protein and it may in fact be such alterations that result in the behavioral phenotype. More recently, inducible and site-specific knockouts have been generated, which enable the role of proteins to be assessed in adult mice negating the compensatory effects. Similar strategies can also be used to knock-in specific genes, which lead to an overexpression of the protein. The development and refinement of more mice behavioral models has also expanded the strength of genetically modified mice and as such they represent a powerful tool with which to study the role of specific proteins in depression.

Selective Breeding in Animal Models of Depression

In order to discriminate potential genetic influences on depressive-like behavior, several attempts have been undertaken using selective breeding programs of animals based on the individual responsiveness in animal models of depression. To this end, rats were selectively bred for susceptible to learned helplessness and for high and low level of immobility in the FST. Other genetic models have been developed based on an underlying alteration in the function of both cholinergic (Flinders Rat) and serotonergic neurotransmitter systems. One mouse model that has been derived from animals bred for spontaneous high or low immobility scores in the tail suspension test, referred to as helpless or nonhelpless mice. In addition to increased immobility in the TST, helpless animals also had an increased immobility in the FST, differences in sleep architecture, disturbance in hypothalamic–pituitary–adrenal, and alterations in serotonergic function. Two other lines of mice and rats (HAB and LAB mice and rats) were selectively bred for their differential sensitivity to anxiety behavior on the elevated plus maze and also have been postulated as an animal model of depression.

It should be noted that any two genotypes that differ markedly in a trait can serve as the basis for a genetic inter-cross that is informative for gene mapping purposes. There is always the possibility that, in undergoing such selected breeding programs, the effects seen may be influenced by genetic drift. This would result in independently selected lines having qualitatively different behavioral responses. The comparison of different common strains of mice and rats has also yielded some potential genetic models of depression; among the most widely used are the Wistar Kyoto rat and the BALB/c mouse both of which have an elevated response to stress and altered behaviors in the FST.

Conclusions

Presently, with the advances in techniques to study mood disorders in humans, there is an opportunity to incorporate such findings into preclinical research. Additionally, the increased awareness of the need for cooperation between psychiatrists and behavioral neuroscientists has led to a more endophenotype-based approach to study single symptomatic clusters. Furthermore, genetic approaches are giving detailed insights into changes that occur in molecular cascades relevant to depression-like behaviors that are used to measure antidepressant action. Initially, such efforts will provide a greater understanding of the pathophysiology of major depression which, in the long term we hope, will lead to novel, faster, and more universally effective antidepressants.

Glossary

Anxiety disorders – A group of disorders involving inappropriate or dysfunctional responses to potential threat.

Anxiolytic and panicolytic drugs – Drugs that reduce anxiety (often focusing on Generalized Anxiety Disorder (GAD)), or Panic Disorder.

Danger learning – Associative learning when a stimulus or situation is paired with pain, or with cues such as cat fur/skin odor that are highly predictive of the presence of a predator. Such stimuli commonly support one-trial learning.

Defensive aggression – Aggression triggered by the attack of a predator or conspecific. In rats and mice, defensive attacks are generally targeted to the head of the attacker, vulnerable sites where the potential for damage may cause the attacker to interrupt or cease its attack.

Defensive behaviors – A group of unconditioned response patterns elicited by threat stimuli. These are conservative across mammalian species and are modulated by features of the threat stimulus and the situation in which it occurs. In the rat and mouse, they include flight, freezing, risk assessment, defensive threat, and defensive attack.

Enabling stimuli – Features of a situation that influence the probability of success of a particular defensive response. As a result of evolution, these have a modulatory role in determining the type of defense seen when a threat is encountered.

Fear/anxiety distinction – A differentiation between responsiveness to a clearly present threat, typically associated with active responses such as escape or avoidance (fear) versus that to an ambiguous or poorly defined threat, typically associated with worry, rumination, and interference with normal activities. It is often (mistakenly) conceptualized as involving normal (fear) versus pathological (anxiety) reactions.

Defensive behaviors are a group of responses or response patterns that have evolved because they are adaptive in enabling animals to deal with threats to survival. A crucial feature of this adaptiveness is the match between defensive behavior and important features of the threat stimulus and the situation in which it is encountered.

Threat Stimuli

Threat stimuli are traditionally divided into three classes: predators, conspecific attackers, and dangerous features of the environment. All three of these are, to varying degrees, factors in the survival of most vertebrate animal species, with predators representing a particularly important, and highly variable, class of threat stimuli. Evidence from a number of bird and mammal prey species indicates that these animals can differentiate aerial, terrestrial, and even subterranean predators, and are capable of signaling to conspecifics – animals of the same species – which type of predator may be present. Some prey species also appear to be able to discriminate the alarm signals of a nonconspecific made in response to the appearance of these disparate types of predators. These discriminant abilities and the signals with which they are associated form part of the defensive repertory of such animals.

Conspecific threats are from another animal of the same species. Despite a commonly held misconception to the effect that fights between animals of the same species seldom result in harm or death, conspecific attack can be lethal, even among animals such as ungulates that are not predators and do not have strongly developed weapon systems. However, conspecific attack may involve particular features such as targeting of bites and blows to relatively nonlethal sites, or reduction of attack when the opponent signals submission or defeat, that tend to reduce the lethality of within-species fighting. These features are especially common among more social species in which proximity of related animals enhances the genetic maladaptiveness of damage or death from conspecific attacks.

Dangerous environmental features such as fires, floods, and earth movements may threaten individuals of any species. Somewhat paradoxically, these tend to have less influence on the complexity of defensive behaviors, as most are either relatively easily avoided (e.g., bodies of water or high places for terrestrial animals), or, almost impossible to avoid except for flying animals, and sometimes not even then (e.g., pyroclastic flow or noxious fumes from an erupting volcano).

Defensive Behaviors

These examples of threat stimuli point to the first requirement for a successful defense: It must involve detecting, and to some degree discriminating, important

features of the threat stimulus. This involves a strong tendency to attend to potential threat in the environment; typically labeled ‘vigilance’ in the context of field studies, or ‘risk assessment’ in laboratory work. These behaviors tend to be measured in terms of specific orientation and movement characteristics, in which the subject first orients toward any danger signals that may be present (e.g., an unexpected movement or sound) and may even approach it, often utilizing a movement pattern that reduces the likelihood of itself being detected as it attempts to approach and investigate the potential danger. In laboratory rodents, this takes the form of low back or stretched approach movements in which the animal alternates periods of immobility with brief forward movements.

After a threat stimulus has been detected, the defensive behaviors that appear to be common to most mammalian species include flight, often followed by hiding if a place of concealment or protection is available; freezing (cessation of movement); defensive threats to the threat stimulus; defensive attack to the threat stimulus; and, especially in highly social species, alarm cries or other signals of the presence of the threat. Other specific behaviors may be related to or comprise components of one or more of these general tactics. For example, the explosive startle reaction measured in tests of conditioned startle responses may function to surprise and even briefly stun an attacker, providing an opportunity for the subject to escape. Defensive burying is likely to have different functions with different types of threat stimuli. With noxious or potentially toxic stimuli, such as a shock prod or a decaying carcass, burying may interpose a barrier that reduces the dangerousness of the stimulus. That this is its major function, however, is brought into question by findings that rats not only bury novel stimuli in their home environment, but also routinely dig them up again. An additional function of defensive burying may simply be that it throws things – dirt or other substrate – at potentially dangerous objects. If the object responds, for example, by movement when hit, then it reveals itself as an animate rather than an inanimate object, thereby confirming its potential as a threat. Defensive threat and attack occur when the danger is imminent. In several rodent species and in domesticated cats, both defensive threat and defensive attack may be differentiated from other forms of aggressive threat and attack by both the actions involved and by the targets on the body of the opponent where weapons (teeth, claws) are aimed. Although less well studied in other animals, a number of species from ungulates to primates have been shown to display different attack patterns and weapon use as a reaction to threat stimuli, as compared to those shown in offensive, conspecific aggression.

The Effectiveness of Defense

In order to evolve, individual defensive behaviors must be effective against the type of threat against which they are utilized. For some threat stimuli, this may be very difficult, and the concept of effective may reflect only a small increment in success against a dismal baseline: if a small mammal is caught by a larger and more powerful predator, the overwhelmingly likely outcome is its death. Any defense that reduces the probability of that outcome, albeit even by 5%, is effective in comparison. The finding that alley cats generally fail to attack wild rats if the latter weigh more than about 200 g suggests that rats of such a size, but not smaller, are capable of damaging the attackers enough to reduce their adaptive potential. Defensive attacks may be adaptive through related conspecifics, even if most of the defensively attacking rats are themselves killed in the process.

If defensive threat/attack or a prodigious startle causes the predator to back off or release its grip on the prey while freezing is ineffective, then the former behaviors are not only more effective than no defense, they are also more effective than freezing, to that particular type of threat stimulus. Conversely, flight may be highly effective against approaching environmental dangers such as a slow-moving flood, against which defensive threat/attack or startle would be useless or counterproductive. The centrality of the relationship between particular types of threat and individual defensive behaviors has resulted in the evolution of relatively specific connections between characteristics of threat stimuli and situation, on the one hand, and the type of defense emitted, on the other. This is manifest as a high probability of that particular response to that type of threat/situation combination. Some important threat/situation characteristics are discussed in the following.

Defensive Distance

Defensive distance, the physical distance between predator and prey, strongly impacts the type as well as the intensity of defense offered. Whereas a distant predator may elicit only continued vigilance with freezing or flight as the distance between predator and prey decreases, defensive threat and then defensive attack (alternatively startle, depending on the prey species) may occur as contact between the two becomes imminent. All of these activities are oriented toward the predator, or directly away from it (flight), but they are clearly distinguishable on the basis of well-defined features of the behavior itself.

Threat Ambiguity

Many threat stimuli are not discrete, obvious, or clearly localized, at least not until it is too late for any specific antipredator defenses to have a good chance of success.

This situation is exacerbated by predators' use of stealth or crypsis in order to reach striking distance to the prey without being detected. As early detection typically produces a sharp reduction in the success of the hunt, mammals of prey species spend a substantial proportion of their time budgets attempting to detect danger, utilizing a pattern of scanning the environment, focused listening, or sniffing, to the detriment of nondefensive activities such as eating, grooming, or care of young. Among animals that live in groups, behaviors of other group members may be observed for indications that the latter have detected danger: In some highly social species, such as meerkats, sentinels rotate the duties of scanning for danger. These activities, labeled vigilance or risk assessment are strongly associated with threat stimulus ambiguity. In laboratory settings, they are particularly prominent when a subject encounters ambiguous or non-specific stimuli potentially associated with threat, such as novel or unexpected places, objects, sounds, and smells. Ambiguous stimuli often elicit approach, investigation, sniffing or other information-gathering activities, with relatively rapid habituation of these behaviors if no actual danger is found. Stimuli with a more specific association with danger, such as the odor of a predator, elicit a similar pattern but one that is much less likely to show rapid habituation.

Enabling or Expediting Stimuli

If evolution is responsible for the development of defensive behaviors, animals showing adaptive defenses, that is, defenses that are appropriate to the situation, have survived and reproduced more successfully than those that did not. These behaviors should represent the most effective defense possible, given not only the particular threat encountered, but also the specific features of the situation in which the encounter takes place. Some examples are given as follows: the presence of an exit feature from a threat situation is crucial in order for flight to be effective. This is not a matter of definition or circular reasoning. Rapid locomotion away from a threat (flight) is physically possible in any fairly large enclosure, but it is not effective against most animate attackers without a way for the subject to actually escape the enclosure. When escape is not possible, other defenses such as freezing and defensive threat/attack have been shown to be more effective in reducing damage to the subject. Other evidence for an association between flight and an escape route is that blocking of an existing escape route may rapidly elicit a switch from flight to freezing in rats. A place of concealment or protection can open up new defensive possibilities: hiding, either alone or in combination with facing out of the hiding place and threatening the oncoming predator. Rodent subjects, in particular, often utilize

even blind tunnels to face outward, confronting their attackers with their most effective weapons, the teeth.

Orientation to such features can be clearly demonstrated. When the silhouette of a predator was displayed overhead, gerbils that had established a place preference during a 15-min exploratory period in the test situation showed a flight path that maximized the distance to the threat stimulus, minus the distance to the preferred area. Animals moved involuntarily to a new location show high-level exploration of the new site. This reflects the importance of information on the presence and location of defense-relevant features such as an escape route or a hiding place, should the new location also contain danger. Notably, when a new site is opened adjacent to a familiar area, such exploration is more tentative and delayed.

An additional expediting or enabling stimulus is the presence of conspecifics. This is necessary for alarm cries to fulfill the function of alerting relatives to the presence of danger, and alarm cries, at least in rats, do appear to depend on the presence of conspecifics. Cries for help, suggested by anecdotal evidence in primate infants or young, might similarly be expected to be facilitated by the presence of familiar adults.

These findings suggest that unconditioned defensive behaviors, elicited and modulated by a host of features of the threat stimulus and situation, are the product of evolution, reflecting differential survival/reproductive success that they afford to individuals that display them appropriately. Because the types of stimuli or factors that provide a direct threat to the bodily well-being of animals of different species are relatively consistent, as are the factors that make specific defenses effective, it is a reasonable hypotheses, for which one set of tests will be later described, that a corresponding consistency may be seen between eliciting stimuli/situations, and specific defenses, across mammalian species. These relationships are outlined in **Table 1**.

Learning and Defense

The relationship between features of the threat stimulus/situation and the form of defense is not one of physical necessity. Moreover, it is often not a matter of learning: in studies using laboratory rodents, all of the relationships described here have been demonstrated in animals that have never had experiences that might have produced such learning. Some studies have shown specific defenses in rat pups, by 12–18 days of age, and by shortly after weaning rats appear to show a relatively wide range of appropriate defenses. Other findings arguing against a learning interpretation of the core relationships between threat stimuli/situations and defensive behaviors include the difficulties of changing the form of an elicited defensive behavior by either lack of reinforcement or by

Table 1 Defensive behaviors as a function of the discreteness or ambiguity of threat, defensive distance, and presence of particular enabling stimuli

<i>Source of threat (and distance)</i>	<i>Enabling Simuli</i>	<i>Behavior</i>	<i>Typical Outcome</i>
Discrete	"Way out" available	Flight	Escapes
Discrete	No means of escape	Freezing	Reduces attack
Discrete	Conspecifics nearby	Alarm cry	Warns conspecifics
Discrete	Hiding place available	Hides	No detection/access
Discrete (close in)		Defensive threat	Threatens attacker
Discrete (contacting)		Defensive attack	Hurts attacker
Discrete (contacting)		Startle	Startles attacker
Uncertain (potential)		Risk assessment	Localize, identify threat
Uncertain (potential)	Substrate	Defensive burying	Elicit animate movement

specific and immediate punishment. These findings do not, of course, suggest that learning has no impact on defensive behavior, a view that is clearly incorrect in terms of the rapidity of associative learning utilizing predators or predator odors as unconditioned stimuli.

Danger Learning

Defensive behaviors show robust and rapid conditioning to stimuli, particularly situational stimuli, when pain is used as the unconditioned stimulus. Many studies of this phenomenon have focused on defensive immobility behaviors, variously labeled crouching or freezing. Such immobility is robust following shock, and also when the subject is replaced in that situation 24 h later, demonstrating one-trial conditioning. The intensity of the response increases as a function of intensity of a (single) shock, but is reduced by previous familiarity with the situation in which the shock is given (latent learning). A particularly important point is that the discriminability of the shock source can change the form of the conditioned defense, evaluated during a later presentation of the CS: highly discriminable shock sources (objects) produce predominant avoidance of that object, whereas shock from a poorly discriminable source (cage flooring) produces a conditioned immobility in the shock situation.

The presentation of a noncontacting cat to a rat that has never previously encountered a cat elicits freezing. Such freezing shows robust one-trial contextual conditioning, indicating that pain, or even contact with the threat source, is unnecessary to support learning. Mice also show a range of defenses when confronted by a mouse-predator, a rat; a paradigm embedded in a number of studies of mouse defensive behaviors, in the Mouse Defense Test Battery. Although even quiet predators may elicit some degree of defensiveness, primarily risk assessment or avoidance, more active predators, such as an approaching cat, rat, or lion, elicit a more intense defense, typically one that is relevant to the action of the predator, for example, flight to an approaching US. Partial predator stimuli (cat fur/skin odor) also elicit risk assessment,

freezing, and, when clearly localizable, avoidance. There may be a relationship between the degree to which a partial predator stimulus elicits risk assessment and the degree to which that stimulus supports, as a US, one-trial aversive or danger conditioning. Cat fur/skin odor has repeatedly been demonstrated to support one-trial conditioning, whereas cat feces or urine, or trimethylthiazoline, a synthetic chemical derived from fox anal gland extracts, all elicit some degree of defensiveness but may not elicit risk assessment and do not appear to support one-trial learning.

Contextual danger learning, such as occurs when a predator or other strong threat is encountered in a particular context, may be evolutionarily adaptive because it results in enhanced defensiveness in situations where danger is likely. It is also possible that stressors might produce a general enhancement of defensiveness as reflecting an increased level of danger. Both exposure to a cat, and to cat fur/skin odor stimuli, have been shown to enhance anxiety-like behaviors in rats in a number of anxiety models, up to 21 days later. This effect is not limited to predator or partial predator stimuli. Stressors such as pair-housing with a more dominant animal or imposition of an array of stressors on a chronic basis have been shown to enhance durations of defensive burying, and freezing. Conversely, early experience of stress-reducing events may be capable of reducing defensiveness; for example, offspring of high-licking mothers showed less defensiveness in both defensive burying tests, and when serving as intruders in resident-intruder tests.

In summary, although defense patterns, at least in rats and mice, are not based on specific experience, they may become conditioned with a single pairing or trial. This very rapid, one-trial conditioning has been demonstrated with painful stimuli, or the actual presence of a predator, or some, but not all, partial predator stimuli serving as the US. The crucial factor in the ability of a threat stimulus to support one-trial conditioning appears to be the degree to which it may predict the presence of danger. In addition, exposure to threat stimuli such as predators or dominant conspecifics, as well as chronic exposure to other types of

stressors, may result in long-term enhancements of emotionality, manifest as increases in both individual defensive behaviors and in more general anxiety measures.

Defensive Behaviors in People

Laboratory and, especially, field studies make it clear that many of these defensive behaviors are included in the defensive repertory of most mammals, not just rats and mice. This brings up the question of the mammalian species most interesting to the vast majority of neuroscientists: humans. If defensive behaviors are to serve as models for investigating and understanding the biology of emotional response to aversive stimuli, it is essential to evaluate whether these systems show strong parallels in human responsiveness to threat. In attempting to determine whether there are meaningful human parallels to these behaviors, the obvious solution is to examine human defenses in the same contexts of eliciting and enabling stimuli that modulate the defenses of rodents.

The most focused attempt to determine how people react in such situations provided brief scenarios that sketched out threat stimulus and situational characteristics, and required subjects to choose their first response to each such situation. Subjects were given a list of possible behaviors, but also allowed to fill in their first choice when this was not on the list. Because most people have had very limited exposure to nonhuman predators, whereas virtually everyone has had some or much personal or vicarious (via TV and films) exposure to human attack, the scenarios described actual or potential human, rather than predator, attack.

When the first response chosen in each such scenario was analyzed in terms of the same range of factors (threat stimulus and situational characteristics) that strongly determine the form of attack in laboratory animal studies, the similarities in these relationships were striking. Over three-quarters of the responses chosen were similar to those identified in animal research, with the remainder reflecting human abilities presumably not available to nonhuman animals, such as negotiate. Significant and sometimes extremely high correlations were found between stimulus/situational characteristics and the defensive behaviors with which they were associated. As an example, the correlation between ambiguousness of stimuli and risk assessment was nearly +0.90. These results have been replicated in published studies based on subjects in several different cultures, each of which utilized a relatively large number of subjects. Comparisons between the results of the studies show only limited evidence of cultural differences on the choice of responses to the different threat stimuli and situations.

The data from all of these studies were consistently consonant with a view that people utilize many of the same defensive behaviors as do rodents, and that major features of threat stimuli and situations that are determinative of defensive responses for rodents have parallels in human behavior. These findings must be taken in the context of scenarios designed to avoid some real complications arising from cognitive and technological differences between human and nonhuman animals, such as an omission of guns or other weapons. Nonetheless, they provide strong support for a view that not only individual human defensive behaviors, but also the patterns of their responsivity to important antecedent and surrounding situations, have some important similarities to those of nonhuman mammals.

Defense and Anxiety

Etymological analyses of the terms ‘fear’ and ‘anxiety’ suggest that, while both describe reactions to threat or danger, they are different in terms of their eliciting stimuli; the behaviors they encompass; and the degree to which they are regarded as normal and adaptive. Sometimes described as free-floating, anxiety is a response to an ambiguous or poorly defined danger, and its manifestations tend to be largely subjective, involving extended worry or rumination. Although these are extremely unpleasant to the individual, they are typically without a definitive outcome in terms of specific action patterns, except for the negative impact they may have on more productive life activities. This combination, of a poorly defined cause and a response that is regarded as relatively unproductive, contributes to a view that anxiety is a less adaptive response than is fear, seen as a normal response to danger.

The foregoing analyses of defensive behaviors suggest that this common differentiation between fear and anxiety is rooted in biology. Ambiguous threat stimuli elicit risk-assessment responses that have a strong parallel in worry and rumination, that is, cognitive efforts to understand an ambiguous or poorly conceptualized problem. Moreover, characterizations of anxiety in terms of ‘apprehensive expectation’ are clearly congruent with the vigilance aspect of defensiveness in potential threat situations. Finally, the notion of jumpiness or physiological hyper-reactivity fits well with observations that risk assessment is associated with muscle tension, likely as a preparation for action should the results of the assessment demand it. Conversely, defensive behaviors to clearly present and differentiable threat, such as flight or avoidance, fall squarely within the range of activities associated with fear and can be seen as potentially effective solutions to the danger presented.

The existence of a biological basis for the differentiation of fear and anxiety does, however, call into question the common view that fear is more normal and adaptive than anxiety. Risk assessment may be the best-possible response when an individual is confronted by an ambiguous threat or difficulty, as it is aimed at identification or understanding of the threat source. This suggests that both fear and anxiety may be normal if they occur in response to appropriate situations and decline in intensity in accord with the degree to which the situation becomes less dangerous. Pathology may occur when the response is out of proportion to the danger, inappropriate to the danger, or fails to decline with reductions in the danger. These conditions may hold for behaviors classifiable as either fear or anxiety, although many problems in human life are so complex, ubiquitous, and difficult to analyze that they provide particular occasion for the elicitation of anxiety. In addition, a history of stressful experience such as may also be common in human life, can also adversely affect cognitive functioning, such that early and prolonged stress would be expected to negatively impact the quality of risk-assessment processes, promoting anxiety in situations with which normal individuals might cope. Indeed, the notion of coping includes cognitive strategies as an important component.

Analyses of defensive behaviors, with their emphasis on differences in both the stimulus/situational elicitors of these behaviors, and in the form and function of the individual behaviors themselves, are also relevant to a consideration of the wide range of ways in which anxiety disorders are expressed, that is, their specific defining symptoms or characteristics. While response similarities in behaviors used as the basis for animal models of anxiety, and behavioral aspects of relevant psychopathologies are often dismissed as face validity, it might be noted that the differentiations among anxiety disorders are typically based on behavioral symptoms that have some parallels to these defensive behaviors. Findings of considerable specificity of response by particular defensive behaviors, to drugs effective against generalized anxiety disorder (GAD), or, panic, raise the possibility that these defensive behaviors are the output of neural systems that are differentiable in terms of hodology, neurotransmitter involvement, or some combination thereof. This possibility, in turn, opens new avenues for pharmacological research, as well as for behavioral treatments that reflect the normal functions of individual defenses.

Responsivity to Anxiolytic Drugs

If, as these findings suggest, defensive behaviors may be embedded in anxiety disorders, then they should respond to antianxiety drugs. It is notable that there are substantial differences in responsivity to particular classes of drugs for different anxiety disorders, and the possibility of specific involvement of various defensive behaviors in these disorders suggests that the latter may also show differential drug response. In particular, drugs effective against GAD have been compared to those that reduce panic attacks: Drugs effective against GAD consistently reduce risk assessment, and defensive threat/attack, whereas drugs that are effective against panic disorder consistently reduce, and propanic drugs consistently enhance, flight. The ability of drugs effective against GAD to reduce risk assessment supports a view that risk assessment is a focal feature of GAD. It is also notable that excessive rumination is more associated with women than men, and that females are overrepresented in GAD by about 2 to 1. The effect of anti-GAD drugs on defensive threat and attack is less obvious, and may relate to the inclusion of irritability or hyperreactivity as a factor often associated with GAD.

In contrast to GAD, a well-developed hypothesis of panic disorder has a focus on flight as a core motivation and response tendency. Because of this hypothesis, a number of studies have focused on the relationship between flight and panic, demonstrating that antipanic drugs and drug schedules increase flight; propanic drugs and drug schedules decrease flight; and drugs without effect on flight also have no effect on panic; all of which provide consistent evidence for the view that defensive behaviors may provide both a conceptual model for analysis of anxiety disorders, and a useful experimental model for the evaluation of drug effects on these conditions.

Glossary

Activity burst – The burst of activity elicited by the aversive unconditional stimulus in fear-conditioning experiments, primarily characterized by jumping and/or rapid locomotion.

Circa-strike defensive behaviors – The behaviors that occur when the animal is attacked by a predator. These behaviors evolved to facilitate escape and are characterized by rapid locomotion, jumping, and counter attacks aimed at the predator.

Conditional response – The behavioral response elicited by the conditional stimulus after a conditional association has been formed with the unconditional stimulus.

Conditional stimulus – An initially neutral stimulus that comes to elicit a behavioral response due to a conditional association with a biologically significant stimulus.

Fear conditioning – A general term applied to procedures in which an aversive unconditional stimulus is paired with conditional stimuli and fear-related conditional responses are measured.

Freezing – The complete absence of all movement except that necessitated by breathing. As the primary postencounter defensive response in rodents, it evolved to prevent detection by predators as well as attack, because movement acts as a releasing stimulus for predatory attack.

Pavlovian conditioning – A learning process where an initially neutral stimulus enters into a conditional association with a biologically significant stimulus and comes to elicit a behavioral response. It is also referred to as ‘classical conditioning.’

Postencounter defensive behaviors – The behaviors that occur when the animal has detected the presence of a predator. These behaviors evolved to prevent detection and, if the animal has already been detected, decrease the probability of attack.

Predatory imminent – The perceived proximity of an animal to predatory attack. This is characterized by a continuum from low predatory imminent, where no predators have been detected, to high predatory imminent, where the animal is currently being attacked. Prey species, such as the rodent, have evolved specific behaviors that optimize survival along this continuum.

Pre-encounter defensive behaviors – The behaviors that occur when an animal is potentially in danger but a predator has not been detected. In general, these behaviors evolved to avoid predator detection and to facilitate escape but still allow for other adaptive behaviors such as foraging for food.

Species-specific defensive reaction – The behavioral responses that evolved to optimize survival in the face of environmental threats that a particular species is likely to encounter in its native habitat.

Unconditional response – The innate behavioral response elicited by the unconditional stimulus.

Unconditional stimulus – An inherently biologically significant stimulus that elicits an innate behavioral response.

Historical Background

The modern study of fear conditioning is based on the assumption that fear is a defensive motivational system that evolved to optimize survival in the face of environmental threats. Activation of this fear system produces highly predictable changes in behavior and physiology and the magnitude of these changes are proportional to the level of fear. A thorough understanding of the parameters which produce fear, combined with the predictability of fear responses, has allowed researchers to delve deeply into its underlying neural mechanisms.

The modern view that fear produces predictable and functionally organized behavioral responses in proportion to the level of fear, was not widely held until the past few decades.

Early studies conducted during the middle of the last century dominated by the theoretical framework of Neil Miller and O.H. Mowrer focused more on how fear is able to modify behavior and less on fear itself. The dominant view for decades of research was that painful stimuli, such as an electric shock, could be used to punish behavior and that termination of signals for punishment could serve to reinforce a particular behavior. These researchers used instrumental avoidance learning procedures in which they made avoidance of shock contingent on an arbitrarily chosen behavior. For example, the animal should be able to learn to run on a running wheel, shuttle between two chambers, rear, or press a lever to terminate fear-producing cues. This view stressed the acquisition of arbitrary behaviors on a trial-and-error basis.

In the early 1970s this prevailing view began to come under fierce assault, most notably by Robert Bolles. In a highly influential paper entitled ‘Species-specific defensive reactions and avoidance learning,’ he questioned the basic theoretical assumptions of instrumental avoidance learning as well as the empirical evidence upon which it was based. First, he argued that fear evolved as a way to defend against predators and that learning the proper response to predators through trial and error is a highly ineffective strategy to avoid being eaten. “Survival is too urgent, the opportunity to learn is too limited and the parameters of the situation make the necessary learning impossible.” A momentary failure to avoid death has much more severe consequences than a temporary failure to obtain food and the learning rules should therefore be different. Bolles pointed out that some avoidance responses, such as flight, could be rapidly and efficiently acquired, whereas others, such as lever-press avoidance, required thousands of trials to achieve mediocre effectiveness. Rapidly acquired avoidance responses, Bolles argued, were part of the rat’s innate defensive behavioral repertoire and did not require reinforcement to be expressed. These behaviors, which he termed ‘species-specific defensive reactions’ (SSDR), evolved to optimize survival in the face of environmental threats that rats are likely to encounter in their native habitat.

The shaping of optimal defensive behaviors, in the SSDR view, occurs at the species level through natural selection, rather than at the individual level through reinforcement or punishment of a particular behavior. In a prey species, such as the rodent, the experiences of countless predator-prey interactions, passed on in the genes of those who avoided predation, supersede the experience of the individual. The precise nature of defensive behavior, that is, its shape, vigor, and duration, is therefore genetically determined and largely impervious

to change by reinforcement contingencies. These behaviors occur because the animal is frightened, not because they have been reinforced by escaping or avoiding pain. The huge number of trials required for some avoidance responses to be acquired suggests that, while instrumental avoidance learning can occur under some conditions, the primary responses to fearful situations are SSDR’s.

In 1988, Fanselow proposed a modification of SSDR theory, which he termed ‘predatory imminence theory.’ It provided a formulation for how different defensive behaviors are expressed under different conditions. Predatory imminence, defined as the perceived proximity of an animal to predatory attack, determines the level of activation of the fear motivational system and this, in turn, determines which defensive behavior will be expressed. In this model, defensive behavior is not only species specific, but also specific to the level of threat. Thus, certain behaviors evolved to optimize survival along a continuum of predatory imminence.

The main points along this continuum are referred to as pre-encounter, postencounter, and circa-strike behaviors. ‘Pre-encounter’ behaviors occur in situations where the animal is potentially in danger but no predator has been detected. These behaviors, such as thigmotaxis (running along walls), preference for the dark and stretched approach (slow, cautious forward movement), minimize the chances of detection by predators, while still allowing other adaptive behaviors such as foraging. ‘Postencounter’ behaviors occur when the animal has detected the presence of a predator. This can be triggered by innately aversive stimuli such as predator odors or by stimuli that have been paired with previous predatory attack. The primary postencounter behavior in rodents is freezing, which helps prevent attack by making the animal less visible to predators, which rely largely on movement for detection of their prey. Additionally, since movement acts as a releasing stimulus for attack, a detected but frozen prey is less likely to be attacked. ‘Circa-strike’ behaviors occur when the predator is actively attacking the animal. The primary circa-strike behavior is an activity burst, which can involve jumping and/or fleeing from the predator. Defensive biting, often aimed at the nose of the predator, may also occur if no escape is available.

Predatory imminence-SSDR (PI-SSDR) theory has proven to be a powerful theoretical framework for predicting and explaining fear-related behavioral changes and it now forms the basis for the study of fear conditioning. Integrating PI-SSDR theory with Pavlovian conditioning theory provides a complete picture for how animals acquire and express fear. Pavlovian, or classical, conditioning refers to a learning process where a neutral stimulus, the conditional stimulus (CS), becomes associated with a biologically significant stimulus, the unconditional stimulus (US). The US is able to produce a response on its own, which is referred to as the

'unconditional response' (UR). After one or more pairings of the CS and US, the CS comes to elicit a conditional response (CR). Pavlov emphasized that the CR requires a dependent, or conditional, relationship between the CS and the US. Thus, the term conditional is the correct and the preferred term, rather than conditioned, which is unfortunately frequently used. In laboratory studies of fear conditioning, the CS can take many forms, with tones, lights, and the conditioning chamber itself being the most common. The US is a painful or startling stimulus such as an electric footshock or loud noise. The CR is a conditional fear response which produces species-specific behavioral and physiological responses according to the level of fear.

Distinguishing what constitutes the UR to the shock versus the CR to cues associated with the shock can be clarified by PI-SSDR theory. In contrast to other Pavlovian paradigms, the UR and the CR are quite different in fear conditioning. As the US is equivalent to attack from a predator, the UR is a circa-strike SSDR, that is, an activity burst. As presentation of the CS is equivalent to detecting a previously encountered predator, the CR is characterized by postencounter defensive behavior such as freezing.

The strength of the CS-US association determines the magnitude of the conditional fear response, which, in turn, determines the amount of freezing. Measuring the

percentage of time the animal spends freezing therefore provides a behavioral measure of the CS-US association. Conditional fear also produces a number of other changes, such as increased blood pressure, alterations in heart rate, analgesia, release of stress hormones, and potentiation of the startle response. The percentage of time an animal spends freezing has become the most commonly used measure of fear.

Pavlovian Fear-Conditioning Procedures

The basic fear-conditioning procedure involves pairing an aversive US with an initially neutral CS. Fear conditioning can be conducted using a wide variety of different parameters that can be tailored to suit the particular needs and theoretical questions of a given experiment. Different CSs can be used; these are usually tones, white noise, lights, and/or the conditioning chamber itself. Different aversive USs can also be used, although electric footshock is the most common. The number of US presentations can be varied to adjust the overall level of conditioning and the CS and US can be presented in different temporal relationships. A brief review of the more standard fear conditioning procedures will be presented below and are outlined in [Figures 1 and 2](#).

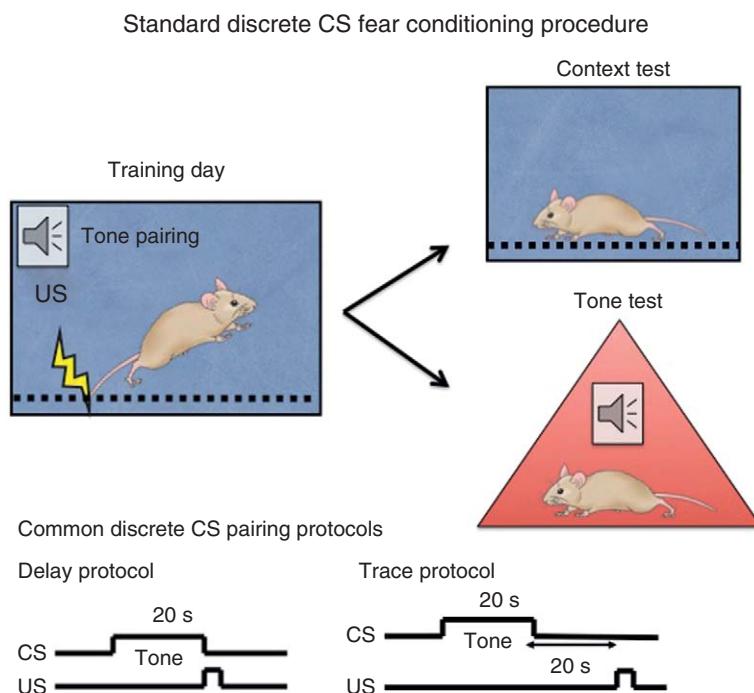

Figure 1 Standard discrete conditional stimulus fear-conditioning procedure. On the training day, the animal receives one or more pairings of the discrete CS with the shock US. Testing consists of returning the animal to the original conditioning chamber for a context test and to a novel chamber for the tone test. The order of tone and context tests can be counterbalanced. Delay and trace conditioning are the most commonly used parameters in discrete CS fear conditioning.

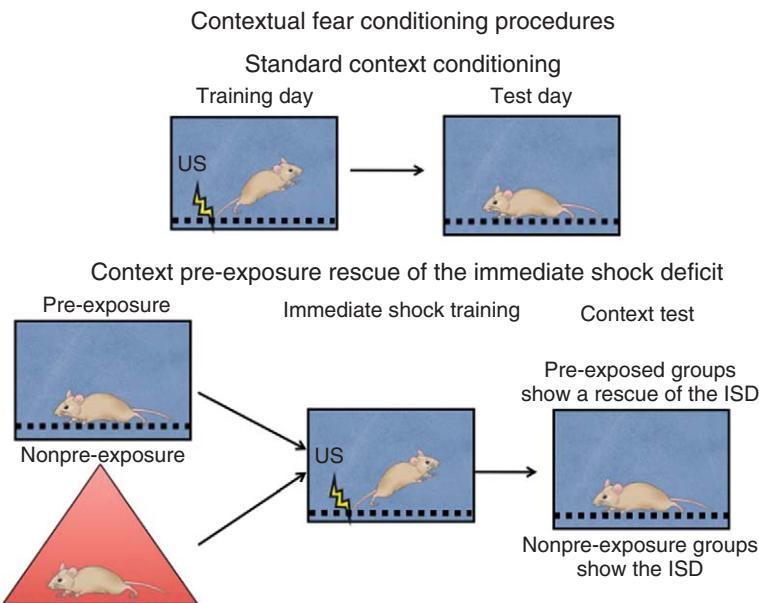

Figure 2 Contextual fear conditioning procedures. The most standard form of context conditioning is to place the animal in the conditioning chamber and then present one or more footshocks. Context fear is then tested by returning the animal to the conditioning chamber for a context test. The context pre-exposure rescue of the immediate shock deficit usually involves two groups: one which is pre-exposed to the training context and one which is not. Both groups receive a single footshock immediately (15 s or less) after being placed in the conditioning chamber. Animals that were not pre-exposed show the immediate shock deficit because they were unable to form a contextual representation to associate with the immediate shock. Animals that were pre-exposed show the context pre-exposure rescue of the immediate shock deficit, that is, they are able to associate the contextual representation formed during the pre-exposure with the immediate shock and acquire contextual fear.

Fear-conditioning procedures can be broken down into three different phases: acquisition, consolidation, and expression/retrieval. The acquisition phase refers to the formation of the CS-US association on the training day. Consolidation is a process that occurs immediately after training and involves solidification of the CS-US association into a lasting memory trace. When the animal is reexposed to the CS on the test day it retrieves the CS-US association, which triggers the expression of fear.

Discrete CS Procedures

Simple stimuli from a single sensory modality, such as a tone, a white noise, or a light, are referred to as 'discrete CSs.' In a discrete CS procedure, the animal is placed in the conditioning chamber and the CS is presented in a precise temporal relationship to the US. The most common procedure is delay conditioning where termination of the CS coincides with the onset of the US. In this terminology, the 'delay' is the time between CS onset and US onset. Delay conditioning tends to produce very robust conditioning to the CS. In trace conditioning, the onset of the US is separated from CS termination by a 'trace' interval. This tends to produce weaker conditioning to the CS and, as discussed below, relies on different neuroanatomical circuitry than delay conditioning. See

[Figure 1](#) for an outline of discrete CS procedures and [Video Clip 1](#) for an example of a tone test.

Context Conditioning

Context conditioning involves placing an animal in an experimental chamber and administering one or more footshocks. Freezing can be measured immediately after the shock(s) to assess short-term acquisition of the context-shock association or, more commonly, the animal is returned to the conditioning chamber at a later time for a context test. Despite the apparent experimental simplicity of this procedure, the mechanisms underlying context conditioning are quite complex and still hotly debated.

The CS in context conditioning is thought to be a configural or unified contextual representation of the multimodal cues in the conditioning chamber. As the animal explores the context, the sights, sounds, smells, textures, and spatial information bind together into a complex CS. It is this complex CS that becomes associated with shock. Forming the contextual representation requires that the animal spend time exploring the context. If the shock is administered immediately after placement in a conditioning chamber, no contextual fear is acquired. This finding, referred to as the 'immediate shock deficit,' occurs because the unified representation of the context has not been formed and, therefore, there is no CS for the shock to

become associated with. The immediate shock deficit can be rescued if the animal is pre-exposed to the conditioning chamber prior to the immediate shock training. This pre-exposure allows the animal to form the contextual representation, which it can then subsequently retrieve and associate with the shock. This view of context conditioning stresses the importance of two separable processes: first the animal must form the contextual representation and then it associates this representation with the shock (see **Figure 2** for an outline of context conditioning procedures and **Video Clips 2a and 2b** for illustration of the context pre-exposure rescue of the immediate shock deficit).

Associative Competition among CSs

One important issue in Pavlovian fear conditioning is that conditional stimuli compete with one another for association with the aversive US. In a discrete CS procedure, for example, the animal acquires conditional fear of the conditioning chamber in addition to the discrete CS. In practical terms, this means that context and discrete CS fears need to be tested separately. This is achieved by returning the animal to the conditioning chamber for a context test and placing it in a novel context to test fear to the discrete CS. Testing in a novel context, which should produce very little conditional fear, allows for a pure assessment of discrete CS fear. This practice is a standard fear-conditioning procedure, as shown in **Figure 1**. It allows for the assessment of two kinds of memory in the same animal, which, as discussed in more detail below, has proven to be an important tool in understanding the neurobiological mechanisms of learning and memory.

Extinction of Conditional fear

After conditional fear has been acquired, repeated presentations of the CS in the absence of the US will eventually lead to a loss of the conditional fear response. This process, referred to as ‘extinction,’ is considerably slower than the original acquisition. A great deal of evidence suggests that it is a form of new learning rather than forgetting of the original CS–US association. Three extinction phenomena, which involve return of the conditional fear response, illustrate this point: (1) An extinguished conditional fear response can be ‘reinstated’ by a single presentation of the US without the CS. (2) The context in which the extinction occurs is critical in the loss of the fear response. If the CS is presented in a different context than where the extinction occurred the CR returns. This is referred to as ‘renewal.’ (3) The conditional fear response can also return spontaneously over time in a process called ‘spontaneous recovery.’ These three return-of-fear effects argue that the original fear is still intact after

extinction but its expression is repressed. A great deal of current research is aimed at determining the mechanisms of extinction due to its clinical relevance as a model of exposure therapy in patients with anxiety disorders.

The Neuroanatomy of Fear

The underlying neurobiological mechanisms of fear conditioning have been intensively studied over that last few decades. Researchers have employed a staggering array of interdisciplinary techniques ranging from lesioning specific brain regions to recording neuronal activity in awake-behaving animals to conducting detailed microscopic analysis of brain slices. Synthesis of a huge number of studies from many different laboratories has led to the formulation of a canonical pathway for conditional fear.

Restricted anatomical lesions produced by electrolytic or excitotoxic stimulation have been one of the most important tools in understanding fear conditioning. If lesioning a particular region prevents the acquisition and/or expression of conditional fear, then that region is likely to be a critical part of the conditional fear pathway. Microinjection of drugs into specific brain regions has also become an indispensable tool as it allows for precise timing and for the use of different pharmacological agents.

Electrophysiological recording can be used to correlate neuronal activity with behavior in awake-behaving animals. Staining techniques, such as immunohistochemistry and *in situ* hybridization, have been used to map patterns of gene expression. Individual neurons express a huge array of enzymes, receptors, ion channels, etc., and each brain region is defined by a unique expression pattern. This information has been combined with genetic techniques where a particular gene can be altered or deleted and the effects of this manipulation can be assessed. This technology has been extensively developed in mice and therefore a great deal of fear-conditioning work is now conducted in genetically altered mice. The increasing sophistication of genetically engineered mice is allowing for targeted genetic manipulations of fear-conditioning pathways to an extent that was not possible with more traditional techniques.

The Canonical Fear Pathway

Conditional fear depends on multiple brain regions, which can be divided into three main categories: sensory input structures, sites of CS–US convergence, and output structures (see **Figure 3** for a simplified diagram of fear-conditioning circuitry). The amygdala is the central hub in the acquisition and expression of conditional fear. The amygdala is divided into a number of important

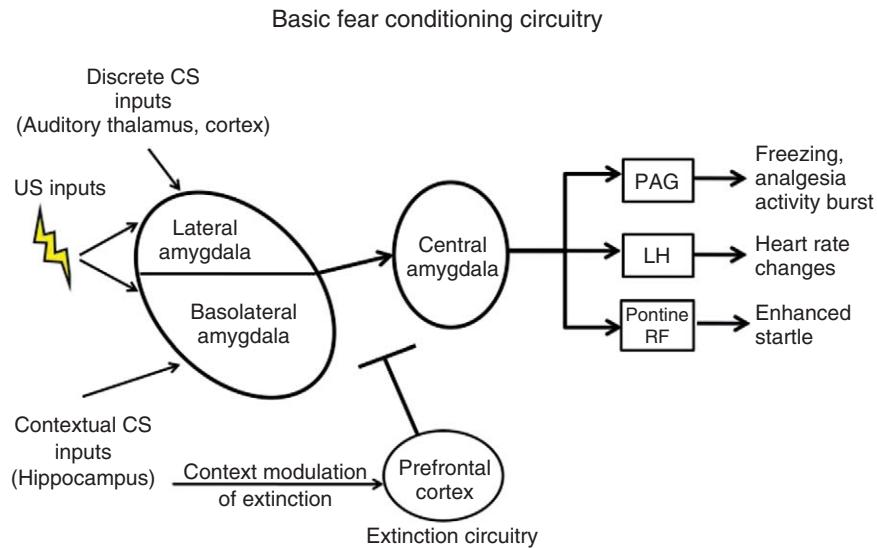

Figure 3 Basic fear conditioning circuitry. This diagram outlines a simplified view of the most important neuroanatomical pathways in fear conditioning. CS and US information converges in the amygdala. During training, co-activation of CS and US inputs strengthen the weak CS input such that after training the CS can activate the amygdala on its own. This drives activity in the central amygdala, which subsequently drives activity in downstream fear output regions such as the periaqueductal gray (PAG), lateral hypothalamus (LH), and pontine reticular formation (pontine RF) to produce conditional fear responses. During extinction, where the CS is presented in the absence of the US, prefrontal circuitry comes to inhibit the activity of neurons in the amygdala. This is a form of new learning that is under complex regulation by contextual information provided by the hippocampus.

subregions. The lateral (LA) and basolateral amygdala (BLA) regions receive sensory input from throughout the brain, which includes both CS and US information. From here, output information flows through the central nucleus of the amygdala (CeA) which projects to fear output regions such as the periaqueductal gray (PAG), lateral hypothalamus, and the pontine reticular formation. The PAG is a complex structure that plays a critical role in coordinating defensive behavior. The dorsolateral portion of the PAG is necessary for the activity burst response to the shock, whereas the ventrolateral portion is necessary for freezing and analgesia. The lateral hypothalamus mediates the cardiovascular aspects of fear, such as increased blood pressure and changes in heart rate. The pontine reticular formation is critical in fear-mediated potentiation of the startle response.

Acquisition of conditional fear is thought to depend on associative synaptic plasticity in amygdala neurons that receive both CS and US inputs. The US produces strong activation of the LA and BLA, which then activates the CeA to produce the UR, that is, the activity burst. CS inputs to the amygdala are initially too weak to produce activation of the CeA; however, CS-US pairings result in the strengthening of the CS input pathways to the amygdala. Thus, after conditioning the CS alone is capable of activating the CeA to produce fear responses. In addition to being a site of plasticity itself, a great deal of work from the laboratory of Jim McGaugh and others has shown that the amygdala also enhances memory storage in other brain regions.

Input Structures

Auditory inputs

Extensive work conducted in the lab of Joe LeDoux and many others has shown that auditory inputs to the amygdala come into the LA through two routes: directly from the auditory thalamus, that is, the medial geniculate nucleus, and more indirectly through the auditory cortex. Lesioning or inactivating these regions can impair the acquisition of conditional tone fear. These inputs differ in the rate, stability, and pharmacology of LTP induction and may also convey different forms of auditory information. The cortical input provides more processed sensory information that may be important, for example, in the proper timing of fear responses. Fear conditioning potentiates responding to the auditory CS in both of these regions, but this potentiation lags behind the plasticity at sites of CS-US convergence in the amygdala.

Hippocampus

The hippocampus receives highly processed sensory information from throughout the cortex. It is important for both episodic memory, that is, autobiographical memory for unique personal experiences, as well as for spatial navigation. Although a thorough discussion is outside of the scope of this article, a combined view of these functions of the hippocampus is that it allows for the encoding of multimodal sensory events, that is, episodes, and is able to connect these events into a complex and flexible cognitive map of the environment. In fear conditioning, the

hippocampus is critically important for the acquisition and expression of context fear. The hippocampus sends outputs to the BLA through the ventral angular bundle and plasticity at these synapses is necessary for hippocampus-dependent forms of conditional fear.

Synaptic plasticity at multiple subregions within the hippocampus is important for the formation of the contextual representations. Electrophysiological recordings in awake-behaving animals have shown that hippocampal neurons, referred to as ‘place cells,’ fire in specific locations in a given environment. The unique firing pattern of a population of these place cells can therefore tell an animal which environment it is in and exactly where it is in that environment. This may represent the neural correlate of the contextual representation and the strengthening of synapses which convey this information to the amygdala may be the site of the context–shock association.

Similar to human amnesic patients, hippocampal lesions produce a profound retrograde amnesia for context–shock associations formed just prior to the lesion. Context conditioning that occurred a few weeks or more before the lesion, however, is still intact. Based on this kind of evidence, researchers believe that the hippocampus is a site of temporary memory storage and that these memories are slowly consolidated in a distributed cortical network over time.

The role of the hippocampus in tone fear is quite complex. Strongly conditioned delay tone fear does not require the hippocampus. Strengthening of the auditory inputs to the amygdala appears to be sufficient. Trace fear conditioning, utilizing trace intervals of greater than about 10 s, does require the hippocampus. The exact role of the hippocampus in trace fear conditioning is still unknown; however, an increasingly plausible possibility is that it is involved in encoding and retrieving an episodic-like memory of the tone–shock pairing.

Alternate Pathways in Fear Conditioning

The canonical pathway discussed above is considered to be the primary pathway that mediates fear conditioning under normal circumstances. A great deal of emerging evidence, however, suggests that there are alternate sites of plasticity that can mediate fear learning when these primary structures are compromised. Extensive overtraining, for example, can overcome the loss of the amygdala. Compensation for loss of the hippocampus in contextual fear conditioning usually requires only a few extra context–shock pairings. Due to this, pretraining lesions of structures in the primary pathway tend to produce much less severe impairments than posttraining lesions. This discrepancy is thought to occur because the primary pathway actively inhibits learning in these alternate pathways. If learning occurs in the absence of an intact primary pathway, that is, with pretraining lesions, then the alternate pathways are able to compensate. If learning occurs in the

presence of primary pathway, which inhibits compensatory learning in the alternate pathways, but is tested in the absence of the primary pathway, that is, after a posttraining lesion, then compensation is largely absent. The exact identity of these alternate pathways and the mechanisms by which the primary pathway inhibits these alternate pathways is still unknown; however, researchers are rapidly identifying potential candidates.

Extinction Pathways

Not surprisingly, there is a great deal of overlap between the structures that are necessary for the acquisition and expression of conditional fear and for the structures involved in its extinction. Extinction results in the active inhibition of fear expression in a context-dependent manner. The ventromedial prefrontal cortex (vmPFC), particularly the infralimbic region, provides inhibitory modulation of the amygdala. The context specificity of this modulation is provided by interactions of the vmPFC with the hippocampus. Plasticity in the hippocampus, vmPFC, and amygdala are all required for the long-term memory of the extinction session. Expression of extinction requires vmPFC-mediated inhibition of the amygdala and proper contextual modulation of extinction requires hippocampal activity.

Fear Conditioning in Humans

Studies in humans have found that the underlying mechanisms of conditional fear are highly conserved between rodents and humans. An elegant study from the Antonio Damasio’s lab looked at fear conditioning in patients with selective bilateral damage to either the amygdala or the hippocampus. They found that the amygdala patients were unable to acquire the conditional autonomic fear response, yet they were perfectly aware that the CS predicted that shock was going to occur. In contrast, the hippocampal patients were able to acquire the CR, but they had no conscious awareness that the CS predicted the shock. Another study conducted in Larry Squire’s lab, which compared trace versus delay fear conditioning, found that successful trace conditioning required conscious awareness of the CS–US association, whereas delay conditioning did not. Thus, the amygdala is critically important in conditional fear responses just as it is in rodents. Furthermore, these studies suggest that the hippocampal contribution to trace fear conditioning may be mediated by its ability to support conscious awareness of CS–US contingencies, perhaps through retrieval of an episodic memory of the conditioning trial. Functional magnetic resonance imaging studies of fear conditioning show a striking consistency with the animal literature. Amygdala activation is consistently seen and

hippocampal activation has been observed with procedures designed to approximate context conditioning. Extinction is associated with vmPFC activation, just as it is in rodents, and the hippocampus seems to show specific activation when the extinction is context dependent.

Proper fear responses are critical to survival; however, improperly regulated and excessive fear responses can be highly debilitating. Specific phobias, anxiety disorders, and posttraumatic stress disorders are just a few examples of clinical disorders in which dysregulation of fear mechanisms is thought to occur. Our ability to treat these disorders depends critically on how well we understand the neurobiological basis of fear.

Fear: Potentiation and Startle

W A Falls, University of Vermont, Burlington, VT, USA

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Acoustic startle circuit – The acoustic startle response is mediated by three synapses: first, at the cochlear root neurons, which then synapse onto neurons of the nucleus reticularis pontis caudalis (PnC), and these then project to motoneurons in the spinal cord.

Acoustic startle response – A characteristic cross-species reflex characterized by a regular pattern of muscle contraction and extension that is elicited by an abrupt, intense auditory stimulus. Acoustic startle is easily and objectively quantified in rodents and the human and is modulated by a variety of environmental conditions including conditioned fear and anxiety.

Anxiolytic drug – A drug that reduces the behavioral signs of anxiety.

Bed nucleus of the stria terminalis (BNST) – An area of the forebrain closely associated with the amygdala (indeed, it has been referred to as part of the ‘extended amygdala’). The BNST is thought to be responsible for many of the behavioral signs of anxiety.

Conditioned fear – A hypothetical central emotional state brought about through Pavlovian conditioning in which a conditioned stimulus (CS), such as a light, is consistently paired with an aversive unconditioned stimulus (US), such as shock. Conditioned fear is inferred from a variety of behaviors (e.g., freezing, potentiated startle, changes in heart rate and blood pressure, defecation, and analgesia) that are elicited by the CS after CS-US pairings.

Fear-potentiated startle – A measure of conditioned fear in which fear is defined as elevated startle amplitude in the presence versus the absence of a stimulus that was previously paired with shock.

Light-enhanced startle – A measure of unconditioned fear in rodents. Startle amplitude is larger when it is elicited in a constant, high level of illumination than when it is elicited in the dark. Light-enhanced startle is selectively blocked by anxiolytic drugs and is thought to depend on the bed nucleus of the stria terminalis. A similar phenomenon has been observed in the human. Human participants show enhanced startle amplitude in the dark.

In the last few decades, considerable emphasis has been placed on examining the neurobiological correlates

of fear and anxiety. Through all of this work we have not only come to understand the principal neural circuitry and physiology of fear and anxiety, but we have also developed a solid understanding of the methods that are used to produce and measure these emotions in the laboratory. One such method is the potentiation of the acoustic startle response. In this measure, fear or anxiety are inferred from an increase in the amplitude of the acoustic startle response. This measure, initially described by Brown, Kalish, and Faber, is derived in part from clinical observations that anxious individuals often exhibit exaggerated startle reactions to sudden, loud noises. While several studies followed this initial observation, it has been largely through the efforts of Michael Davis and colleagues that startle potentiation has become one of the most well-understood and valuable measures of fear and anxiety.

Pavlovian Conditioned Fear and the Fear-Potentiated Startle Procedure

In the typical Pavlovian conditioned-fear procedure, a neutral stimulus – such as a light – is paired with a mildly aversive stimulus – such as a footshock. After a few of these pairings, the light conditioned stimulus (CS) comes to elicit a variety of behaviors that are indicative of learned fear. In the fear-potentiated startle procedure, learned fear is assessed by measuring the acoustic startle response in the presence and absence of the CS after it has been paired with shock. Conditioned fear is operationally defined as elevated startle amplitude in the presence versus absence of the CS. It is important to note that facilitation of the startle response by the CS is the measure of conditioned fear. The CS does not elicit startle nor is the startle stimulus ever paired with shock. Instead, it is assumed that the conditioned response (CR) elicited by the CS is a state of fear. This state of fear potentiates the startle response that is elicited by the acoustic startle stimulus.

Fear-Potentiated Startle Is a Valid Measure of Conditioned Fear

Fear-potentiated startle is observed following training in which the CS is explicitly paired with shock and not when the CS is explicitly unpaired with shock or when CS and shock are presented randomly. Thus, fear-potentiated

startle is not the result of pseudoconditioning or shock-induced sensitization but instead reflects the learning that occurs with the association of the CS and shock. Moreover, fear-potentiated startle, like other measures of conditioned fear, has been measured over long training-to-testing intervals and has been measured following fear conditioning with visual, auditory, olfactory, tactile, and contextual CSs. Fear-potentiated startle has also been used to examine extinction of conditioned fear, as well as second-order conditioning and conditioned inhibition of fear indicating that it is a reliable measure of conditioned fear that is sensitive to experimental manipulations of learning.

It has been more than three decades since Davis and Astrachan touted fear-potentiated startle as an “easy and economical way to study classical [fear] conditioning.” In this time we have learned that fear-potentiated startle has many unique attributes that distinguish it from other measures of conditioned fear. These unique attributes rest squarely with the attributes of the acoustic startle reflex and because of them, studies using fear-potentiated startle have contributed a great deal to our understanding of behavioral and neural correlates of conditioned fear (and anxiety, see below).

Fear-Potentiated Startle and the Temporal Aspects of Conditioned Fear

Acoustic startle is a highly characteristic and rapid pattern of muscle flexion and extension that is elicited by an abrupt, intense acoustic stimulus. The latency of acoustic startle can be as short as 8 ms measured electromyographically in the hind leg of rats and last less than 200 ms. In the context of fear-potentiated startle, this allows for a momentary assessment of conditioned fear at any point during the CS. Capitalizing on this, Davis, Schlesinger, and Sorenson examined the temporal specificity of conditioned fear following conditioning with various CS + shock intervals. Separate groups of rats were given fear conditioning in which the interval between the onset of the light and the onset of the 500-ms shock (the inter-stimulus interval – ISI) was 0, 25, 50, 100, 200, 800, 3200, 12 800, or 51 200 ms. In the fear-potentiated startle test that followed, the brief (50 ms) startle-eliciting stimulus was presented at each of the nine ISIs on separate trials for all rats. Thus, for each group, the startle stimulus was presented at the time the shock had occurred in fear conditioning as well as at shorter and longer ISIs. Their results clearly demonstrated the temporal specificity of conditioned fear: each group of rats showed the greatest fear-potentiated startle at the CS + shock interval that was used in fear conditioning and much less fear-potentiated startle at intervals on either side of the conditioning interval. As Davis and colleagues point out, these results suggest that rats learn to time the occurrence of the shock,

even at very short intervals. Thus, a mechanism for timing must be part of the neural circuit for fear. Such timing experiments would be very difficult, if possible at all, with other measures of conditioned fear where responses are slower to develop or persist for a time after the offset of the CS.

In another examination of timing in fear conditioning, Falls and Davis were able to use fear-potentiated startle to document the transition from fear expression to fear inhibition in a serial feature-negative discrimination procedure. Rats were given fear conditioning in which a light was paired with foot shock. On some trials, the light was immediately preceded by a noise, and the combination was not paired with shock (noise → light no shock). As a result, the noise acquired the ability to inhibit fear to the light: fear-potentiated startle on light trials was significantly greater than on noise → light trials. Somewhat unexpected, however, was the observation that startle was also potentiated by the noise: startle amplitude in the presence of the noise alone was similar in magnitude to startle amplitude in the presence of the light CS. Thus, it appeared that the noise had acquired the ability to both elicit fear when presented by itself (perhaps through a process of second-order conditioning) and inhibit fear when presented in combination with the light. To examine this further, Falls and Davis used procedures similar to those used by Davis and colleagues to examine the temporal transition of fear to the inhibition of fear. Rats were trained for conditioned inhibition, and in the subsequent fear-potentiated startle test, startle was elicited at various time points during the noise and light on noise → light trials. The results showed that the fear to the noise was present until its offset, at which time it inhibited fear to the light. The ‘trace inhibition’ by the noise was subsequently confirmed when it was found that trace fear conditioning to the noise-conditioned inhibitor (a procedure in which the shock is presented after the offset of the noise at the time when fear inhibition is thought to occur) was weaker following conditioned-inhibition training. Similar to the temporal specificity of conditioned fear, the ability to momentarily assess conditioned fear at any point during the CS has allowed the use of fear-potentiated startle to explore aspects of conditioned fear not easily assessed using other measures.

Fear-Potentiated Startle and Pharmacology of Conditioned Fear

Fear-potentiated startle has a nonzero baseline and, as a result, has proven useful as a model for screening drugs. In fear-potentiated startle, conditioned fear is measured within the subject by comparing startle amplitude in the presence and absence of the CS. Unlike other measures of conditioned fear, manipulations that affect conditioned fear can be easily dissociated from those that affect the

behavioral measure of fear (i.e., startle amplitude). A number of drugs reduce fear-potentiated startle, most of which do so without affecting startle amplitude. For example, drugs that are anxiolytic in the human, such as the serotonin 1_A partial agonist buspirone, the γ -aminobutyric acid-A (GABA-A) agonists diazepam, or morphine and bupenorphine, as well as novel anxiolytics such as metabotropic glutamate agonists, nonpeptide bombesin receptor antagonist, and secretin reduce fear-potentiated startle without the confounding influence of reducing startle amplitude in the absence of the CS. Thus, the nonzero baseline that is inherent in the fear-potentiated startle procedure (i.e., startle amplitude in the absence of the CS) serves as an important measure for evaluating the nonspecific (e.g., sensory or motor impairing) effects of drugs.

However, there have been some reports in which putative anxiolytic drugs reduced both fear-potentiated startle and startle in the absence of the CS. In the fear-potentiated startle procedure, conditioned fear is defined as elevated startle amplitude in the presence versus the absence of the CS. It is assumed that fear is more or less restricted to the time during which the CS is present and that startle in the absence of the CS reflects a baseline of little or no fear. However, under certain circumstances, startle may also be modestly potentiated in the absence of the CS, and this potentiation of baseline startle may reflect contextual fear that may also be sensitive to anxiolytic drugs. Guscott, Cook, and Bristow showed that following CS and shock fear conditioning, rats demonstrated a robust fear-potentiated startle to the CS as well as potentiation of startle in the absence of the CS. However, if rats tested in an apparatus that was different from the training apparatus, they did not show potentiation of startle in the absence of the CS despite showing robust fear-potentiated startle to the CS. Interestingly, although the GABA-A partial agonists FG8205 and bretnazene attenuated fear-potentiated startle regardless of the apparatus the rats were tested in, they reduced startle in the absence of the CS (i.e., baseline startle) only in rats trained and tested in the same apparatus. This suggests that, under some circumstances, startle in the absence of the CS may be potentiated by contextual fear and that this fear is also sensitive to anxiolytic drugs. Hence, the nonzero baseline may not necessarily reflect startle in the absence of fear, and care should be taken to fully evaluate possible baseline changes when measuring fear-potentiated startle.

The Neural Circuit for Acoustic Startle and Fear-Potentiated Startle

A great deal is known about the neural circuit for acoustic startle, making it unique among measures of conditioned fear. A combination of anatomical, lesion, and stimulation

experiments have shown that acoustic startle is mediated by three synapses: first, at the cochlear root neurons, which then synapse onto neurons of the nucleus reticularis pontis caudalis (PnC), and these then project to motoneurons in the spinal cord. Although other studies have suggested that startle may also involve projections from the posteroverentral cochlear nucleus to an area ventral and medial to the ventral nucleus of the lateral lemniscus and projections to the PnC, more restricted lesions of these areas failed to interfere with acoustic startle suggesting that they are not obligatory synapses in the acoustic startle reflex.

Numerous studies have shown that the amygdala is essential for the acquisition and expression of conditioned fear and several studies have shown that lesion or pharmacological inactivation of the amygdala also interferes with fear-potentiated startle. It is widely believed that CS and shock information converge at the lateral nucleus of the amygdala and that fear conditioning is mediated by changes in neurons in lateral or basal nuclei of the amygdala. The major output of these amygdala nuclei is through the central nucleus of the amygdala. Using a combination of anatomical, lesion, and stimulation techniques, studies have shown that the central nucleus projects directly to the PnC and these projections mediate fear-potentiated startle. The direct projection from the central nucleus to the PnC may involve the release of corticotropin-releasing factor (CRF) because CRF containing cells of the central nucleus projects directly to the PnC and micro-injection of the CRF antagonist, α -helical CRF, into the PnC blocks fear-potentiated startle without affecting startle amplitude. Indirect projections appear to involve the midbrain in an area identified as the superior colliculus/mesencephalic area. A combination of anatomical, collision, and lesion studies suggests that synapses in this area serve as a relay between the central nucleus and the PnC. Thus, areas in addition to the central nucleus of the amygdala may participate in fear-potentiated startle. Through all of this work one thing is clear: as a result of the firm understanding of the acoustic startle pathway, we have come to understand the pathways through which fear modulates acoustic startle making the ‘fear-potentiated startle circuit’ one of the most well understood in the vertebrate brain.

Fear-Potentiated Startle in Rodents, Nonhuman Primates, and the Human: Translational Potential of Fear-Potentiated Startle

Acoustic startle is a ubiquitous cross-species reflex that is easily measured in rats, mice, monkeys, and the human. Fear-potentiated startle has also been examined across these species. The startle has been examined in inbred, genetically modified mice, and has been used for high-throughput examination of conditioned fear in

mutagenized mice. Fear-potentiated startle has also been examined in nonhuman primates and, like fear-potentiated startle in rodents, is reduced by anxiolytic drugs. However, it is its use in the human that has truly highlighted the translational power of the fear-potentiated startle procedure. Startle is reliably increased in the presence of fear-eliciting stimuli and the human shows reliable fear-potentiated startle following fear conditioning in which a light is explicitly paired with shock. The human also shows fear-potentiated startle to a light that signals the threat of shock even if shock is never explicitly paired with the light.

The Human Appears to Show Consistent and Robust Contextual Fear-Potentiated Startle

In a series of experiments, Grillon and colleagues have shown that following fear conditioning in which a CS and shock are presented explicitly unpaired (i.e., temporally discontiguous), or in an unpredictable fashion, the startle response in the absence of the CS is potentiated. In these instances, potentiation in the absence of the CS is thought to reflect context conditioning or a more sustained form of potentiation that reflects learning around the unpredictability of shock. Interestingly, it is the context potentiation (i.e., the sustained potentiation) that is most sensitive to anxiolytic drugs. For example, chronic citalopram (daily for 2 weeks) did not affect fear-potentiated startle to a CS that was previously paired with shock. However, chronic citalopram reduced the startle potentiation in the absence of the CS in participants who were given random presentations of the CS and shock (i.e., contextual fear, sustained potentiation). Similar results were obtained with the benzodiazepine alprazolam and the β -blocker propantheline. Interestingly, contextual fear may also highlight differences among clinically anxious populations. Individuals with posttraumatic stress disorder (PTSD) or panic disorder show normative fear-potentiated startle to a CS that was previously paired with shock and exaggerated contextual fear following unpredictable shock. In contrast, participants with generalized anxiety disorder showed normative fear-potentiated startle to both the CS and context. Together, these results suggest that startle responses to CS paired with shock and to a context may represent different aversive states and may be pharmacologically distinct. Once again highlighting the translational value of potentiated startle, rodent-potentiated startle experiments have also suggested that there are distinct aversive systems in the brain. These systems may distinguish fear to discrete CS and fear (or anxiety) that is more generalized and sustained (see below).

Anxiety, Fear, and Unconditioned Potentiation of Startle

Unconditioned Potentiation of Startle as a Model of Anxiety

As mentioned at the outset, fear-potentiated startle was developed in part from the observation that clinically anxious individuals often show exaggerated startle reactions. Acoustic startle is not only used to measure conditioned fear, it is also used to measure unlearned aversive states – such as those produced by fear-arousing pictures or pain and those produced by ‘anxiety’ or anxiogenic drugs. The recognition that startle is potentiated by these other aversive states led Walker and Davis to investigate whether unconditioned stimuli (US), such as bright lights, could also potentiate startle. If so, such unconditioned potentiation could be used to investigate unlearned fear while holding on to many of the advantages of fear-potentiated startle. In a series of experiments, they demonstrated that when rats were placed in a constant high level of illumination, they showed higher startle amplitude than when they were placed in the dark. This so-called light-enhanced startle effect was a function of the level of illumination and was attenuated by the anxiolytic buspirone. Since this initial report, light-enhanced startle has also been demonstrated in mice and has been shown to be blocked by a variety of anxiolytic drugs. Light-enhanced startle has been used to examine anxiety associated with nicotine withdrawal as well as sex differences in anxiety. It is worth noting that the human, as a diurnal animal, instead shows dark-enhanced startle.

The Neural Substrates of Anxiety-Potentiated Startle
