Lesions of the bed nucleus of the stria terminalis (BNST) abolish the anxiogenic effect of intracerebroventricular CRF and, like the central nucleus of the amygdala, the BNST receives projections from other amygdalar nuclei and projects to the brain regions mediating behavioral responses to fear, including the PnC. This led Walker and Davis to examine whether the BNST mediated the light-enhanced startle effect – an effect, like CRF, that produces a sustained potentiation of startle. Rats were given either BNST, central nucleus of the amygdala, or sham lesions and tested for light-enhanced startle or fear-potentiated startle to a light CS. As expected, lesions of the central nucleus abolished fear-potentiated startle to the light CS. Central nucleus lesions did not affect light-enhanced startle. In contrast, lesions of the BNST abolished light-enhanced startle but did not affect fear-potentiated startle. This double dissociation of the role of the central nucleus of the amygdala and the BNST

in conditioned and unconditioned fear has led to the hypothesis that the central nucleus of the amygdala mediates fear to discrete, predictable stimuli whereas the BNST mediates sustained fear, or anxiety, to long-duration, unpredictable threats. Following this initial observation, experiments have shown that lesions of the BNST in rats also abolish fear to long duration CSs as well as contextual stimuli.

Recalling the effects of anxiolytic drugs in human fear-potentiated startle, it is interesting to speculate that the unpredictable nature of unpaired or random CS and shock presentations engages the BNST which, unlike the central nucleus of the amygdala, may be more sensitive to the effects of anxiolytic drugs. Following this further, given that individuals with PTSD or panic disorder show exaggerated sustained fear, it is also interesting to speculate that these disorders may involve dysregulation of the BNST.

Conclusion

The acoustic startle response has utility in both basic and clinical science. For more than 50 years, scientists have studied the acoustic startle and have used it as a tool to investigate the behavioral, pharmacological, and neuroanatomical correlates of conditioned fear and anxiety. Owing to the insights and creativity of these scientists, we now have a solid understanding of startle potentiation. Future studies in rats, mice, monkeys, and the human are certain to build on this foundation and create an even deeper understanding of conditioned fear and anxiety.

Feeding

P G Clifton, University of Sussex, Brighton, UK

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Behavioral satiety sequence – A sequence of behavior that is characteristic of the transition from feeding through satiation to satiety. In rodents it is typically associated with a short period of activity followed by grooming and inactivity. A similar behavioral sequence is observed in many other mammals, including the human.

Conditioned satiety – A phenomenon in which sensory characteristics of a food that are consistently associated with the energy value of that food come to influence consumption during *ad libitum* feeding.

Conditioned taste aversion – A phenomenon which leads to reductions in consumption of food that was previously associated with illness. A wide variety of manipulations, including those that may have rewarding effects in other contexts, can lead to conditioned taste aversions.

Devaluation (of a food reward) – Any process that leads to reduced motivation to consume a particular food can be described as resulting in devaluation of that food.

Diet-induced obesity – An increase in body weight, most of which can be attributed to adipose tissue, that results from increased caloric intake of a palatable diet.

Hunger – A motivational state in which feeding behavior is very likely, providing that an appropriate food is available.

Meal – A short period of time during which feeding behavior occurs at high intensity. Meals are operationally defined using a ‘meal criterion.’ The characteristics of a sequence of meals include measures of meal size, duration, inter-meal interval, and feeding rate.

Meal criterion – The operational definition(s) used to define a meal. The definition will normally comprise a time between consumption of food items which, when exceeded, signal that the next occurrence of feeding will be part of the following meal. Optionally there may also be a requirement that a meal involves consumption of more than some minimum amount of food.

Pair feeding – A behavioral paradigm that is used to determine whether the effects of a particular manipulation on body weight depend on changes in energy intake or energy expenditure.

Satiation – The process that occurs during an extended period of feeding and leads to its cessation. Satiation normally develops in response to a combination of

cognitive and pre-ingestive cues associated with feeding.

Satiety – A state in which feeding behavior has become unlikely because of recent consumption of food. Satiety is usually maintained by a combination of postingestive and postabsorptive cues.

Sham feeding – A preparation, most usually in rats, in which consumed foods or liquids drain from the stomach through a surgically prepared fistula. This paradigm can be used to eliminate postingestive cues and thus assess their role in influencing food intake. Most commonly, sham feeding leads to very substantial increases in intake.

Introduction

The amount of food eaten in a test situation is almost certainly the most widely used behaviorally dependent measure in behavioral neuroscience. It is necessarily employed in the context of studies where the primary interest concerns the neural circuits or physiological mechanisms underlying food intake and energy balance. However, it is also often used as a ‘control’ condition in studies of other motivational systems, especially of those that involve self-administration of drugs. Finally, food is the most frequently used positive reinforcer in studies of learning and memory. Even in such studies, the amounts that are consumed make it useful to have some appreciation of the properties of feeding behavior.

In rodents, and many other commonly used laboratory animals, feeding has a complex behavioral structure. Feeding behavior – at least when food is easily available – takes place several times a day in clearly defined meals. Small laboratory rodents, such as rats and mice, may take 10–20 such meals during a 24-h period. Feeding is also subject to strong circadian influences which can entrain other behavior as well as physiological responses, such as hormone secretion and neurotransmitter synthesis.

Feeding behavior is organized and modulated by a distributed neural network that includes structures such as the parabrachial nucleus and nucleus of the solitary tract within the brainstem, medial and lateral hypothalamic systems, as well as ventral and dorsal components of the striatum and a number of cortical areas. These different brain areas rely on a wide range of neurotransmitter

systems and receive peripheral inputs that signal both short- and long-term correlates of energy reserves. The distinction between appetitive and consummatory components is often made for motivated behaviors such as feeding. Although it may be simplistic, it does reflect some important differences in the underlying neural and physiological systems. The distinction is followed here, with consummatory behavior referring to the behavioral processes that are engaged once an animal is in close proximity to, and consuming, food, whereas appetitive behavior relates to those components which might be expressed as foraging in a natural environment. In the laboratory, the study of appetitive behavior typically involves behavioral responses that have been conditioned by food reward. For example, an animal may react to discrete or contextual cues that predict the presence of food (Pavlovian responses) or may be performing responses that have, in the past, led to food reward (instrumental responses). This dichotomy, although somewhat artificial, does reflect important differences both in underlying mechanisms and in the relevant behavioral paradigms.

Consummatory Behavior

'Simple' Measures of Food Intake

The simplest paradigm that can be used to investigate feeding is to allow an animal to feed for a fixed period time and record the mass of food eaten by the end of that period. However, even in this apparently simple case, a host of decisions must be taken that will influence the amount of food that is eaten and modify the relative effect of any experimental manipulation that is being studied. Is the animal to be deprived of food before the test? Will it be presented with its habitual food? If a different food is to be used, will it be novel, or one to which the animal has been exposed previously? Often an animal will be deprived of food for a period of time before an intake test. The chosen time period is frequently 24 h or greater for rats. Following withdrawal of food for such a period, the animals will eat rapidly for a protracted period. The factors that determine intake in this situation will be very different from those that operate when food is freely available. Intake will be at close to ceiling levels, which means that the measure will be quite insensitive, especially to manipulations that tend to increase feeding behavior. Excessive periods of food withdrawal should also be avoided on welfare grounds. The motivation to feed can be increased in a number of other ways, most obviously by supplying food that is more attractive than the maintenance diet. When increases in feeding are expected, it will be common practice to use nondeprived animals. Some manipulations, such as intra-accumbens administration of γ -amino butyric acid (GABA) agonists,

lead to very robust increases in intake. Other manipulations, such as the administration of noradrenaline into the paraventricular nucleus (PVN) of the hypothalamus, generate increases in feeding which are harder to demonstrate. For example, simply presenting 'satiated' rats with a weighed, fresh supply of their maintenance diet is often sufficient to stimulate intake of a 1–2 g over the following 30 min. This will be quite sufficient to mask a noradrenaline-induced increase in feeding. Merely presenting the rats with fresh pellets 30–60 min in advance of testing and then presenting the weighed portion of these pellets following drug administration will provide a much more sensitive measure of the drug effect.

Accurate measurement of food intake will require assessment of the degree of spillage which may well be treatment dependent. In addition, laboratory rodents will often respond to the presence of a more novel food with defensive burying.

The degree of food intake may be enhanced in a variety of ways. Where there is no wish to vary the dietary constituents, then adding water to a standard, dry laboratory diet will often be sufficient to make a very palatable mash. Rats presented with a short daily period of free access to mash made in this way will consume between one-third and one-half of their daily caloric intake within 30–40 min, even when the mash is presented during the light phase of the photoperiod when intake is otherwise minimal.

There has been considerable interest in the idea that changes in some neurotransmitter systems associated with feeding, especially serotonin, may modify diet selection. Studies investigating this idea typically allow animals a choice between pure macronutrients such as casein (protein), lard (fat), and either a simple or complex carbohydrate (e.g., glucose or polyose, respectively). One important issue, which should never be ignored, is the extent to which differences in texture, water content, and taste – rather than macronutrient type – are responsible for any observed changes in intake.

Responses to cues previously associated with food may also have a powerful influence on the amount that is consumed during a test session (see section titled 'Pavlovian influences'). Effects of this type were first explored systematically by Weingarten. He showed that if hungry rats were periodically presented with food after presentation of conditioned stimulus, such as tone, they would soon learn to approach the receptacle into which the food was delivered. If, at a later test session, they were given access to food when sated then they would eat more if the tone was sounded during the test session. More recent experiments have demonstrated that the effect is selective to the stimulus associated with food delivery and not to another stimulus that was not associated with food delivery. It is also clear that the stimulus is not simply generating an approach response to food that then leads to

consumption. If the animals have learnt to expect food in a different place, although this has not previously been associated with presentation of the stimulus, they will nevertheless approach and eat food. This suggests that the conditioned stimulus has a broad effect that increases the motivation to feed. It is important to be aware that effects of this kind may occur inadvertently during repeated simple tests of food intake.

Long-Term Feeding Studies

Chronic increases in food intake may be increased by modifying the diet. In rodents, and many other mammals, provision of a diet relatively rich in fat and simple, sweet-tasting sugars will increase total caloric intake. This may be accomplished by either using a preprepared commercial diet in place of regular chow, or by providing additional food types in a ‘cafeteria’-style diet (e.g., a separate container of lard and a bottle of sucrose solution in addition to regular chow and water). When a preprepared diet is used, then further increase in caloric intake – and body weight – can be achieved by giving access to a high-calorie fluid such as Ensure. It is often argued that diet-induced obesity, especially when it also involves choice among dietary constituents, offers a better model of common human obesity than genetically manipulated animals such as the *ob/ob* mouse.

In some feeding studies, a critical question will be the extent to which changes in body weight over a period of some days have resulted from changes in energy intake and energy output. Energy intake should be approximated by the energy content of the food eaten during the relevant period, although there may be changes in the efficiency of digestion and absorption, especially when intake is being restricted in some way. Energy output may be estimated directly using indirect calorimetry or other techniques. However, an alternative way of tackling this question is to use a pair-feeding paradigm.

A typical experiment of this type might use three groups: the first receives the manipulation in question (perhaps a drug treatment or brain manipulation that increases body weight), a second group receives the same manipulation but has its food intake restricted to that of a third control group which receives no active treatment. Such an experiment may have a number of potential outcomes. One possibility is that the degree of weight increase in the two experimental groups is very similar and higher than that seen in the control group. This would indicate that the mechanism underlying weight increase is one that depends on a reduction in energy output. It might reflect a lowering of the metabolic rate, but it is also possible that reductions in voluntary activity, perhaps induced by a sedative or muscle-relaxant effect of a drug, might be responsible for such an outcome. Direct behavioral observations should help to separate

these options. An alternative outcome might be that the weight of the pair-fed and control groups is similar, and lower than that of the experimental group given unrestricted access to food. This would strongly suggest that increased food intake is responsible for the increase in body weight produced by this manipulation.

The same kind of design can be applied to a treatment that is associated with a reduction in body weight. In such cases there will be a single drug-treatment group and two control groups, one of which receives *ad libitum* access to food and the other of which has its food intake matched to that of the drug-treated group. Although these designs may seem ideal for separating the effects of energy intake and output, the results from a particular experiment may be ambiguous in several ways. If the experiment is under-powered and the data of the pair-fed group is intermediate between the treatment and control groups, then the conclusion drawn will depend on which of the (nonsignificant) paired comparisons is judged to be more important. A frequent outcome, especially when the experiment is conducted over a longer time period, is that there may be differences between the pair-fed and unrestricted group which become less evident with time. Several points are relevant in interpreting such an outcome. First, energy intake cumulated over the study period may remain substantially different and sufficient to explain the observed weight differences. Second, there may be gradually emerging adaptive changes to perceived energy deficits that occur at either a behavioral or physiological level. These may be exacerbated by the very different daily intake patterns that emerge as the experiment progresses.

Detailed Measures of Consummatory Behavior

The consummatory phase of eating may be studied at several levels. Observations at the macro-level often involve recording some variant of the behavioral satiety sequence. This technique, which originated with Richter in the 1930s, and was refined by Bolles and Antin in the 1960s before the development of the present form of analysis, is especially useful for distinguishing the development of normal satiety from reductions of eating as a result of illness, pain, or stress induced by an experimental manipulation. For rodents, the method utilizes relatively broad behavioral categories, such as feed, groom, inactive, and rear. These may be recorded continuously, typically from prior recording of the experimental sessions. An alternative method, which provides very similar data, is to utilize live sequential one-zero recording from a complete experimental cohort of subjects. Although the sequence will be variable from one individual to another, common features include an initial period of intense eating followed by increased activity (both locomotion around the cage and rearing), grooming, and – provided

the observation period is long enough – a period of inactivity. One conventional, though arbitrary, indication of the onset of satiety is the point at which the proportion of time devoted to eating is less than that spent in inactive behavior.

A second, macro-level technique is the recording of free-running meal patterns. Again this may be achieved in several ways. One method, deriving from Kissileff's development of a pellet-delivering eatometer, allows a rodent to take standard, grain-based pellets (rat: 45 mg; mouse: 10 or 20 mg). Intake of pellets and water should be monitored with good temporal resolution (at least to a fraction of a second). Such a system will allow accurate assessment of the instantaneous feeding rate as well as the microstructure of feeding and drinking bouts. However, it will be less easy to manipulate dietary constituents, and if this is required then it may be better to use a recording system that depends on repeated automatic weighing (usually via built in strain gauges) of food- and water-containers. Temporal resolution will be significantly worse with such systems, and estimation of instantaneous feeding rate is not possible.

Once a record of intake has been obtained, it will require further analysis to extract meal patterns. An initial choice of a bout or meal criterion is required to define individual meals (**Figure 1**). The meals can then be characterized in terms of their size, duration, intra-meal feeding rate, and inter-meal interval. Although time-based meal criterions are most commonly used, some authors also impose a minimum size for a meal. One recent development has been to combine meal-pattern analysis in free-feeding animals with the recording of the behavioral satiety sequence. These studies have confirmed that the sequence is not an artifact of regularly presenting animals with a palatable, easily eaten food. They have also suggested that the most appropriate criterion for meal termination should include consideration of both feeding and drinking responses.

Microstructural analysis of licking patterns is frequently used when a liquid food has been provided. These techniques, especially as developed by Davis, Smith, and colleagues, are conceptually similar to meal-

pattern analysis, although they operate at a finer level of analysis. Changes in palatability and caloric load produce distinct patterns of change in the resulting licking-bout analysis.

Another technique which holds out the promise of distinguishing between hedonic and reward-related effects of a manipulation is the taste-reactivity task. This paradigm, developed by Grill and Berridge, is best known for its supportive role in the incentive sensitization theory of addiction. Animals, typically rats, are prepared with an intra-oral catheter through which more or less palatable solutions can be introduced in measured volumes. The animal's responses are scored and can be divided into negative and positive hedonic components. This relatively pure measure of hedonic responses to food-related stimuli can then be compared with the reward-related aspects that are measured using more conventional instrumental tasks (see section titled 'Instrumental tasks').

Appetitive Behavior

Pavlovian Influences

A variety of Pavlovian procedures may be used to study appetitive components of feeding behavior. They share the common feature that, during training, food is presented in combination with a conditioned stimulus without regard to the animal's current behavior. When the conditioned stimulus is discrete and signals the imminent availability of a small reward, animals will usually display an orienting reflex to the stimulus before moving toward the likely source of food. As training proceeds, the orienting reflex will often become less pronounced, especially when the relationship between stimulus and food is entirely predictable. An animal may also direct behavioral responses toward the conditioned stimulus. These are usually referred to as autoshaped responses and their form is strongly related to the relevant consummatory behavior. Under some circumstances these responses may be easily measured, as when the stimulus is a lever inserted briefly into the cage and is pressed, or a light is illuminated in an aperture where the animal may make a nose poke.

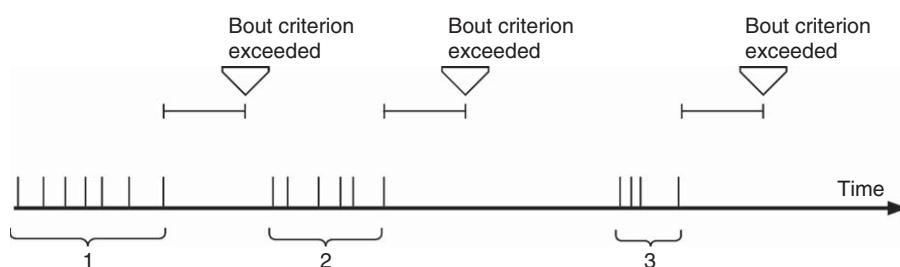

Figure 1 Applying a bout criterion to a series of individual feeding responses (short vertical lines). In this case, the process would generate three meals of sizes 7, 6, and 4.

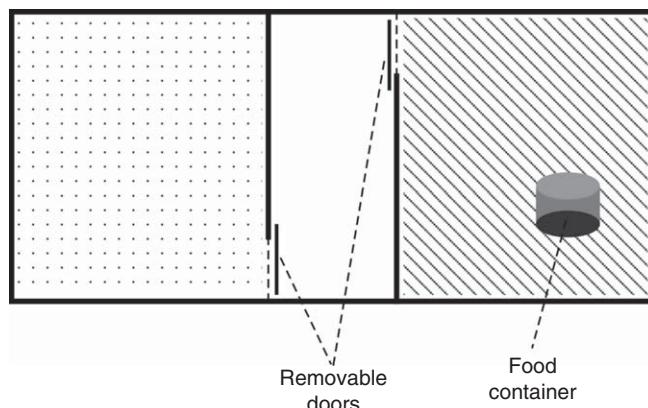

Figure 2 A typical two-chamber conditioned place-preference chamber. During the training the doors are left in place. They are removed during testing and the animal can then move from one chamber to the other through the central corridor. The food container is also removed during testing.

Contextual stimuli may also be used to condition approach responses. One classic version is the conditioned place task. It uses a two-compartment chamber, each with distinct contextual cues. During training, animals are confined to one of the two chambers (Figure 2). Food is made available in one and not in the other. During test sessions, animals are free to enter either compartment. They are likely to spend a greater proportion of time in the food-associated chamber. This learnt preference is susceptible both to reversible revaluation (e.g., the preference increases with an increasing level of food deprivation) and to more permanent devaluation (e.g., induction of a conditioned taste aversion to the particular food reward associated with the reinforced chamber). Testing is always carried out in the absence of food. One consequence is that the response is susceptible to extinction both within and across test trials. Place-preference tasks are susceptible to differences in initial preferences for the different compartments and the decision as to whether to fully randomize the assignment of animals to possible training conditions, or to train against any initial preference, is an important one.

Instrumental Tasks

Food is a potent reinforcer and many different instrumental responses have been used to estimate components of feeding motivation. In most of these paradigms, food is provided, so they do not provide pure measures of appetitive responding during the test session.

One example – historically important, and still in use today – is running speed to a food reward at the end of a straight alley. Running speeds are sensitive to the value of the reward that is provided. For example, providing a larger-than-expected food reward will produce a clear increase in running speed on the next few trials, while a smaller-than-expected reward will have the opposite

effect (the Crespi Effect, described in 1942). The decrease in running speed over a series of trials can provide a sensitive index of satiation. For example, a drug treatment that decreases satiation will have little effect on running speed in early trials but enhance it, relative to a control condition, later in the session.

Lever-press, or nose-poke, operant responses also provide useful measures of feeding motivation. The great majority of studies use animals that are mildly food deprived and tested in short sessions. Ratio or interval schedules may be used. Fixed or variable ratio schedules will tend to produce high response rates that are sensitive to feeding motivation whereas interval schedules are less useful in this regard. However, response rate on a ratio schedule will also be sensitive to other factors such as motor impairment or sedation induced by a particular experimental manipulation. An alternative approach is one in which the number of responses required for reward gradually escalates during the session. Animals on such progressive ratio schedules will eventually stop responding. The ratio at which they stop is termed the breakpoint, and will be less sensitive to extraneous effects of an experimental manipulation than the response rate. The operant requirement may escalate through either an arithmetic or a geometric series (Table 1). Food consumption prior to the breakpoint is likely to be higher with an arithmetic sequence, and hence the potentially confounding effects of satiation may be greater.

Any of the schedules described so far will result in food consumption and hence initiate satiation. A purer measure of appetitive behavior may be obtained by using a modified second-order schedule. Responding can be sustained for an extended period, especially at the beginning of a test session, if a conditioned stimulus is associated with food delivery and lever pressing is initially only rewarded with presentation of this stimulus. Schedules

Table 1 Performance measures on two progressive ratio schedules

<i>Breakpoint (B)</i>	<i>Schedule 1</i>	<i>Total presses</i>	<i>Schedule 2</i>	<i>Total presses</i>
1	1	1	1	1
2	4	5	4	5
3	7	12	6	11
4	10	22	9	20
5	13	35	12	32
6	16	51	15	47
7	19	70	20	67
8	22	92	25	92
9	25	117	32	124
10	28	145	40	164
11	31	176	50	214
12	34	210	62	276
13	37	247	77	353
14	40	287	95	448
15	43	330	118	566
16	46	376	145	711
17	49	425	178	889
18	52	477	219	1108
19	55	532	268	1376
20	58	590	328	1704

Break points, operant requirements and total lever presses for an arithmetic (1) and a geometric schedule (2). On Schedule 1 the operant requirement increments by 3 for successive rewards. On Schedule 2 the schedule is determined by the relationship $5 \times e^{b \times 0.2} - 5$. Schedule 1 is slightly harder at low breakpoints but Schedule 2 is much harder at high breakpoints.

of this kind can be used with rats and mice and can easily provide a measure of responses rate, over an initial non-food-reinforced period of 5 min in a 30-min test, which remains stable from one test session to another. This allows comparison of the effects of a several related manipulations (e.g., different drug doses) using a within-subject design.

Several other paradigms, including conditioned reinforcement and Pavlovian to instrumental transfer, deserve consideration if the research question concerns the extent to which conditioned stimuli may energize a feeding response. For example, in Pavlovian to instrumental transfer, animals undergo a two-component training process in which, separately, they acquire a Pavlovian association between a stimulus and food delivery and also learn to perform an instrumental response for that food. In the test sessions, which may be carried out in extinction or with food reward provided, instrumental response rates are measured in alternating periods during which the conditioned stimulus either is, or is not, present. Pavlovian to instrumental transfer is measured as the extent to which responding is facilitated in the presence of the conditioned stimulus.

Choosing an Appropriate Model

A number of factors will determine the appropriate animal models of feeding for a particular study. Only

rarely will the results from a single test paradigm be sufficient to determine the behavioral mechanism of action of a manipulation that affects food intake. The better approach will be to choose a test battery which reflects the neural and behavioral mechanisms of interest. Detailed behavioral analysis is likely to be rewarding in many circumstances. In addition to maximizing scientific utility, it will be important to consider how animal welfare can be enhanced by considering the principles of refinement and reduction. For example, long periods of food deprivation – which may also be scientifically undesirable – should be avoided and within-subject designs will frequently be more powerful than a between-subject approach and will also minimize the number of animals that are required for a particular study.

Glossary

Congenic – A line of species that is genetically identical except at a selected locus.

Epigenetics – Changes in gene function independent of changes in DNA sequence.

Gene – A sequence of DNA that is the basic unit of inheritance.

Heterosis – When offspring from a cross of two inbred lines have greater fitness or performance compared to the parental lines.

Heterozygous – Containing two different alleles at a given locus.

Homologous recombination – The swapping of genetic materials that have similar sequences.

Homozygous – Containing two identical alleles at a given locus.

Mutation – A change in DNA sequence.

Phenotype – The observable expression of genotype.

Polygenic – A phenotype dependent upon two or more genes.

Polymorphism – An alternate allele that is expressed with some degree of regularity.

Synteny – Conservation of gene sequences and chromosomal order across species.

Transgene – A segment of exogenous DNA that has been incorporated into the host genome.

Today, it is clear that the relationship between nature and nurture, or for the purpose of this article genes and environment, is a reciprocal relationship. Perhaps this relationship is best exemplified by Escher's 1948 lithograph, Drawing Hands. In this famous work, a hand emerging from a sketch is drawing another hand, which in turn is drawing the aforementioned hand. There is neither a beginning nor an end to this image; each hand cannot exist without the other and together they complete the picture. Substitute genes for one hand and environment for the other, and substitute behavior for the complete image and the relationship between genes, environment, and behavior are well represented. While we are born with our individualized genetic code, this alone is not sufficient to dictate behavior. Genes are only influential if their code is translated into proteins, and both internal factors and external factors such as the environment can drive gene transcription and translation. If genes solely drove behavior, then identical twins would have identical personalities and behaviors, and if environment solely drove behavior, adopted children would be as similar in behavior as identical twins. Clearly, neither is the case and the modern scholar recognizes this and the importance of understanding the relationship between genes, the environment, and behavior.

This article examines how animal models have fostered a greater understanding of the influence that genes have on behavior. This topic is too expansive to be covered in a single article as books have been written on it. Thus, it is impossible to cover every important study done in the field of behavioral genetics. Instead, examples of different behavioral genetic approaches and how these approaches have been successfully implemented to address a research issue are presented to illustrate the power of these approaches. Numerous animal systems have been used in behavioral genetics studies, with three of the more common species used being *Drosophila* (fruit fly), *Caenorhabditis elegans* (*C. elegans*, nematode), and mice (*Mus musculus*). The following sections briefly examine the *Drosophila* model and the *C. elegans* model, and examine the mouse model in more detail.

Introduction

Behavioral genetics is well intertwined with the history of humankind. The domestication and selective breeding of dogs to assist in day-to-day activities is an excellent example of the application of behavioral genetics. Even with the long history of humankind systematically using genetics to improve the quality of life, whether through domestication of dogs or the development of more bountiful lines of livestock, science and philosophy once debated whether nature versus nurture dictated behavior. The position, often associated with John Locke, that the mind was a tabula rasa was in contrast and conflict with the idea favored by Descartes that behaviors or ideas were innate. Over the years, nature has sometimes been replaced with genes, as individuals favoring the nurture argument felt that an underlying motivation in the study of behavioral genetics was to demonstrate that behavior was written in the genes and thus immutable.

Behavioral Genetic Techniques

Strain Surveys

Multiple approaches with different strengths and weaknesses have been employed to study the genetics of

behavior. One approach is to examine the effects of naturally occurring genetic variation on behavior and a complementary approach is to induce genetic mutations and observe behavioral changes. Comparisons of inbred strains are one method to examine the effect of natural genetic variation on behavior. For example, in mice, 20 consecutive generations of inbred mating result in lines that are genetically identical. Thus, if environment is held constant, differences across strains should reflect genetic influences on behavior. Because genetics is held constant within an inbred strain, differences between strain members should reflect environmental influences. Strain comparisons can be used to determine if behaviors are genetically correlated. Using the strain mean performance from multiple lines of inbred mice, correlations across behaviors can be calculated. A significant correlation between behaviors indicates that common genes are involved in the behaviors.

Selective Breeding

In addition to comparisons between inbred strains, outbred strains can be selectively bred to generate lines that differ in phenotype and genotype. For example, if it is observed that some members of an outbred strain perform at a high level for a given phenotype while other members of the strain show a low level of performance, the high performers can be inbred and the low performers can be inbred. The resulting lines will be genetically different and will also differ on at least the phenotype of interest. These lines can then be used to identify which genes segregate with the phenotype and to identify if other behaviors segregate with the targeted phenotype, which would suggest some linkage between the genes of the targeted behavior and the co-segregating behavior.

Quantitative Trait Loci Analysis

Inbred strains that differ on a given phenotype and lines developed by selective breeding of opposing phenotypic responses can be used in recombinant strain studies and quantitative trait loci (QTL) studies to identify the underlying chromosomal regions or genes associated with a targeted phenotype. In QTL analysis, homozygous subjects from different populations that differ in a phenotype of interest are crossed, resulting in an F1 generation. Although the F1 generation is a combination of two homozygous genotypes, all F1 individuals are genetically identical. Crosses between F1s or between an F1 and one of the parental lines will produce an F2 generation segregation of genes including genes associated with the phenotypic trait. Offspring are then tested for the presence or absence of the targeted phenotype.

Known markers such as microsatellite DNA and restriction fragment length polymorphisms (RFLPs)

along with restriction enzymes can be used to map targeted genes. Restriction enzymes are found in bacteria, which use them to cut invading DNA into pieces. Since 1978, when Nathans, Arber, and Smith were awarded the Nobel prize in medicine for the discovery of restriction enzymes, thousands of restriction enzymes have been identified. These enzymes recognize specific nucleotide sequences, called restriction sites, and cut the DNA at those sites. The resulting pieces of DNA will vary in length depending on the location of the restriction sites. The RFLPs can be mapped to chromosomes. If the quantitative trait is associated with an altered nucleotide sequence at a restriction site, then the presence of the targeted phenotype would be associated with the absence of a given RFLP. Using a previously existing map, the chromosomal location of the RFLP can be located and the trait can be associated with a finite region of a given chromosome. Microsatellites are short segments of nucleotides that are repeated multiple times. These sequences can also be mapped to chromosomes and if a phenotype of interest is associated with altered microsatellite sequence, the absence of a microsatellite can be used to map a phenotypic trait to a chromosomal region.

Random Mutagenesis

Just as naturally occurring mutations can be used to map genes to behavior, induced mutations, either random or targeted, can be used to link genes to behavior. In random mutagenesis, a mutating agent such as radiation, N-ethyl-N-nitrosourea (ENU), or ethylmethanesulfonate (EMS) is administered to males of the species. The males are bred with females and offspring are tested for altered behavior. Offspring with altered behavior are bred to test if the altered behavior breeds true, which would suggest the presence of a mutation. If there is a mutation that breeds true, the location can be mapped.

Genetic Engineering

Transgenic mice

An alternative to linking a defined behavior to an unknown gene is identifying the function of a known gene through genetic engineering. Examples of such approaches are transgenic techniques and knock-out techniques. A transgenic animal is one that has had foreign DNA inserted into its germ line. The first animal with successful transfection of the germ line is referred to as the founder. The founder is then bred with a strain of interest to produce heterozygous animals, and this becomes the genetic background of the transgenic animals. Homozygous transgenic animals are produced via mating of animals that are heterozygous for the transgene. Transgenic animals, wild types, and sometimes heterozygotes are tested for behavioral phenotypes of interest and

for any behavioral changes that could confound interpretation of the effects of the transgene on behavior.

Other factors, in addition to expression of the transgene, can produce behavior changes. For instance, phenotype expression can be influenced by where the transgene lands in the genome, that is, expression of a transgene may be influenced by the chromosomal location. The location of the insertion can also alter behavior by affecting expression of an endogenous gene. Finally, expression of a transgene may lack temporal and spatial control. However, new techniques in genetic engineering allow expression of the transgene to be under the control of promoters of gene transcription that have spatially restricted expression and promoters that can be temporally activated.

Knock-out mice

In contrast to transgenic animals that have a foreign gene inserted, knock-out animals, as the name suggests, have an endogenous gene rendered nonfunctional. A genetic construct for a gene of interest is created that has a change in the sequence that will result in either production of a nonfunctional protein or no production of the protein at all. The knocked-out gene is inserted into an embryonic stem cell which has two functional copies of the gene of interest. Through homologous recombination, the knock-out sequence is taken into the embryonic stem cell genome. Because the gene of interest is knocked out throughout the genome early in embryonic development, some knock-out animals show developmental lethality. To circumvent this problem, conditional knock-outs can be used to restrict the knock-out temporally and spatially using the Cre-loxP system, for example, to excise the gene. Cre is a recombinase bacteriophage protein that excises DNA flanked by loxP sites and ligases remaining DNA. A transgenic animal is created with the Cre gene and a spatial or temporal promoter that can be used to regulate expression. Another line is created with the targeted gene flanked by loxP sites. The presence of Cre will excise, and thus knock out, the targeted gene when the promoter is introduced. The following sections examine three animal models, *C. elegans*, *Drosophila*, and mice, commonly used in behavioral genetics studies that employ some of the techniques just reviewed.

Animal Models

C. elegans

At first pass, the *C. elegans* may be considered a reduced preparation in that it has only 959 cells, about a third of which are neurons, but this species has been important for understanding both genetics and behavior. The *C. elegans* genome shares approximately half its genes with the human genome. The homology between the human

genome and the *C. elegans* genome is important because genes in *C. elegans* have been linked to complex processes such as learning and aging. For example, EMS mutagenesis was used to create and isolate eight mutant strains of *C. elegans* with increased life spans. Following this discovery, it was found that a single recessive mutation of the gene *age-1* increased longevity 1.4- to 1.7-fold. Interestingly, the increased longevity was associated with a fivefold decrease in fertility, suggesting that in wild-type *C. elegans*, increased fertility would come with the tradeoff of decreased longevity. Subsequent work from multiple investigators has identified over 40 single-gene mutations associated with increased life span. One factor heavily associated with increased longevity was a decrease in susceptibility to stressors such as free radicals and radiation. These important studies advanced the field of aging research by furthering the understanding of how the interaction between environmental stressors and genetics alters aging.

Drosophila

The *Drosophila* is well suited for behavioral genetics work. The *Drosophila* has a short gestational period and it is easy to maintain large *Drosophila* colonies because of their small size and low maintenance costs. The sequencing of the *Drosophila* genome in 1998 combined with the ability to rapidly generate mutants and study complex behaviors, such as courtship and learning, has facilitated identification of genes associated with these behaviors. Many of the identified genes have homologous genes in the human genome. The naming of *Drosophila* mutants and associated genes has often been colorful to say the least. For example, the Ken and Barbie mutant of either sex lacks external genitalia.

The pioneering geneticist Seymour Benzer contributed greatly to the understanding of genes and how mutations contribute to alterations in behavior. His work with *Drosophila* identified an amazing number of mutations that affected behaviors and processes such as locomotion, circadian rhythms, mating, learning, and longevity. In a classic behavioral genetics study, Dudai, Jan, Byers, Quinn, and Benzer identified a mutant with learning deficits. The offspring from the EMS-treated male *Drosophila* were classically conditioned by pairing an odor with a shock. One line showed a deficit in odor preference that was not related to sensorimotor deficits and was subsequently named *dunce*. The associated gene *dnc* was later sequenced and shown to code for cyclic adenosine monophosphate (cAMP) phosphodiesterase; the *dunce* mutation had lower levels of cAMP phosphodiesterase resulting in higher levels of cAMP. Research on the *dunce* mutation in many laboratories has been instrumental in understanding the role of cAMP in memory not only in flies but also in mammals.

Mice

The mouse has become the gold standard in animal studies of behavioral genetics. Multiple factors have contributed to the popularity of the mouse model. These factors include the availability of numerous behaviorally characterized strains of inbred mice, the well-developed techniques for manipulating the mouse genome, the reasonable balance between gestational period length and complexity of behavioral repertoire, the simultaneous sequencing of the mouse and human genome, and the high degree of homology and synteny between the human and mouse genome. Human and mouse genes show a 99% homology and a 96% conservation of syntenic regions.

History of mouse genetics

The history of the relationship between human, mouse, and genetic research is well described in the book *Mouse Genetics, Concepts and Applications* by Lee Silvers. As discussed by Silvers, domestication and even reverence for mice dates back to the ancient Greeks and Romans, but it was an interest in mice with unusual appearances in Asia that led to the emergence of businesses that developed numerous mutant lines through selective breeding. This interest in fancy mice reached Europe and America in the 1900s, and the interest and entrepreneurship of a mouse fancier, Abbie Lathrop, led to the development of many of the lines of inbred mice currently used in research today. Miss Lathrop was a retired school teacher who began to breed fancy mice in 1900. By the time of her death, it was estimated that she had up to 11 000 mice breeding on her farm. She provided early geneticists such as William Castle at Harvard University and Leo Loeb at the University of Pennsylvania (with whom she ran experiments and published on the genetics of cancer) with lines of mice, many of which are currently used in research such as C57BL/6 and C57BL/10 mice.

As director of the Bussey Institute at Harvard University, Castle, along with his students, began studies on the inheritance of traits in the fancy mice. It is easy to consider Castle as the founder of modern-day mouse genetics as many of his students went on to become prominent geneticists. Castle and his students realized the utility of lines of inbred mice for genetic research, and one of his students, Clarence Little, went on to start the Jackson Laboratory in Bar Harbor, Maine, which today is known as both a center of mouse genetic research and a vendor of mouse lines. The Jackson Laboratory lists over 200 lines of inbred mice alone. Currently, there are multiple sources of inbred and outbred mice that include B and K Universal, Charles River Laboratories, Harlan, and Taconic. Of note, Gregor Mendel perhaps would have been the first mouse geneticist if Bishop Anton

Ernst Schaffgotsch of Austria had not forbidden him to continue breeding experiments on mouse coat color.

It is beyond the scope of this article to review all the important studies that have employed mouse genetics. The following sections will provide examples of some of the tools in mouse behavioral genetics by reviewing select studies that used inbred mice or genetically engineered mice to study the link between genes and behavior. We start with an examination of inbred strains used to examine genetic correlations in behavior; this is followed by QTL analysis in the mouse, ENU mutagenesis in the mouse, and finally, an example of problem solving with genetically engineered mice.

Mouse strain surveys

A series of experiments in the laboratory of Jeanne Wehner at the Institute for Behavioral Genetics, University of Colorado examined the performance of 12 inbred strains of mice and seven F1 crosses of select inbred strains across six behavioral tasks (open field activity, y-maze activity, acoustic startle response, prepulse inhibition of the acoustic startle response, fear conditioning, and Morris water maze performance). The rationale for the study was twofold. First, complex behaviors are most likely polygenic traits and thus comparisons across strains allow investigators to determine if behaviors involve common genes, that is, if behaviors are genetically correlated. Second, transgenic and knock-out mice generated to examine the function of a gene in a behavior may be influenced by the genetic background in which the mutation is expressed; thus, knowledge of background phenotype will facilitate selection of the background strain for the mutation.

Although several behaviors were genetically correlated, the behaviors that were not genetically correlated may be even more interesting. Acoustic startle response was correlated with prepulse inhibition of the acoustic startle response, which may not be too surprising. In addition, acoustic startle was correlated with open field activity and y-maze activity. Interestingly, cued fear conditioning was not genetically correlated with contextual fear conditioning. This may be because contextual fear conditioning is critically dependent on the hippocampus, but cued fear conditioning is not, and thus, the engagement of different brain regions may also engage different groups of genes. Perhaps even more surprisingly, contextual fear conditioning and Morris water maze performance (both of which require the hippocampus) were not genetically correlated. Thus, it cannot be assumed that just because tasks share a common neural area, they are dependent on common molecular and genetic substrates.

Issues with inbred mice

These studies not only highlight the power of behavioral genetics but also bring forward issues that must be

considered when conducting behavioral genetic studies. First and foremost is that background strain matters. ‘A mouse is a mouse is a mouse’ is simply not true; all mice are not created equal. Thus, statements such as ‘mice are poor learners’ are too general and should be questioned. For example, LP/J mice are poor learners in the Morris water maze but are good at contextual fear conditioning, whereas 129/Svev TacfBr mice are good at both fear conditioning and the Morris water maze. Second, parental strain performance does not always predict performance in F1 crosses. For instance, mice from the 129B6F1 cross outperform both parental lines (i.e., 129/Svev TacfBr mice and C57BL/6 mice) in contextual fear conditioning. This demonstrates heterosis, also known as hybrid vigor, which may result from: (1) the reversal of inbreeding depression associated with the expression of harmful genes and/or (2) overdominance resulting from the heterozygote F1 generation having a greater variety of beneficial gene products.

Whereas studies of inbred mice are a powerful research tool for numerous disciplines such as behavioral, genetic, and neuroscience research, there are some important caveats to remember. First, inbred mice can differ in copy number of a gene and this could influence gene expression. Second, genetic drift can alter behavior between substrains of an inbred mouse strain that are bred by separate sources. Thus, a behavioral phenotype of interest seen in an inbred strain from one vendor may differ from the behavior of the same strain from another vendor. Third, care must be taken in deciphering the cause of the phenotypic variation between inbred strains. For example, an inbred strain could show poor Morris water maze learning, but the behavior could reflect a genetic defect that alters visual acuity and not learning processes. Another example would be the case where one strain shows greater conditioned place preference for a drug of abuse than another strain. One could conclude that the first strain finds the drug more rewarding and attribute the behavioral differences to genes involved in reward processes. However, it is also possible that the strains differ in genes involved in the metabolism of the drug or in learning. Finally, whereas the behavior of mice from an inbred strain should be consistent across laboratories when environmental factors are controlled, this is not always the case. In an eloquent series of experiments, Crabbe, Wahlsten, and Dudek compared behavioral profiles of several strains of inbred mice tested at different laboratories while environment and methodologies were controlled to produce the highest degree of consistency across laboratories as possible. Surprisingly, there was variation in behavior within strains across laboratories. Thus, even small changes in environment may influence gene expression and related behavior. These findings reinforce the strong relationship between genes and the

environment, and the fact that it is not nature or nurture but both that influence behavior.

Natural genetic variance in mice

An example of the power of using genetics to understand behavior comes from a series of experiments by Stitzel and colleagues examining the genetics of sensitivity to nicotine. Studies in both human and animal subjects indicate that genetics contributes to the effects of nicotine. Multiple polymorphisms could produce changes in sensitivity to nicotine. It was found that sensitivity to nicotine covaried with a single nucleotide polymorphism in the gene coding for the $\alpha 4$ nAChR subunit, Chrna4, that results in either alanine (A) or threonine (T) at position 529 on the $\alpha 4$ protein. This polymorphism alters $\alpha 4$ nAChR function and sensitivity to the behavioral effects of nicotine across strains of mice that differ in expression of the A529 versus T529 variant. These results are consistent with human data that suggest altered sequence of CHRNA4 influences smoking behavior, and thus could influence development and persistence of nicotine dependence.

Mouse QTL studies

While QTL studies have been successful in linking behavioral phenotypes to chromosomal regions, there are two behavioral QTL studies that stand out as excellent examples of how a QTL study can link behavior all the way down to a specific gene. Flint, Mott, and colleagues successfully used QTL analysis to link the gene *Rgs2* on chromosome 1 to changes in anxiety-related behavior. They used outbred MF1 mice to identify a QTL related to changes in anxiety as measured in the open-field arena. They next used quantitative complementation (the process in which mice with the identified QTL are crossed to mutants that contain candidate genes of interest) to demonstrate that *Rgs2* modulates anxiety-related phenotypes. *Rgs2* codes for a protein that regulates G-protein signaling and it may be through altering such signaling that mutations in *Rgs2* increase anxiety.

QTL analysis has also been used to identify a gene linked to withdrawal-related seizures. Buck and colleagues used congenic mice that possessed small chromosomal segments from C57BL/6J mice combined with greater than 99% DBA/2J background. DBA/2J mice show severe withdrawal symptoms compared to mild symptoms shown in C57BL/6J mice. Thus, depending on which segment of C57BL/6J DNA segregates, congenics could show C57BL/6J or DBA/2J withdrawal phenotypes. Sixteen candidate genes for alcohol and pentobarbital withdrawal sensitivity were identified in a 1.8 Mb QTL interval on chromosome 4. Of the 16, five emerged with high confidence and only one of the five, *Mpdz*, was significantly associated with withdrawal severity. Buck and colleagues proposed that *Mpdz* expression

may mediate drug effects through actions on targets such as γ -aminobutyric acid-B (GABA-B) receptors and 5-HT₂ receptors.

Mouse mutagenesis

Just as QTL analysis in mice can be used to link genes to behavior, so can mutagenesis studies. One of the classic mutagenesis studies comes from the laboratory of Takahashi. This study examined genes related to circadian rhythms. Male C57BL/6J mice were treated with ENU and, after recovery, were mated with untreated female C57BL/6 mice. Changes in wheel running behavior in offspring during normal light/dark cycle and during constant darkness were used to assess changes in circadian rhythm. One mouse out of 304 showed a change in circadian rhythm, a lengthening of the circadian rhythm during testing in constant darkness. The phenotype was shown to be heritable and offspring were backcrossed to BALB/cJ and C3H/HeJ mice. The mutation, *Clock*, segregated as a single gene and a (BALB X B6)F1 X B6 backcross was used to generate 100 mice for linkage analysis with simple sequence length polymorphisms as DNA markers. The *Clock* mutation was linked to chromosome 5. A follow-up study used positional cloning to identify the candidate *Clock* gene.

Mouse knock-out studies

It is beyond the scope of this article to discuss the generation of knock-out and transgenic mice and all of the important studies conducted with such mice. Instead, one example is provided of how knock-out mice can be used to address issues not resolved through other techniques. Nicotine withdrawal refers to a host of symptoms that include somatic changes, insomnia, increased appetite, anxiety, decreased affect, difficulty in concentrating, and learning and working memory deficits. A major issue in research on nicotine addiction is which nicotinic acetylcholinergic receptors are involved in nicotine-withdrawal symptoms and whether all symptoms are mediated by common receptors. The problem confronting this research is that there are numerous nicotinic acetylcholinergic receptor subtypes composed of α 2– α 10 and β 2– β 4 subunits, but nicotinic receptor antagonists do not have the selectivity to distinguish between the subunits involved in the behavior change.

Genetic knock-out studies have resolved the issue of what subtypes are involved in various withdrawal symptoms. β 2 Knock-out mice showed somatic symptoms during withdrawal. In contrast, β 4 knock-out mice exhibited significantly reduced somatic withdrawal symptoms, suggesting that somatic symptoms of nicotine withdrawal involve β 4-containing but not β 2-containing nicotinic acetylcholinergic receptors; further studies in knock-out mice suggest that the somatic signs of withdrawal may

also involve α 7 nicotinic acetylcholinergic receptors and α 5-containing nAChRs. β 2-Containing nicotinic acetylcholinergic receptors are, however, involved in the affective and cognitive nicotine-withdrawal symptoms. By demonstrating that different nicotinic receptor subunits are involved in different nicotine-withdrawal symptoms and by suggesting how genetic variation in nicotinic receptor function could alter withdrawal symptoms and potentially nicotine addiction, these studies show how genetic manipulations such as knock-out techniques can be used to answer questions that would not be answerable with other techniques.

Summary

Animal models continue to help us understand the intricate relationship between environment and genetics, which has many benefits including advancements in medicine. The links between behavior and genes have led to identification of related gene products that serve as targets for therapeutic interventions. The field of behavioral genetics, however, is only beginning. As we learn more about the genome and epigenetics, behavioral genetics studies will continue to play a critical role in understanding the relationship between genes and behavior.

Glossary

Fear conditioning – A Pavlovian learning task in which rodents learn the association between a conditioned stimulus (CS; e.g., tone or context) and an unconditioned stimulus (US; e.g., mild electric footshock). Memory is assessed by measuring freezing (unconditioned response; UR) during the presence of CS. Freezing is the cessation of all movement, except respiration, and is thought to reflect rodent predator-escape responses.

Inducible transgenic mice – To avoid the potential drawbacks of conventional knock-out and transgenic mice, such as expression during development and disruptions in multiple tissues and cell types, methods capable of improved spatial specificity and temporal control were developed. For example, expression of a transgene under the tet promoter can be temporally regulated by doxycycline, and fusions with mutant versions of the ligand-binding domain of the estrogen receptor allow for temporal control of proteins of interest.

Long-term potentiation (LTP) – A stable and long-lasting change in synaptic strength, which is induced by repeated synaptic stimulation. This form of synaptic plasticity is found in many types of synapses in different brain areas both *in vivo* and *in vitro*. Importantly, many studies have indicated that LTP occurs during memory formation, and the results reviewed here demonstrate a role for this synaptic mechanism in learning and memory.

Morris water maze – A behavioral task classically used to study spatial learning and memory. Rodents are trained to learn the position of a submerged platform by using spatial cues in the testing room. Following several training sessions, memory is assessed by a probe trial where the platform is removed from the pool and the mice are allowed to search for its location (target quadrant) for a short amount of time (e.g., 60 s).

Object recognition task – A nonaversive, nonspatial hippocampal learning task. Mice are allowed to interact with two objects for a certain amount of time (e.g., 10 min) in a training session. Memory is assessed in a test session in which one of the objects is replaced by a new object. The stronger the memory of the initial objects, the more time the mice spend with the novel object.

Introduction

In the past 20 years, the development of powerful molecular genetic approaches has dramatically changed neuroscience, including studies of learning and memory (L&M). Knock-outs (gene deletions), knock-ins (point mutations), and traditional transgenics (gene additions) allowed exquisitely specific molecular manipulations that had the additional virtue of being highly reproducible, a considerable departure from previous drug manipulation studies that often fell short on both accounts. With these novel molecular genetic approaches, it was possible to target any gene/protein/molecular process of interest. Most importantly, once the mutant mice were engineered, they could be easily shared with other investigators, thus allowing for collaborative multidisciplinary studies of behavior. This integrative approach forged a new brand of multilevel analyses that has changed the scope of behavioral studies and led to the emergence of a new field in *Neuroscience: Molecular and Cellular Cognition*. Molecular and cellular cognition has evolved into a large field with its own international society with branches and meetings in America, Europe, and Asia and with nearly 3000 members. It is no longer sufficient to address neuroscience problems at one level of analysis; the flexibility and efficiency of molecular genetic tools have raised the standards, and now it is both commonplace and expected that the best neuroscience studies should include mechanisms and explanations that cut across levels, from molecules to behavior. But how do we make compelling connections between levels of analyses? For example, how do we connect gene function with behavior?

In making a compelling argument for the function of a specific gene/protein in behavior, there are four different convergent strategies that are often used in molecular and cellular cognition studies. These strategies include: (1) negative alteration (delete, mutate, etc., the gene and determine whether the behavior is affected), (2) positive alteration (upregulate the function of the gene with transgenic, viral manipulations, etc., and determine if the behavior of interest is altered in a manner opposite to negative alteration), (3) nonintervention (determine whether gene expression/protein activation precedes the behavior of interest, and (4) integration (find out how the gene of interest fits within known molecular mechanisms of the behavior of interest, so as to make predictions of its mechanistic role).

Molecular and cellular cognition studies started with a couple of articles published in 1992 reporting the effects of the deletion of the alpha calcium calmodulin kinase II (α CaMKII) gene in hippocampal long-term potentiation and spatial L&M. Fifteen years later, there are now over 1000 papers published on more than 200 genes included in studies of hippocampal-dependent L&M. Majority of these manipulations resulted in deficits in L&M, but, unexpectedly, more than 30 different genetic manipulations actually resulted in enhancements of L&M. Because of the large scope of molecular and cellular cognition studies and the numerous reviews available of studies focused on how mutations disrupt L&M, this review is focused specifically on the genes whose bidirectional manipulations cause bidirectional changes in L&M: when overexpressed, enhance performance, but when deleted or inhibited, impair L&M, or vice versa.

In addition, since molecular and cellular cognition studies have focused on the connections between molecular and cellular mechanisms of behavior, we also discuss how genes regulate physiological processes and their implications to L&M. We classify the studies reviewed into several groups according to the signal transduction pathways affected and briefly summarize how each of the mutations is thought to affect synaptic plasticity and L&M.

NMDA Receptors

Negative Alterations of NMDAR and Impaired L&M

There is considerable evidence that lesions of various types of NMDA receptors (NMDARs), as well as drugs that interfere with this receptor's function, disrupt L&M. NMDARs are composed of a core subunit (NR1) and other modulatory subunits, including NR2 (with A, B, C, and D subtypes) and NR3 (with A and B subtypes). Deletion of NR1 impaired long-term potentiation (LTP) and spatial memory without confounding nonspatial learning ability. In addition, hippocampal subregion-specific deletion of NR1 in CA3 and dentate gyrus also impaired different aspects of cognition, including pattern completion and separation, respectively. Deleting NR2A, which is the dominantly expressed NR2 subunit in the adult brain, also resulted in deficits in hippocampal LTP and hippocampus-dependent learning tasks. The behavioral role of NR2B could not be examined with knock-out (KO) mice since these mutants died shortly after birth.

Positive Alterations of NMDAR and Enhanced L&M

To investigate the role of NR2B in memory and synaptic plasticity, NR2B was overexpressed in the mouse forebrain (the *doogie* mouse). The longer NMDAR currents,

resulting from overexpression of NR2B, led to enhancements of hippocampal CA1 LTP in this mutant. Importantly, *doogie* showed enhanced performance in several hippocampal L&M tasks, including novel-object recognition, spatial memory tested in the Morris water maze, and contextual conditioning. Aged mutants were also found to outperform controls of similar ages. These results were interesting, but alone they would not have made a strong case for a role for NMDARs in LTP and L&M. Below, we review a number of other molecular genetic manipulations that affected NMDAR levels, LTP, and L&M.

A mutant mouse in which the $\beta 3$ subunit of the voltage-dependent Ca^{2+} channel $\text{Ca}_v\beta 3$ was knocked out also showed enhanced LTP and memory. The $\text{Ca}_v\beta 3$ KO mice outperformed controls in several hippocampal L&M tasks, including contextual fear conditioning, novel object recognition, and social transmission of food preferences. Interestingly, NMDA-mediated currents and NMDAR-dependent LTP were increased in the hippocampus of these mice. Although the underlying molecular mechanism is unclear, NR2B expression was slightly, but significantly, increased in the KO mice. Similarly, NR2B mRNA and protein levels were also higher in transgenic mice overexpressing KIF17, a protein that is thought to transport NR2B along microtubules. These transgenics also showed superior spatial learning and working memory than controls. It is possible that enhanced transport of NR2B, and subsequent higher levels of this subunit in synaptic NMDARs, could be the cause for better learning in mice overexpressing KIF17.

Cyclin-dependent kinase 5 (Cdk5) may regulate calpain-dependent proteolysis of NR2B. Calpain is activated by Ca^{2+} entry through NMDARs, and it rapidly cleaves NMDAR subunits, resulting in a decrease in the number of functional NMDA receptors in the postsynaptic density. Accordingly, deletion of Cdk5 in adult mouse forebrain reduced NR2B degradation, consequently increasing NMDA-mediated currents, which resulted in larger LTP and enhanced contextual fear conditioning, faster fear extinction, and more flexible learning in the reversal water maze task. Transient expression of p25, an activator of Cdk5, in mice forebrain increased NR2A phosphorylation and NMDAR-mediated currents, enhanced synaptic plasticity and hippocampus-dependent memory, including contextual fear conditioning and the Morris water maze. However, prolonged activation of p25 impairs synaptic plasticity and L&M.

Mice lacking nociceptin receptor (ORL1) showed enhanced L&M in the Morris water maze and passive avoidance tasks. This mutation resulted in enhanced NMDA receptor function, more rapid activation of its key downstream effector α CaMKII, and, consequently, larger LTP. Interestingly, application of the nociceptin peptide and the ORL1 agonist Ro 64-6198 had opposite

molecular, electrophysiological, and behavioral effects to the nociceptin receptor KO. Thus, these results suggest that nociceptin-mediated signaling regulates NMDA-receptor-dependent activation of α CaMKII and functions as a key constraint of plasticity and L&M. The findings described in this section demonstrate that upregulation of NMDAR function can result in enhancements of L&M, while deletions of this receptor cause deficits.

Kinases and Phosphatases

There is growing evidence that opposing kinases and phosphatases downstream of NMDARs determine whether incoming signals enhance or suppress synaptic plasticity and therefore facilitate or dampen L&M processes. CaMKII, PKA, MAPK, and PKM ζ are well-known positive regulators, while the phosphatase calcineurin (PP2B) and protein phosphatase 1 (PP1) serve as negative regulators of both synaptic plasticity and L&M. Moreover, it has been shown that shifting the balance between kinases and phosphatases can enhance memory.

Negative Alterations of Kinases and Impaired L&M

The critical roles of α CaMKII in synaptic plasticity and L&M have been addressed by using multiple mutant lines in addition to the original null mutant mentioned above. For example, transgenic expression of a constitutively active form of α CaMKII (α CaMKII T286D) in the adult brain showed impaired synaptic plasticity and L&M. One of the interesting features of this kinase is that it undergoes autophosphorylation (e.g., Thr286 and Thr305/306). The importance of these autophosphorylation events was investigated by using knock-in mice. Mice with a point mutation that prevents autophosphorylation at Thr286 (T286A) were severely impaired in both LTP and spatial L&M. While the phosphorylation at Thr286 is facilitatory, the autophosphorylation at Thr305/306 is inhibitory. Mutant mice expressing α CaMKII with a T305D mutation, which mimics the inhibitory autophosphorylation, were impaired in both LTP induction and hippocampal-dependent L&M, such as Morris water maze and contextual fear conditioning. Blocking inhibitory autophosphorylation by substituting α -CaMKII $^{Thr305/306}$ by nonphosphorylatable amino acids (α CaMKII $^{TT305/6VA}$ mice) reduced the threshold for LTP induction, but still impaired L&M. These results suggest that lowering the thresholds for synaptic plasticity does not always lead to an enhancement in L&M.

The Ras–Raf–MAPK signaling cascade plays critical roles in various functions in the nervous system, including in synaptic plasticity and L&M. Transgenic mice expressing a dominant-negative MEK1, the upstream activator

of ERK1/2, showed impaired fear conditioning, implicating this signaling pathway in L&M. However, ERK1 KO mice did not show deficits in behavior, raising the possibility that ERK2 compensates for the deficiency. Alternatively, ERK2 is the major MAPK involved in L&M, and ERK1 has other roles in the central nervous syndrome (CNS). Indeed, either deletion or reduction of ERK2 resulted in impairments in L&M, including fear conditioning and Morris water maze, showing that ERK2 is the isoform responsible for the L&M.

Adenylyl cyclases (ACs) couple NMDAR Ca^{2+} signaling to downstream cAMP-dependent pathways, including the PKA-dependent phosphorylation of I-1 and therefore the inactivation of PP1. Of all the ACs identified, AC1 and AC8 are the only Ca^{2+} -sensitive ACs in brain. Deletion of AC1 resulted in slight impairment in the initial slope of LTP, but L-LTP was comparable with that of wild-type controls. AC1 KO mice were impaired in Morris water maze, but showed normal performance in contextual fear conditioning and passive avoidance tests. However, mice lacking both AC1 and AC8 showed severe deficits in L-LTP and long-term memory in contextual fear conditioning, passive avoidance, and object recognition, suggesting that cAMP–PKA signaling has a critical role in long-term synaptic plasticity and memory.

Positive Alterations of Kinases and Enhanced L&M

Genetic manipulations using viral vectors provide an alternative approach to mutant mice, and generally have better regional specificity since the viral vectors are delivered to specific areas of interest. Viral overexpression of α CaMKII in the hippocampus was shown to enhance spatial L&M in the Morris water maze. Although LTP in α CaMKII-overexpressing hippocampus remains to be examined, this result suggests that bidirectional manipulations of α CaMKII expression produce bidirectional changes in L&M. Previous transgenic studies indicated that in some cases overexpression of CaMKII could lead to deficits in L&M. This kinase is in abundance in the CNS, and it can phosphorylate many different substrates. It is possible that inappropriate expression of the kinase can lead to phosphorylation of proteins that are not usually modulated by this kinase, and thus to physiological pathologies that leads to L&M deficits.

AC1 transgenic mice showed an enhancement of PKA-dependent LTP. Moreover, this mutant showed enhancements of both memory in an object-recognition task and remote memory for contextual conditioning. The activities of MAPK and CREB, which are downstream molecules of cAMP/PKA pathway and also critically involved in long-term memory (see below), were significantly increased in the hippocampus of AC1 transgenic mice.

A positive alteration of MAPK signaling also enhances synaptic plasticity and memory. Studies of mice expressing a constitutively active form of H-ras (H-ras^{G12V}) in the axons of pyramidal neurons of the postnatal hippocampus revealed a role for Ras/MAPK signaling in presynaptic neurotransmitter release during high-frequency stimulation in LTP and L&M. H-ras^{G12V} presynaptic expression resulted in increases in the activation of MAPK and in the phosphorylation of its presynaptic substrate, synapsin I. In addition, these mutants showed a number of other convergent presynaptic phenotypes, including higher number of docked vesicles, increased frequency of mEPSCs, and altered paired-pulse facilitation. Accordingly, LTP induced under physiological parameters was increased in this mutant. Behavioral studies demonstrated dramatic hippocampal-dependent learning enhancements in several tasks tested. Importantly, a synapsin I mutation, which alone had no measurable effect in LTP and learning, reversed the physiological and behavioral enhancements of the H-ras^{G12V} mice, indicating that H-Ras/MAPK-dependent phosphorylation of synapsin I played a key role in the learning enhancements of these mutants. These results provide strong evidence that the learning enhancements described were caused by presynaptic mechanisms involving Ras/MAPK upregulation and subsequent phosphorylation of synapsin I at its MAPK site.

Positive Alterations of Phosphatase and Impaired L&M

Calcineurin is a Ca²⁺-activated phosphatase, which is composed of catalytic and regulatory subunits. Calcineurin can affect synaptic plasticity in many different ways, including modulation of NMDAR-mediated currents and regulation of another phosphatase PP1. Mice expressing an active form of calcineurin showed increased phosphatase activity and exhibited deficits in hippocampal LTP. Moreover, these transgenic mice have defective long-term memory whereas short-term memory is normal in spatial and object-recognition tasks, supporting the idea that this phosphatase can act as an inhibitory gate for LTP and learning.

Negative Alterations of Phosphatase and Enhanced L&M

A calcineurin inhibitor was expressed in an inducible manner using the doxycycline system. The phosphatase activity in the hippocampus and cortex of the adult mutant mice was significantly reduced, leading to enhancements in LTP both *in vitro* and *in vivo*. Importantly, memory was found to be enhanced in various behavioral tasks, including object recognition, which had been found impaired in transgenic mice

overexpressing calcineurin. These and other studies have indicated that decreasing calcineurin activity facilitates LTP and L&M. However, not all published studies reported findings consistent with this simple idea. For example, deletion of the regulatory subunit of calcineurin (CNB1) in excitatory forebrain neurons of adult mice led to the suppression of hippocampal LTD and only to slight enhancements of LTP. This mutant failed to show enhancements and even showed impairments in L&M tasks. Another study in rats also reported ambiguous results; blocking calcineurin expression by infusing anti-sense oligonucleotides (into brain ventricles) enhanced hippocampal LTP induction and contextual fear conditioning, but not spatial learning in the Morris water maze. The problem with being certain that the results reported truly reflect the L&M capacity of the animals is that not all publications demonstrate that the tests were carried out under conditions that avoid both floor and ceiling effects. Considering the complexity of calcineurin signaling in neurons, it is not entirely surprising that two different manipulations with different degrees of calcineurin inhibition resulted in inconsistent cellular and behavioral phenotypes.

Calcineurin can regulate the activity of another serine/threonine phosphatase (PP1) by dephosphorylating Inhibitor-1 (I-1). Phosphorylated I-1 is a potent inhibitor of PP1, and thus dephosphorylation of I-1 by calcineurin results in the activation of PP1. PP1 has an important role in LTD, and like calcineurin, PP1 is thought to be a negative regulator of memory. To suppress PP1, a constitutively active form of I-1 (I-1*) was inducibly and reversibly expressed in the adult brain. The induction of I-1* expression suppressed PP1 activity by ~70% in the hippocampus. Mice expressing I-1* showed improved object-recognition memory when they were trained in short intervals (massed training). It is well known that longer intervals (e.g., 10 min) between training trials generally trigger better L&M than shorter intervals (e.g., 1 min). Interestingly, the mutant mice were not different from wild-type controls when they were trained with longer intervals, suggesting that these longer intervals occluded the advantage conferred by the expression of the I-1* transgene. The mutants also showed enhanced L&M in the spatial version of the Morris water maze. Strikingly, inhibition of PP1 after training strengthened memory, suggesting that PP1 functions as a negative regulator of memory stability. Whether PP1 is involved in memory erasure or retrieval remains to be resolved. CaMKII, the AMPA receptor GluR1, and CREB-dependent gene expression are modulated by PP1, and changes in any of one of these components could modulate the stability of memory.

The studies reviewed in this section demonstrate that the balance between kinases and phosphatases is crucial for plasticity and learning and that shifting this balance

toward kinases either by activating kinases or by suppressing phosphatases can enhance L&M.

CREB-Mediated Transcription

In addition to the covalent modification of preexisting molecules, the transcription and then translation of new proteins can lead to molecular changes required for L&M. For example, the cAMP response-element-binding protein (CREB) is a transcription factor known to be required for the stability of synaptic plasticity and memory. The role of CREB in plasticity and memory is evolutionarily conserved from invertebrates to mammals. Recently, CREB has also been suggested to affect the probability that a given neuron in a circuit is recruited into a specific memory trace (memory allocation).

Negative Alterations of CREB and Impaired L&M

The targeted deletion of the CREB α and δ isoforms in mice lead to deficits in both LTP and long-term memory tested in a wide range of tasks, including Morris water maze, fear conditioning, social recognition, and conditioned taste aversion. In addition, conditional activation of a dominant negative form of CREB (CREB^{S133A}), with the ligand-binding domain (LBD) of the estrogen receptor transgenic system, impairs the consolidation of fear memory and conditioned taste aversion, confirming the critical role of CREB in long-term memory.

The activity of CREB can be regulated by CaMKIV-dependent phosphorylation of Ser 133. The CaMKIV null mutant mice showed lower CREB activation and, subsequently, deficits in both hippocampal LTP and long-term memory assessed by fear conditioning (1 and 7 days after training). Another CaMKIV mutant mouse expressing a dominant negative form of CaMKIV are impaired in the Morris water maze and contextual fear conditioning (not 1 day, but 7 days after training). Accordingly, this mutant showed deficits in the late-phase of LTP. These results indicate that downregulation of CREB activity by reducing CaMKIV impairs LTP and memory.

Positive Alterations of CREB and Enhancements L&M

Transgenic overexpression of a constitutively active form of CREB (VP16-CREB) lowered the threshold for L-LTP. Gene expression analysis of this transgenic showed BDNF as a key molecule for the maintenance of LTP. However, excessive activation of CREB resulted in abnormalities, such as hippocampal neuronal loss and epileptic seizure, and thus L&M could not be assessed in this transgenic. On the other hand, viral overexpression

of wild-type CREB was shown to enhance memory: viral expression in amygdala enhanced fear conditioning while expression in the hippocampus enhanced spatial memory.

The activity of CREB can be regulated by molecular interactions with other transcription regulators in the nucleus. In *Aplysia*, inhibiting a negative regulator of CREB, ApCREB2 was shown to lower the threshold for long-term synaptic plasticity. Recently, three different mice models show that manipulating CREB suppressors can also enhance synaptic plasticity and memory in mammalian brain. First, expression of a broad dominant-negative inhibitor (EGFP-AZIP) of the C/EBP family of transcription factors in mouse forebrain was found to suppress the repressor isoform of C/EBP β and decrease the expression of the activating transcription factor 4 (ATF4). ATF4 is a negative regulator of CREB. Thus, EGFP-AZIP, by suppressing two different transcriptional repressors, shifts the balance toward transcriptional activators, in both the CREB and C/EBP families. Importantly, expression of EGFP-AZIP lowered the threshold for LTP and memory formation: a tetanus that induces only early stages of LTP (E-LTP) in controls can induce transcription-dependent later forms of LTP (L-LTP) in EGFP-AZIP mice. Behavioral analysis revealed enhanced learning in mutant mice trained with a weak protocol in the Morris water maze. Second, mice heterozygous for a point mutation that prevented phosphorylation of the eIF2 α at serine 51 (eIF2 $\alpha^{+/S51A}$) showed decreased levels of ATF4 protein. Stimulation that induced E-LTP in controls was capable of inducing L-LTP in the eIF2 $\alpha^{+/S51A}$ mutants. Importantly, these mice showed improved L&M in a variety of behavioral tasks, including contextual and cued fear conditioning, conditioned taste aversion, and latent inhibition. Finally, deletion of GCN2, a conserved eIF2 α kinase, reduced phosphorylation of eIF2 α , subsequently suppressed the translation of ATF4 mRNA. Similar to the eIF2 $\alpha^{+/S51A}$ knock-in mutant, the threshold for L-LTP was lowered and spatial learning was enhanced in the GCN2 KO mice. These studies support the hypothesis that the transcriptional repressor ATF4 is an important negative regulator of synaptic plasticity and memory and suggest that translation may be an important regulatory node in plasticity and memory.

Overexpression of CaMKIV in mouse forebrain led to an increase in the levels of CREB activity and to larger LTP in both hippocampus and anterior cingulate cortex. Moreover, these transgenics showed enhanced contextual fear and social recognition memory. Interestingly, CaMKIV overexpression rescued age-related decline in fear conditioning. Taken together, these studies showed that enhancing CREB activity either by suppressing its negative regulators or by activating its positive regulators can enhance synaptic plasticity and memory.

Extracellular Structure

Another important feature of long-term memory and synaptic plasticity is structural changes such as the growth of new synapses. For example, studies in both invertebrates and vertebrates showed that abnormal regulation of cell adhesion impairs long-term synaptic plasticity and synaptic growth.

Negative Alterations of Structural Proteins and Impaired L&M

Downstream from CREB, tissue-type plasminogen activator (tPA) was identified as an immediate early gene whose mRNA is rapidly induced by neuronal activity in the hippocampus. The tPA expression is also induced by LTP. A tPA is an extracellular serine protease that converts plasminogen into plasmin. Genetic deletion of tPA in mice resulted in deficits in L-LTP, supporting the idea that the downstream products of CREB-mediated gene expression are crucial for L-LTP. This mutant is also impaired in several forms of memory, such as contextual fear conditioning, object exploration, and active avoidance tasks.

The brain-growth-associated protein, GAP-43, has been shown to be involved in neural development, structural plasticity, and presynaptic neurotransmitter release. The homozygous GAP-43 KO is lethal, but the heterozygous KO mice ($\text{GAP-43}^{+/-}$) could be studied for behavioral phenotypes. $\text{GAP-43}^{+/-}$ mice showed deficits in contextual fear conditioning but normal cued fear conditioning, suggesting that hippocampus-dependent L&M is impaired. GAP-43 is a presynaptic substrate of PKC. Interestingly, mutant mice overexpressing a non-phosphorylatable form of GAP-43 (S42A) were also impaired in spatial learning.

Heparin-binding growth-associated molecule (HB-GAM), an extracellular matrix-associated protein, is known to regulate neurite outgrowth, axon guidance, and synaptogenesis. Mice lacking HB-GAM were impaired in hippocampus-dependent memory tasks, such as the Morris water maze and contextual fear conditioning. However, anxiety-like behavior is altered in HB-GAM KO mice, and this might confound the interpretation of cognitive phenotypes in these mice.

Positive Alterations of Structural Proteins and Enhanced L&M

Transgenic neuronal overexpression of tPA enhanced both LTP and hippocampus-dependent spatial memory. Recent findings indicated that plasmin converts brain-derived neurotrophic factor precursor (proBDNF) to mature BDNF (mBDNF) and that this conversion is

critical for L-LTP in mouse hippocampus. There is a variety of findings that indicate that BDNF has a key role in synaptic plasticity and learning. It is possible that the increased conversion of proBDNF to mBDNF in the tPA mutants contributes to enhanced LTP and memory.

Overexpression of GAP-43 and HB-GAM also enhanced spatial memory. GAP-43 transgenics showed enhanced *in vivo* LTP. Interestingly, moderate overexpression of GAP-43 was shown to enhance memory in the Morris water maze, whereas higher expression impairs learning in the water maze. Taken together, these studies show that beyond CREB-mediated transcription, structural proteins, which orchestrate or mediate synaptic structural changes, play critical roles in synaptic plasticity and memory.

Glial Regulation

Although studies of L&M have largely focused on neuronal cells, there is increasing physiological and behavioral evidence that glial cells play an active role in L&M. For example, mice lacking glial fibrillary acidic protein (GFAP) showed altered synaptic plasticity in hippocampus and cerebellum, which is accompanied by impaired eye-blink conditioning.

Positive Alterations of S100B and Impaired L&M

S100B is a Ca^{2+} -binding protein, which is secreted from astrocytes. Overexpression of S100B in astrocytes impaired hippocampal synaptic plasticity and spatial learning in the Morris water maze. Interestingly, elevated S100B has been observed in pathologic brains like Down's syndrome and Alzheimer's disease.

Negative Alterations of S100B and Enhanced L&M

Targeted disruption of S100B enhanced LTP and exogenous S100B treatment reversed this enhancement. Null mutant mice showed better performance in the spatial version of the Morris water maze. In addition, contextual fear memory was also enhanced in KO mice. However, it is still unclear how memory was enhanced in this mutant. S100B might bind its receptor in the neuron and trigger signaling involved in synaptic plasticity. These and other results suggest the involvement of glial processes in L&M.

Conclusions

KOs and other transgenic manipulations have had a considerable impact in neuroscience, including in the study of L&M. Although in the early days of molecular and

Table 1 List of mutant mice with enhanced/impaired learning and memory (L&M)

<i>Signaling pathway</i>	<i>Mutants with enhanced L&M</i>	<i>Mutants with impaired L&M</i>
NMDA receptors	NR2B Tg, $\text{Ca}_v\beta 3$ KO, KIF17 Tg, Cdk5 KO, p25 Tg (transient), ORL1 KO	NR1 KO, NR2A KO
Kinases	α CaMKII (virus), AC1 Tg, H-ras ^{G12V} Tg (in presynaptic neuron)	α CaMKII KO, α CaMKII ^{T286D} Tg, α CaMKII ^{T286A} KO, α CaMKII ^{TT305/6VA} KO, AC1/AC8 KO, ERK2 KO
Phosphatases	Calcineurin (inhibitor) Tg, Inhibitor-1 (active) Tg	Calcineurin (active) Tg
CREB-mediated transcription	CREB (virus), EGFP-AZIP Tg, eIF2 $\alpha^{+/S51A}$ KO, GCN2 KO, CaMKIV Tg	CREB $\alpha\delta$ KO, LBD-CREB ^{S133A} Tg, CaMKIV KO
Structural proteins	tPA Tg, GAP-43 Tg, HB-GAM Tg	tPA KO, GAP-43 KO, HB-GAM KO
Glial protein	S100B KO	S100B TG

Tg, transgenic; KO, knock-out; Ki, knock-in

cellular cognition most studies focused on the phenotypes of specific genetic manipulations, current studies in the field are focused instead on connections between molecular, cellular systems and behavioral function. These connections cannot be made with single mutant mice, but require instead a number of convergent manipulations, including transgenic and KO mutations that overexpress and delete the gene of interest. The emerging gold standard in the field is to determine whether opposite results are obtained with pairs of bidirectional genetic manipulations. To illustrate this process, we reviewed a set of mutations of genes that have been manipulated in this manner (**Table 1**). These studies identify NMDAR signaling and CREB-dependent transcription as important mechanisms of L&M and indicate several other signaling pathways involved in processing and storing spatial and contextual information in hippocampal networks.

Remarkably, bidirectional manipulations of L&M phenotypes were highly correlated with similar changes in LTP in the vast majority of mutant mice reviewed, a result that demonstrates that this form of synaptic plasticity has a key role in L&M. It is important to note, however, that not all increases in LTP lead to L&M enhancements, since often there are other parallel changes that affect behavior, including L&M. The remarkable consistency of the reviewed findings provides considerable evidence for a role of LTP mechanisms in L&M. Furthermore, there is compelling evidence that, during learning, synaptic transmission is strengthened in a manner consistent with LTP. Perhaps, the most surprising finding is that the vast majority of these results converge on a signaling pathway that starts with NMDAR activation and eventually involves CREB-dependent transcription. The consistency and convergence of these findings establish the signaling mechanisms underlying LTP as a cornerstone of the biology of memory.

Nevertheless, it is also important to note that there are some caveats that need to be considered when interpreting

each of the findings reviewed: most of the studies mentioned included only a limited behavioral analysis and did not explore in detail the behavioral nature of the L&M enhancements reported. It might be possible that some of the L&M enhancements reviewed have unknown behavioral costs that escaped the incomplete behavioral characterization of these mutants. In addition, tests that are more extensive might reveal other behavioral deficits that were not detected yet. Nevertheless, the extent and consistency of the findings reviewed demonstrate that LTP-like mechanisms have a role in L&M, and that there are at the core of rate-limiting mechanisms that could be used to enhance L&M. Targeting these core mechanisms may contribute to the development of general therapies for cognitive disorders.

Glossary

- Adrenocorticotropin hormone (ACTH)** – A polypeptide hormone, which is secreted by the anterior pituitary gland in response to stress. It mediates synthesis and release of glucocorticoids from the adrenal cortex.
- Corticotrophin releasing factor (CRF)** – A 41-amino-acid polypeptide involved in coordination of behavioral, endocrine, and autonomic responses to stress. It acts via two main systems: (1) CRF neurons in the paraventricular nucleus of the hypothalamus and (2) the CRF neurons in the central nucleus of the amygdala and the bed nucleus of the stria terminalis.
- Central benzodiazepine (CBZ)** – The CBZ binding site is a component of the GABA_A receptor complex. Binding of an agonist to the CBZ site increases affinity of the GABA_A receptor to GABA and enhances GABAergic neurotransmission.
- γ-Aminobutyric acid (GABA)** – A main inhibitory neurotransmitter in the mammalian CNS.
- Long-term potentiation (LTP)** – A long-lasting improvement in communication between two neurons as a result of their simultaneous stimulation. It is considered as a form of synaptic plasticity and a cellular mechanism of learning and memory.
- Neuropeptide Y** – A 36-amino-acid polypeptide which acts as a neurotransmitter in the brain and the autonomic nervous system. It is involved in several functions, including regulation of food intake, learning/memory, and epilepsy.
- Oxytocin** – A peptide of nine amino acids that can act as a hormone and as a neurotransmitter. It is synthesized in magnocellular nuclei of the supraoptic and paraventricular nuclei of the hypothalamus and released from the posterior pituitary into the blood stream. Oxytocin is involved in a number of reproductive functions, pair-bonding, maternal behavior, and social recognition.
- Arginine vasopressin (VPA)** – A peptide which is synthesized in the hypothalamus, stored in the posterior pituitary, and can act as a hormone and as a neurotransmitter. VPA has been involved in a number of functions, including circadian rhythms, pair-bonding, and aggression.

Early neonatal environment has profound impact on the development of the mammalian central nervous system (CNS). Environmental stimuli interact with the genetic blueprint in shaping individual phenotypes and their subsequent perception and reactivity to various challenges. Increasing basic, clinical, and epidemiological evidence support the notion that exposure to an adverse early environment may underlie vulnerability to, and later expression of medical illness and psychopathology. A number of laboratories employed the procedure of maternal deprivation to investigate early adverse experience as a developmental risk factor for psychopathology.

The importance of mother-child interaction and its enduring effect on human behavior was first postulated by Freud in the beginning of the twentieth century. However, the critical importance of maternal environment in normal behavioral development of the offspring was clearly shown by Harlow in his seminal studies of maternally deprived rhesus monkeys. Animals that were raised with peers in the absence of the mother developed abnormal behaviors and altered reactivity to stress. In the early 1960s in a series of experiments, Ader, Denenberg, and Levine showed that in rodents, early environmental stimulation in the form of neonatal handling can have enduring effect on behavioral and neuroendocrine reactivity to stress. The last several decades have seen heightened interest in the long-term effects of early environment. Numerous procedures, including prenatal stress, maternal deprivation, handling, and isolation rearing have been developed by many laboratories to study the effects of early adverse environment on behavioral reactivity and the CNS. The key feature of virtually all of these manipulations has been long-term alteration of the hypothalamic–pituitary–adrenal (HPA) axis and neural circuits that modulate or are modulated by this system.

This article is primarily focusing on the consequences of maternal deprivation in the rat. A brief introduction into the regulation of the HPA axis, mother–infant interaction, and CNS plasticity of the neonate is presented before introducing maternal deprivation models.

Introduction

Regulation of the HPA Axis

Stimuli associated with perceived or actual challenges, external or internal threat, pain, infection, or metabolic perturbations are communicated to the hypothalamus

through stressor-specific pathways where this information is integrated in the paraventricular nucleus (PVN) of the hypothalamus. Parvocellular neurons of the PVN secrete corticotrophin-releasing factor (CRF) and arginine vasopressin (VPA) which are transported to median eminence nerve terminals and released into circulation. At the level of anterior pituitary they stimulate synthesis and release of adrenocorticotrophic hormone (ACTH). When released into the systemic circulation, ACTH in turn stimulates synthesis and release of glucocorticoids (GRs) (corticosterone in rodents and cortisol in primates) from adrenal cortex; they are essential for energy mobilization. Concentrations of glucocorticoids are regulated by glucocorticoid-mediated negative feedback inhibition of further HPA activity at pituitary and hypothalamic sites via two types of corticosteroid receptors, mineralocorticoid (MR) or type I and glucocorticoid or type II. MR receptors have a high affinity for glucocorticoids and show high degree of saturation even under basal HPA activity. MR is thought to be involved in modulation of the circadian rhythm of glucocorticoid secretion, in particular its diurnal trough. GR receptors, in contrast, have a low affinity for glucocorticoids and are thought to modulate negative feedback during the circadian peak and following an acute stressor. The central distribution of these receptors varies in a species-typical and brain-region-specific manner. In rodents MR is distributed primarily in the hippocampus and septum, whereas GR is present in the PVN, hippocampus, cortex, and cerebellum. The central distribution of MR and GR in primates is broader than in rodents with high levels of expression in the neocortex. This may reflect greater role of glucocorticoids in modulation of primate cognition, mood, and social behavior.

In addition to its major role as a regulator of the HPA axis, CRF acts as a neurotransmitter in the widespread circuitry throughout the CNS, integrating information and mediating endocrine, autonomic, and behavioral responses relevant to signs of stress, depression, and anxiety. Acting via neuronal projections that connects amygdala and hypothalamus with the locus ceruleus (LC) CRF stimulates noradrenergic neurotransmission forming a feed-forward cascade of the circuit, which regulates vigilance, anxiety, and fear-like reactivity. In contrast, gamma-aminobutyric acid (GABA), neuropeptide Y (NPY), and oxytocin appear to offset the effects of CRF in stress response.

CNS Developmental Plasticity and Mother-Infant Interaction

While the basic CNS structure and connectivity are programmed by the genetic blueprint, environmental stimuli play a key role in shaping the patterns and connectivity that, in part, are responsible for individual differences in

reactivity to the environment. Developmental processes that occur during the neonatal period include dendritic development, synaptogenesis, granule cell neurogenesis, and apoptosis. The CNS in neonatal rodents is protected from pronounced fluctuations of the HPA axis that can be detrimental to the development of the immature brain. Specifically, there is reduced sensitivity of the HPA axis to activation during the neonatal period (postnatal day (PND) 3–16), which is also known as stress hyporesponsive period (SHRP). This period appears to be essential for the normal brain development in rodents. However, the reduced HPA axis responsiveness during this period is not absolute and can be circumvented by sufficiently strong physical or psychological stressors, including maternal deprivation.

For most newborn mammals, the mother is the most salient feature of early environment and the primary source of environmental stimulation. The newborn rat pups are almost entirely dependent upon the mother for thermoregulation, nutrition, stimulations of micturition, and protection for at least the first 2 weeks of life. Maternal behaviors exhibited by the lactating female rat, include licking, grooming, and arched-back nursing.

Normal mother–infant interactions are believed to be essential for the proper development of the CNS. It has been suggested that the mother acts as a hidden regulator of the infant physiological system. For example, stimulation associated with feeding stimulates heart rate in the infant rat, while licking (stroking) facilitates growth via stimulating secretion of growth hormone and expression of ornithine decarboxilase, a rate-limiting enzyme involved in growth. Furthermore, maternal behaviors play an essential role in suppressing adult-like stress response, in maintenance of the SHRP. In particular, feeding causes desensitization of the adrenal glands to circulating ACTH, whereas licking/stroking inhibits the release of ACTH from the anterior pituitary. Therefore, it is not surprising that separation from the mother is potent enough stimulus that can induce a substantial HPA response in the neonatal rat during the SHRP.

Rodent Models of Maternal Deprivation

There are numerous procedures of maternal deprivation developed to study the long-term effects of early adverse experience. These procedures vary greatly among various research groups, ranging from a single 24-h separation to repeated episodes of separation lasting 12, 6, or 3 h and administered on PND 1–2 through PND 14–21. Also, while in some of these procedures newborns are kept together as a litter, in others they are kept isolated from each other during the separation episode.

In rodents, the best-characterized procedure on long-term effects of maternal separation involves Long Evans hooded rats separated daily from the dam on PND 2–14.

In particular, maternally separated (MS) animals are removed from the dam as a litter and are kept in a warm incubator for 180 min daily. The MS group is compared to animals with the experience of daily separations from the dam for 15 min (handled, H) or animal facility reared (AFR) controls. Some studies also include animals that were undisturbed (or nonhandled, NH) during the same period. These manipulations are performed between 08:00 and 12:00 a.m. each morning. Pups are reared normally beginning PND 15. They are weaned on PND 21 and tested beginning after PND 60. This model has been developed based on naturalistic and seminaturalistic observations of mother-litter interaction in the rat. Under normal conditions, the lactating female rat leaves the maternal nest regularly. However, the duration of these, naturally occurring mother-litter separation episodes appears to be linked to her social status. Dominant female rats build their nests in close proximity to food and water resources and thus can keep regular separations from the offspring relatively brief (15–30 min). However, subordinate females are forced to build their nests in the periphery, resulting in markedly longer (2–3 h) foraging periods and longer periods of separation from the litter.

Consequences of Maternal Deprivation

Changes in Maternal Behavior

Behavior of the mother toward the offspring appears to undergo significant change as the consequence of the maternal deprivation protocol. These changes include increases in latency to retrieve pups to the nest and to initiate licking and nursing. Also, normally coordinated pattern of maternal behavior is disrupted and appears disorganized in the mother as the result of the maternal deprivation protocol. MS pups exhibit elevations in circulating ACTH and corticosterone within 5 min of reunion with the mother. At weaning MS animals weigh less than H or AFR animals, which is another sign of a deficit in maternal care. This difference in body weight can persist well into adulthood. Also, according to recent evidence maternal deprivation protocol results in profound and long-lasting changes in emotional reactivity of the mother and her sensitivity to opioid drugs.

These observations have been the basis for the maternal mediation hypothesis according to which deficits in maternal care upon reunion of the mother with her litter account for a large portion of the neurobehavioral differences observed in the adult offspring. This hypothesis is supported by the observation that many effects of the separation procedure observed in adult offspring can be eliminated by cross-fostering procedure. Also, naturally occurring variations in the frequency of pup licking and grooming (LG) provided by the mother is associated with individual differences in stress responsiveness,

emotional reactivity, and cognitive functioning in adult offspring. As adults, offspring of low compared to high LG mothers show features that are similar to those of MS animals. These include enhanced HPA response to stress and elevation of fear- and anxiety-like behaviors. Furthermore, offspring of low LG mothers exhibited impaired performance in tests of spatial learning and object recognition that was paralleled with shorted dendritic branch length and lower spine density in CA1 cells as well as impaired long-term potentiation (LTP).

Behavioral Adaptations

Using multiple tests for emotional reactivity (novel arena, novelty-induced suppression of appetitive behavior, open field, elevated plus maze, defensive withdrawal, acoustic startle, and startle-induced ultrasonic vocalization) many research groups found that MS animals exhibit signs of neophobia and increases in anxiety, fear, and depression-like reactivity in comparison to H or AFR animals.

MS animals are markedly more hesitant than H or AFR animals to explore a novel arena, which is interpreted as a sign of neophobia. Similar results are found in a test of novelty-induced suppression of appetitive behavior. In this test, food-deprived animals are presented with food in the center of a novel open arena, thus assessing internal conflict between voluntary approach and withdrawal tendencies. In accord with notion of increased neophobic responses, MS animals exhibit longer latencies to approach the food and to feed, also spending less time feeding than H animals.

Furthermore, in the open field test MS animals spend markedly less time than H animals exploring the inner area of the arena. In the elevated plus maze test, a classical test of anxiety and fear-like reactivity, MS animals spend less time on open arms of the maze than either H or AFR animals, often freezing or jumping off the apparatus. Signs of elevated anxiety and fear are also seen in defensive withdrawal test in which MS animals are slower to leave a safe compartment, re-enter to this compartment more often, and spend more time in it than either H or AFR animals. While in the tests for emotionality discussed above, an animal is tested for voluntary exploration of an aversive environment, in the acoustic startle response test an animal is challenged by an acute, uncontrollable stress (loud noise). MS animals exhibit exaggerated startle responses (higher amplitudes) and are quicker to respond than H animals. Similar to other types of aversive stimuli, such as attacks from conspecifics, or electric foot-shock, startle-inducing acoustic stimuli induce rats to emit ultrasonic distress vocalizations. In accord with the data obtained from other tests, MS animals are more likely to vocalize in response to startle than H controls.

In an animal model of anhedonia, one of the key signs of depression, MS animals consume markedly less sucrose solution than either H or AFR animals.

HPA Axis Adaptations

HPA axis adaptations can be considered as a key feature of the maternal deprivation procedure. MS animals exhibit exaggerated HPA responses to stress compared to either H or AFR animals, as indicated in **Table 1**. MS, H, and AFR animals do not differ in basal concentrations of ACTH and corticosterone. However, in response to psychological stressor (air puff, novel environment, and brief handling) MS animals exhibit augmented ACTH and corticosterone response. Furthermore, exogenously administered steroid drug dexamethasone fails to restrain diurnal rise in plasma ACTH and corticosterone in MS animals. Thus, both endogenous and exogenous negative feedback appears to be reduced in MS animals as a result of maternal deprivation procedure.

Table 1 HPA effects of neonatal maternal deprivation as compared to either handling or animal facility rearing

Variable	Effect
<i>HPA axis function</i>	
Basal ACTH	↔
Basal corticosterone	↔
ACTH stress response	↑
Corticosterone stress response	↑
Dexamethasone resistance	↑
<i>CRF receptor binding</i>	
PVN	↑
Pituitary	↓
<i>CRF content</i>	
PVN	↑
Median eminence	↑
<i>CRF mRNA</i>	
PVN	↑
<i>MR mRNA</i>	
Overall hippocampus	↑
CA1	↑
CA2	↔
CA3	↑
DG	↑
Septum	↔
<i>GR mRNA</i>	
Overall hippocampus	↓
CA1	↔
CA2	↔
DG	↔
PVN	↔
FC	↓
CG	↓
<i>MR/GR mRNA ratio</i>	
CA1	↑
CA2	↑
DG	↑

This reduction in negative feedback can be explained by opposing changes in central MR and GR densities in MS versus H groups. MS animals have increased densities of MR mRNA in the hippocampal regions of CA1, CA3, and the dentate gyrus (DG), and have decreased GR mRNA densities in overall hippocampus as well as in the frontal cortex (FC) and the cingulate gyrus (CG). The increased hippocampal MR/GR mRNA ratio in MS animals may contribute to the increased fear-like reactivity and impaired cognitive functions.

Exaggerated responses to stress found in MS animals can also be explained by increased expression of CRF mRNA, especially in the PVN. Furthermore, MS animals exhibit increased CRF content in the medial eminence and increased CRF receptor binding in the PVN. Therefore, the CNS of maternally deprived animals is characterized by increased CRF content and increased sensitivity to CRF.

Extrahypothalamic Effects

There are numerous adaptations in the CNS of MS animals especially in those neurocircuits that modulate or are modulated by the HPA axis, as shown in **Table 2**. The involvement of the extrahypothalamic CRF neurocircuits is particularly important since these circuits mediate neuroendocrine, behavioral, autonomic, and cognitive responses to stressors.

CRF mRNA in the central nucleus of the amygdala and bed nucleus of the stria terminalis (BNST) paralleled by CRF content in those regions is increased in MS animals in comparison to either H or AFR animals.

Table 2 Extrahypothalamic effects of maternal separation in comparison to handling or animal facility rearing

Variable	Effect
CSF CRF	↓
CRF receptor binding	
LC	↑
Raphe	↑
<i>CRF content</i>	
BNST	↑
Central nucleus of the amygdala	↑
Hippocampus	↔
LC	↔
<i>CRF mRNA</i>	
BNST	↑
Central nucleus of the amygdala	↑
Hippocampus	↔
<i>α2 adrenergic receptor binding</i>	
LC	↓
Nucleus of the solitary tract	↓
<i>GABA_A receptor binding</i>	
Amygdala	↔
LC	↓
Nucleus of the solitary tract	↓

These CRF pathways project directly to brain stem nuclei, including the LC where CRF directly activates noradrenergic neurons. The LC has been well established as a site that mediates vigilance and anxiety-like states in rodents and primates. It sends wide projections to multiple cortical and subcortical areas, including prefrontal cortex, hippocampus, amygdale, and hypothalamus. Thus, activation of the LC can further drive the HPA axis. MS animals exhibit reduced α 2-adrenergic receptor binding in the LC and nucleus of the solitary tract, suggesting that once neurons of the LC are active it will be difficult to reduce their firing rate. Also, in addition to the LC, MS animals exhibit increased CRF receptor binding to the raphe nuclei. Thus, changes in the CRF system as the result of maternal deprivation may lead to cascade of adaptations, including both the noradrenergic and serotonergic systems. MS animals are also characterized by reduced central benzodiazepine (CBZ) receptor binding in the LC and the nucleus tractus solitarius when compared to H animals. Therefore, increased CRF, reduced CBZ, GABA_A, and α 2-adrenergic receptor binding all contribute to increased responsiveness to psychological stressors as the result of maternal deprivation.

Summary

In summary, studies involving the procedure of maternal deprivation in the rat provide direct evidence that exposure to adverse events early in development results in exaggerated stress reactivity and alterations in several neural circuits that persist into adulthood. Many of the neurobiological alterations seen in maternally-separated animals parallel those described in patients with depression and anxiety disorders that have a history of various childhood traumas, such as physical or sexual abuse, neglect, psychological maltreatment, or chronic illness. Taking into account the contribution of early adverse events to mental illness can result in improved understanding of the biology of the disorder, its classification, and treatment.

Motivation

S G Anagnostaras and J R Sage, University of California, La Jolla, CA, USA

© 2010 Elsevier Ltd. All rights reserved.

Glossary

- Addiction** – A behavioral pattern of drug use characterized by compulsive drug taking, compulsive drug seeking, and a high tendency to relapse after withdrawal.
- Conditioning** – A phenomenon by which responses are acquired by virtue of pairing with (classical or Pavlovian conditioning), or allowing one to obtain or avoid (operant or instrumental conditioning), a biologically motivating stimulus.
- Dependence** – A physiological state whereby after prolonged use of drugs, a marked physiological withdrawal syndrome occurs upon cessation of drug use.
- Drive** – An internal motivating state (e.g., hunger or thirst) that energizes behavior when homeostasis is unbalanced. Drives are assumed to be aversive in nature and the subject seeks to reduce them.
- Hedonism** – A view of motivation in which people are motivated by obtaining pleasure and avoiding punishment.
- Incentive** – An external motivating stimulus that elicits an appetitive response.
- Instinct** – Heritable dispositions or patterns of behavior.
- Motivation** – An internal state (need, desire, or want) that serves to activate behavior and give it direction.
- Reinforcement** – The strengthening of a response by means of application of reward (positive reinforcement), or removal of an aversive stimulus (negative reinforcement); not synonymous with reward. In the context of fear conditioning, an aversive stimulus could also positively motivate defensive responding.
- Reward pathway** – A hypothetical common mechanism of reward in the brain, argued to be the mesolimbic dopamine system.
- Sensitization** – A progressive increase in response to the same dose of the drug with repeated administration.
- Tolerance** – A progressive decrease in response to the same dose of the drug with repeated administration, or, the need to take a higher dose of the drug to achieve the same drug effect as before.

Motivation may be described as an internal state (need, desire, or want) that serves to activate behavior and give it direction. What we do is largely determined by the

expected consequences of our actions. Anytime reward or punishment is considered as a cause of behavior; motivation is an essential principle of explanation. However, our understanding of exactly what motivates us has been the subject of debate since at least the time of the ancient Greeks. Here we review some basic approaches to motivation – with special emphasis on two dominant viewpoints: drive and incentive theories.

Historical Views on Motivation

Since the time of the ancient Greeks, motivational views could be divided into two categories: those that emphasize intrinsic causes of motivation, and those that emphasize environmental causes. The fourth-century Greek philosopher Thrasymachus (*c.* 459–400 BCE) theorized that people are motivated by self-interest. Any appearance of societal interest or greater good will ultimately be reducible to some sort of calculated long-term self-interest. This form of motivation, in which people and animals are motivated by obtaining pleasure and avoiding punishment, has come to be known as ‘hedonism.’ However, Socrates rejected this view, arguing that people use moral judgment, regardless of their self-interest, to guide their behavior. He posited that individuals can generally agree on what is right or wrong, and are motivated to do what is right. The dichotomy between environmental and intrinsic determinants of actions closely models contemporary incentive and drive theories of motivation.

The first scientific approaches to motivation are typically attributed to René Descartes (1596–1650), who originated the concept of the reflex. Descartes noted that an environmental input, which he called a stimulus (e.g., fire), could sometimes elicit a direct response (e.g., withdrawal). He suggested that nervous pressure was transmitted to the brain by nerves and then reflected back to the muscle, causing it to contract. This causal analysis suggested that behaviors could be studied mechanically, similar to examining the workings of a machine. Although this ingenious theory was poorly received at the time, it is the basic reductionist principle of functional neuroscience today. Over time, biologists consistently found that the machinery of animals was well suited for the environment in which they lived. That is, animals were highly successful at finding food, mates, mothering, and other skills necessary for living in

their home environment. Charles Darwin (1809–82), in the *Origin of Species* (1859), argued that species that were successful in surviving and breeding possessed biological and behavioral traits selected for by nature – traits adaptive for the particular environment. The machinery that controlled behavior generated instincts, or heritable dispositions and action patterns of behavior. Originally, instincts were used to explain behavior only in animals, but over time the concept became accepted as an explanation of some human behavior as well.

Perhaps no other person had more influence on motivational theories than Sigmund Freud (1856–1939). Freud's psychoanalytic theory emphasized unconscious motivation, in which individuals are strongly motivated by thoughts of which they are not fully aware. Freud referred to unconscious motivation as the Id, which contains basic drives, and is compelled to seek pleasure and reduce pain. These basic drives include instinctive needs for food, water, and sex. Freud emphasized the persistence of these urges, in that they arise in childhood, can only be suppressed, and become manifest in complex and sophisticated ways, reflecting the Id's hedonic essence. In contrast, the SuperEgo is our conscience and strives for moral perfection. Finally, the Ego utilizes reason and common sense, navigating external stimuli to mediate the conflict between the Id and SuperEgo. In essence, Freud's theory of behavior was the beginning of drive theory, because the goal of behavior was to reduce the conflict between the Id and SuperEgo. Freud's theories made common sense, and have become everyday explanations of behavior among educated people, even today. However, Freud was a neurologist by training, who emphasized case studies, and his lack of scientific approach and literary license meant that most of his ideas would not be directly integrated into psychology as it emerged as a science in the early twentieth century.

The beginning of the academic discipline of psychology includes John B. Watson (1878–1958) and Ivan Pavlov (1849–1936), both influential behaviorists. Watson and Pavlov redefined psychology as the study of behavior, emphasizing the circumstances surrounding behavior, and specifying the relationship between stimulus and response. The behaviorists endeavored to eliminate in scientific discourse the discussion of all unobservable mental events – including consciousness, which Watson believed was superfluous. They posited that behavior could be explained in terms of reflex stimuli (termed unconditioned stimuli, or USs) which generate automatic, instinctive responses (termed unconditioned responses, or URs), becoming associated with neutral stimuli (termed conditioned stimuli, or CSs). By virtue of being paired with a US, a CS would come to produce a conditioned response (CR) functionally related to the UR, a phenomenon known as Pavlovian or classical conditioning. Likewise, the behaviorist Edward L. Thorndike

(1874–1949) extended learning to include voluntary action in his famous law of effect: "Of several responses made to the same situation, those which are accompanied... by satisfaction... will... be more firmly connected with the situation, so that, when it recurs, they will be more likely to recur... those... followed by discomfort... have their connections... weakened" (Thorndike, 1911, quoted in (Bolles, 1978)). This form of learning came to be known as instrumental, or operant, conditioning. Together, behaviorists believed that Pavlovian and instrumental conditioning could explain the causation of most behavior. While Darwin undoubtedly influenced behaviorist thinking, the behaviorists stressed extrinsic factors as sole causes of behavior.

Around the same time, zoologists and biologists studying behavior in the natural setting were emphasizing instinctive patterns of intrinsically generated behavior. This science came to be known as 'ethology.' Ethologists described the presence of a number of instinctive behaviors, including those that behaviorists had categorized as USs. Eventually, ethologists and behaviorists found a middle ground, and depicted a complex interplay between instinctive and learned patterns of behavior. However, modern motivational theories tend to favor either intrinsic or extrinsic factors.

Drive Theory

Whereas behaviorist psychology emphasizes observable behavior, drives are thought of as organizational motivational states evoked by internal physiological regulatory processes. Drive theorists, such as Clark Hull and Kenneth Spence, argued that drives were a major cause of behavior. Two fundamental concepts are important for understanding drives: homeostasis and the negative-feedback loop. Homeostasis is the required regulation of physiological and psychological variables within biologically defined limits. In some early conceptions of drive (such as those of Hull), drives did not generate specific behaviors but rather generally energized behavior. This became quickly untenable and other theorists, such as Guthrie, added mechanisms to make the behavior specific to the need. For example, if blood sugar becomes too low, our body generates a hunger drive, which energizes behavior to obtain and consume foods with sugar in them. Alternatively, if sugar rises too high, a sense of satiety terminates eating. Thus, feeding behavior is viewed as part of a homeostatic system that keeps sugar levels at an optimal equilibrium. Other drives play a similar role: thirst leads us to drink water; and sexual arousal leads us to pursue sexual relief. In the concept of relief, we can understand the negative-feedback component of homeostatic regulation. Each drive accumulates energy, pressuring the individual to reduce it. In turn, when the action is performed, the drive is reduced (the energy

released) and the subject experiences relief. Thus, drives can be viewed as aversively motivating through the mechanism of negative reinforcement. During negative reinforcement, we produce behavior to terminate an ongoing aversive stimulus. Models involving drive theory therefore are also known as drive-reduction or tension-reduction models.

In an influential series of experiments supporting drive reduction as a substrate of behavior, the physiologist Walter B. Cannon examined hunger, which he believed was a sensation arising from the stomach. Cannon had subjects swallow a pneumatic balloon that measured stomach muscle contractions, and found that when the empty stomach contracted (hunger pangs), subjects reported being hungry. Others extended this work and showed that low blood sugar caused the stomach contractions. Cannon concluded that hunger originated from a signal in the body, and a similar view was adopted for thirst. In these cases, it is presumed that hunger, thirst, and other drives are inherently aversive, and that subsequent behavior arises from a desire to reduce them.

Theorists, such as Hull, argued that drives were also a major cause of learning, although their role is less defined. Primary reinforcers (e.g., food) are those that can reduce drives directly. However, secondary reinforcers (those, such as money, which have been paired with primary reinforcers) can also come to motivate behavior. Drive theory cannot adequately explain how secondary reinforcers reduce drives. Likewise, with the increasing discovery of physiological processes that stimulate behavior, such as the influence of androgens on male sexual behavior, it became unclear why the concept of a sexual drive (or energy) would be required. However, drive states are still used to explain some behaviors, especially in cases where the circuitry is not adequately understood, such as sleep. When we are sleep deprived, an aversive sleep pressure and sleep debt are believed to build up, which can only be relieved with proper sleep.

Today, the emphasis on drive theory has decreased, and research has focused more on the role of secondary reinforcers, and how they come to influence behavior.

Acquired Motivation

Most modern views on motivation hold that biologically based drives and incentives account for only a tiny fraction of behavior. Behavior can occur when we are not hungry, sexually aroused, thirsty, etc.; learned motives are therefore critical to understanding behavior. Two kinds are typically considered, ‘acquired drives’ and acquired ‘incentives.’ An example of an acquired drive is the sense of doom (fear) elicited by the sight of a tornado. This drive would motivate one to seek shelter or hide, which

offers a goal or incentive – the relief from fear and avoidance of harm. One learns that the sight of a tornado is something to be feared. Acquired incentives can include foods that are normally unpalatable, but over time, acquire incentive value. Consider liquor, which is commonly considered foul tasting the first time it is consumed. Access to liquor is limited, requires us to spend considerable money, and can put some of us at risk with the law. Yet, many people work hard to obtain liquor. There is no clear inborn motivational state that generates this action. We may not be thirsty at all, and consumption of liquor might actually increase thirst. Thus, the desire to consume liquor is a learned phenomenon.

Whereas acquired drives generate an internal pressure for action that has been learned, acquired incentives offer an external pull for action. By understanding the mechanisms of learning, we can understand how these factors come to control behavior. Conditioned fear provides an excellent example of acquired drive. Pain is a powerful motivator, and the threat of pain generally elicits both conditioned fear and avoidance. Conditioned fear reflects Pavlovian conditioning, whereby stimuli associated with pain come to elicit the fear response. Avoidance, on the other hand, reflects instrumental conditioning where the responses of escape come to be reinforcing because expected pain and fear are averted. The buildup of conditioned fear exerts pressure on the animal or person much in the same way as instinctive fear. Thus, conditioned drives can be viewed as enhancing fitness by expanding the effective repertoire of instinctive drive.

A second type of acquired motivation is conditioned reward (conditioned incentive). This reflects a process by which a stimulus that has no reinforcing properties on its own (such as money) comes to acquire the power of natural rewards, through learning. Conditioned reinforcement occurs when a stimulus is consistently paired with a natural reward through Pavlovian or instrumental conditioning. For example, animals can be trained to work for tokens that can be traded for food. However, subjects will also come to value cues that have no value. For example, if a clicking noise is paired with the delivery of food consistently, subjects will, over time, work for the click alone. These stimuli will eventually lose their effectiveness as reinforcers if the food is never delivered, but it is puzzling that they alone can act as reinforcers, supporting the acquisition of new behaviors. Conditioned incentives, such as that elicited by the click, may arise because they predict the occurrence of a natural reinforcer. Alternatively, it may simply be that pairing with the natural reinforcer confers some of its characteristics to the conditioned reinforcer. For example, Ludwig and colleagues gave detoxified alcoholics a small amount of alcohol when they pressed a button. Subjects rated their subjective craving. The subjects were then exposed to

cues that had been associated with alcohol in the past – namely the sight, and a small taste of, their favorite bottle of liquor. After exposure, subjects worked harder at pressing the button, and reported greater craving. The stimuli had thus been imbued with qualities of the incentive, and subsequently motivated behavior that gained access to alcohol. Conditioned reinforcers can serve a number of functions, such as providing information on how to obtain natural reinforcers, or simply becoming pleasant in their own right. This phenomenon can be understood in the context of classical conditioning and is typically referred to as Pavlovian incentive learning.

Acquired drives are thus internal states that motivate behavior. Similar to biological drives, they generate negative feelings or internal states (such as fear) that can be reduced when the appropriate behavior is performed (such as avoidance). Conditioned incentives are likewise learned, but reflect an external draw on behavior by virtue of their association with natural reinforcers.

Opponent-Process Theory

Opponent-process theory is a more complex theory that attempts to integrate both aversive and appetitive reinforcement. Richard Solomon and John Corbit developed this theory based on the time course of positive and negative feelings that emerge over time. The general concept is that over time any emotional state (A process) will convert into the opposite (or opponent, B process) state. After the experience of a happiness-invoking situation, a swing toward negative feelings will emerge over time. This is, in essence, a homeostatic theory of mood. Opponent-process theory brings emotion into the same general conception of equilibrium that is appreciated throughout biology. In Solomon and Corbit's original conception, the B process could change over time and was subject to conditioning. The theory has been especially useful in explanations of dependence and addiction. Thus, as an exercise in understanding motivation, the rest of this article focuses on theories of dependence and addiction.

Drug Dependence and Addiction

Most scientists agree that certain drugs may initially be taken to bring about an end to some unpleasant state (e.g., pain or depression), while others are taken in order to bring about some pleasant state (e.g., euphoria). Thus, initial drug use can involve both negative and positive reinforcement. However, as drug use becomes problematic and habitual, two competing views on addiction emerge.

Negative Reinforcement Models

Negative reinforcement theories of addiction emphasize aversive outcomes of terminating drug use, especially withdrawal and depression. These theories explain escalating drug use as being a result of tolerance to drug effects. Thus, these theories can be directly mapped to drive-reduction theory. Positive reinforcement theories of addiction, on the other hand, emphasize the ability of drugs to induce positive hedonic states, or reinforcement, by activating reward-related circuitry in the brain. Positive reinforcement theories rely on sensitization (described below) to explain escalating drug use. Finally, to explain relapse, both theories rely on conditioning – either conditioned withdrawal, or craving elicited by cues associated with drug use.

Physical dependence is generally defined as the presence of an aversive withdrawal syndrome upon cessation of the drug. Withdrawal is typically defined as a marked physiological disturbance that occurs upon cessation of the drug. Withdrawal symptoms are usually the opposite of drug-induced effects, and can be viewed as opponent, or drive, processes. In this view, opponent processes (known as compensatory adaptations) increase over time, forming the basis for tolerance, and increased drug use. The physical dependence theory of addiction has become a less tenable explanation for drug addiction for several reasons: First, physical dependence and withdrawal fade fairly quickly after drug cessation, and can be effectively managed in rehab; however, high relapse rates persist for years. That is, withdrawal is an acute condition, but addiction appears to be a chronic disease. Second, many drugs that produce addiction do not produce a marked physical withdrawal syndrome, such as the stimulant drugs amphetamine and cocaine. Moreover, the intensity of the withdrawal syndrome is not necessarily predictive of a drug's addictive potential. For example, the withdrawal syndrome produced by barbiturates and alcohol is life threatening, and far more intense, than that produced by heroin or cocaine, and yet the latter are viewed as more addictive. Third, persistent high doses of drugs are required to produce physical dependence, yet habitual drug taking can occur at much lower doses. Modern use of hydrocodone, a fairly weak but popular narcotic, would usually fall into this category. Finally, addictive potential depends heavily on how quickly the drug acts in the brain, and requires the use of a rapid route of administration (e.g., injected heroin is much more addictive than morphine tablets); however, equivalent dependence can be produced by slow and fast methods of administration. Given these findings, the definition of addiction (below) has come to exclude physical dependence as a necessary or sufficient component of addiction.

Nonetheless, several modern negative reinforcement theories can explain addiction and still resemble drive

theory. Prominent among these are psychological dependence models and the allostatic theory of addiction. Allostasis proposes that under chronic instability outside of the homeostatic range (such as chronic activation of the reward circuit), physiological systems become mobilized to find an equilibrium around the altered allostatic set point, including a new set point for mood. Opponent-process compensatory adaptations over time come to mask the initial hedonic effects of the drug. Aside from physiological adaptations that manifest as physical withdrawal, the allostatic (and psychological dependence) model proposes that there exists also a reward-related adaptation in mood that manifests as persistent depression, irritability, anxiety, and generalized emotional distress. This distress syndrome is posited to outlast physical withdrawal. In this sense, when the addict relapses and begins taking drugs again, the reinforcing effects of the drugs can be viewed in terms of drive reduction – rather than producing pleasure or positive reinforcement, they merely attenuate aversive drive states of the addict (such as depression).

A third negative reinforcement view of addiction that closely mirrors drive theory is the self-medication hypothesis. In this view, addicts begin, and continue, to take drugs in order to correct innate homeostatic imbalances in mood or other affective states. The drug of choice is not random, but rather matches some psychological need; opiates might be taken because of their ability to mute psychological pain, while cocaine might be taken to correct inherent behavioral depression.

Overall, a number of negative reinforcement models of addiction have been proposed which closely mirror drive (or acquired drive) theory. In all of these models, drug taking reduces intrinsic negative physical or emotional states.

Positive Reinforcement Models

In positive reinforcement models of addiction, addicts take drugs because of their rewarding or reinforcing properties. Some recent definitions of addiction stress incentive properties of drugs, and seek to exclude dependence as a necessary or sufficient condition for addiction. Jaffe describes addiction as a behavioral pattern of drug use characterized by: (1) overwhelming involvement with the use of a drug (compulsive drug taking), (2) the securing of its supply (compulsive drug seeking), and (3) a high tendency to relapse after withdrawal. Positive reinforcement has been the central emphasis of addiction research for many years, with the mesolimbic dopamine system viewed as the central reward pathway. This system innervates areas involved in action, planning, and learned behavior (e.g., nucleus accumbens prefrontal cortex and amygdala) with dopamine from the ventral tegmental area, and is well positioned to control behavior. In

particular, the nucleus accumbens has been argued to be an interface between motivation and subsequent action. Indeed, natural reinforcers and all drugs of addiction activate this pathway, and by one argument, addictive drugs are essentially hijacking this natural reinforcement pathway.

Positive reinforcement models of addiction gained popularity when animal models of reinforcement (drug place preference and self-administration, in particular) emerged in the twentieth century. These behavioral models of drug reward predict addictive potential better than the strength of withdrawal symptoms. In most reward models, drugs function as biological incentives, directly activating reward circuitry. However, in this simplest form, the reward theory of drug addiction inadequately explains escalating drug use and the emergence of compulsive over-involvement with the use and seeking of the drug.

Robinson and Berridge have proposed that sensitization, a process by which repeated intermittent administration of the same dose of drug leads to an increase in response, can help us understand the transition to addiction. In particular, the psychomotor response, mesolimbic dopamine activity, and reinforcing properties of many drugs, especially psychostimulants, undergo sensitization, and this is accompanied by synaptic remodeling in reward-related circuitry in the basal ganglia and prefrontal cortex. Robinson and Berridge propose that the incentive qualities, or psychological wanting, of the drug also undergo sensitization, which leads to escalating drug seeking, drug use, and loss of executive control. In this conception, the hedonic properties of the drug (psychological liking) are separate from incentive salience, because addicts report decreased pleasure with repeated drug use (i.e., tolerance). However, the ability of drugs to reinforce responses and increase approach undergoes sensitization, consistent with a view of increased incentive. Finally, CSs that are present at the time of administration (e.g., the sight of the drug, or even contextual stimuli) become imbued with conditioned incentive value which escalates, and can elicit craving and energize behavior toward drug taking. As an alternative explanation, which does not necessarily require sensitization, Di Chiara, in 1999, proposed that one key difference is dopamine response to rewards: the response to natural rewards habituates, whereas the response to drug rewards does not diminish. This allows drugs to exert an ever greater influence on learning as compared to other reinforcers. Conceptually, this is similar to an addict who pays more and more attention to drugs, and less and less attention to other matters in his life, such as home, family, and work.

Positive reinforcement models of addiction are frequently viewed as the mirror opposite of negative reinforcement models. This conception can create an unnecessarily narrow perspective, in which positive or negative reinforcement is exclusively viewed as the basis of drug addiction. However, these processes are not mutually exclusive, and could actually work together to produce addiction. That is, people may initially take drugs for pleasure, and subsequently transition to compulsive behavior as the incentive value of the drug sensitizes. In turn, withdrawal syndrome (or reward allostatic) could make the termination of drug use very difficult. Finally, conditioned cues may trigger relapse by eliciting craving. In this sense, both drive-like and incentive states contribute to the phenomena of addiction and dependence. Nonetheless, several addiction theorists have focused on what is necessary and sufficient for addiction, in which case reward-related processes are more central to addiction than physical dependence. Even Koob's allostatic theory focuses heavily on reward homeostasis, and discredits physical withdrawal.

Contemporary theories of addiction, incentive sensitization and reward allostatic, differ in terms of emphasis on positive or negative reinforcement, with origins ultimately tracing back to the earliest drive and incentive views of motivation, as reviewed at the beginning of this article.

Mouse Genetic Approaches to Psychiatric Disorders

S L King, University of Sussex, Brighton, UK

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Epistasis – The contribution of multiple genes to one phenotype.

Genotype – The genetic makeup of an organism, described as a combination of alleles for a gene.

Phenotype – A measurable observable trait that is a product of the genotype and environment.

Pleiotropy – The multiple consequences of one gene in different systems.

Polymorphism – A variation in gene sequence.

trait related to a psychiatric disorder, a bottom-up approach. This article does not seek to describe genetic models of human psychiatric disorders but describe how mouse genetic studies contribute to our knowledge of disorders and how different gene manipulations can be used to study behavioral outcomes. As a companion to disease-specific articles this should allow the power, complexities, and caveats of the different approaches to be understood.

Top-Down Approaches

Mouse Breeding and Behavioral Traits

As with domesticated animals, mice have been bred for specific traits for hundreds of years. For example, a popular breed among mouse fanciers was the Japanese Waltzing Mouse, selectively bred because they dance in circles. It has since been established that this trait is due to a genetic mutation causing inner ear dysfunction. More recently, researchers have taken advantage of advances in genetics to map specific genetic components of heritable behavioral traits. This has been greatly facilitated by the sequencing of the mouse genome (completed in 2002), which has allowed mapping of single base pair changes within the mouse genome. Two main strategies have been taken to pinpoint genes involved in behavioral traits. First, through comparing behavior of inbred strains of mice and identifying naturally occurring polymorphisms and second, by inducing genetic mutations, and selecting mice with abnormal behavioral traits.

Inbred Strains

The foundation work for much of the mouse behavioral genetic research occurring today stems from work in the early 1900s developing inbred strains of mice where all offspring carry identical DNA. Screening inbred strains of mice, and congenic lines derived from crosses of the parental strains, allows different behavioral traits to be ascribed to alterations in specific areas of the chromosome, termed quantitative trait loci. Genetic polymorphisms within these loci can be identified and then the role of the affected genes further elucidated. The use of congenic lines has enabled an efficient mapping of genetic variants and since the publication of the genomic sequence of one host strain of mouse (C57BL6/J), the identification of changes in DNA sequence has become

Introduction

Heritability studies have shown that almost every psychiatric disorder has a genetic component, for example, if a person suffers a disorder there is an increased likelihood that their parent or sibling will suffer from it too, and this is more likely the more genes they have in common. For example, it is more likely a monozygotic twin (identical DNA), than a dizygotic twin (sharing 50% DNA), of a schizophrenic will also suffer. However, no single gene variant has been discovered to explain a psychiatric disorder. Rather, the psychiatric disorders are products of a complex blend of variations in multiple genes and contributing environmental factors – physical, psychological and social. A specific gene polymorphism may confer susceptibility to a disorder but for the disorder to manifest it may need to be present with particular variations of other genes and the occurrence of additional environmental factors or stressors, such as drug exposure or an adverse life event.

For many years mice have provided a valuable tool for studying the genetic contribution to behavior. Mice share 99% of the approximately 30 000 genes expressed in man. This conservation across species and the ability to genetically manipulate mice makes them a valuable model organism with which to study the role of specific genes in disorders. Mouse genetics has been used to approach the identification and study of disease-related genes from two directions: First, genomic studies seek to find novel genes that might be implicated in a disorder, a top-down approach, from the behavior to the gene; and second, candidate gene studies, where specific genes are manipulated, and their role determined in a behavior or complex

more straightforward. A collation of genetic and behavioral measures collected from many research groups working on the same strains of mice is making it possible for an *in silico* approach to be taken where researchers can correlate their behavioral data with the current genetic information (WebQTL).

Random Mutagenesis

Rather than looking for naturally occurring polymorphisms, which may have relatively subtle effects on behavior, another strategy has been to induce changes in the genome by random mutagenesis, and then search for heritable abnormal behavioral traits in the mutagenized lines. Random mutations are introduced into the genome by means of a chemical mutagen or radiation. Historically, induced mutagenesis has been a successful strategy for finding novel genes that have a role in disease. However, it is a costly process requiring vast colonies of mice and resources. There are several sites around the world that have embarked on large-scale mutagenesis studies, screening for genes relating to a number of traits, including neurological and behavioral changes. They rely on an initial high-throughput screening to identify mice performing abnormally on standard behavioral tests. These mice are then bred and the heritability of the behavioral trait tested. At this point the genetic location of the mutation is identified and the gene function and altered phenotype further explored and characterized. To date this strategy has proved successful in identifying genes involved in a number of neurological functions and the maintenance of circadian rhythmicity.

Utility of Genetic Association

These strategies begin with no formal hypothesis as to what gene may be involved in a behavioral trait. Looking for naturally occurring polymorphisms that influence behavior by comparing across strains of mice most closely mirrors heritable behavioral traits in humans as they are likely to be evolutionarily stable. As a result, the effects of these genetic variations are subtle (not life threatening to the animal) and to elicit a large effect probably requires variation in a number of genes (polygenic). Thus through this strategy genes with relatively small effects may be missed or their actions only become apparent on a specific genetic background (in one strain). On the other hand, searching for mutations that cause a change in behavior, in mutagenized mice, allows us to identify novel genes, but not necessarily genes whose differential expression predisposes a person to a psychiatric disorder as genes whose mutations cause large (possibly deleterious) effects on behavior are less likely to have evolutionary stability and would often be bred out of populations. This kind of study does however provide a powerful tool for

identifying novel targets for further investigating the underlying neurobiology of behavior.

Bottom-Up Approaches

Traditionally, lesion studies or pharmacological approaches have been used to understand how the brain works. While these remain important in the last two decades, with the advent of genetic engineering and the utility of mice as a genetically tractable species, there has been a rapid increase in studies determining the contribution of specific genes and their products to behavior. These techniques, developed to study different physiological systems, have been exploited by neuroscientists to study the function of the wealth of genes expressed in the brain. They have enabled the identification of pharmacological targets of drugs and allow a dissection of the molecular mechanisms by which behavioral changes occur.

Genetic Manipulation of the Mouse

The methodologies used to mutate genes *in vivo* to ascribe function to their products are becoming ever more elegant and precise. The first transgenic mice (in which a gene is introduced to a mouse) were made in the early 1980s followed by the first knockout mice, in 1989, where mutations were introduced to endogenous genes in embryonic stem cells that could be used to generate mice bearing the gene, often functional. Current techniques now allow us to investigate the function of genes with both regional and temporal specificity. We can test the precise role of a protein in a specific cell population at a specific time in development. Studying the behavioral consequences of manipulating genes has allowed us to investigate both the intrinsic mechanisms of behavior and the actions of drugs in mediating behavioral change. Targeting specific genes known to have a role in psychiatric disorders enables us both to research the molecular events and pathologies leading to the disorder, and perform a behavioral characterization of the genetic model, that might point to new endophenotypes of the disorder.

Utility of Genetic Manipulations

Directed manipulation of genes allows hypothesis-driven research by exploiting how the expression of individual genes contribute to behavior and by extrapolation to the underlying neuropathologies of different psychiatric disorders. Candidate genes may be chosen for study due to: their high expression in specific brain circuits; their regulation in response to a perturbation; a prediction based on pharmacological or neurochemical knowledge; or identifications of disease associated polymorphisms in the human genome. For example, studies regarding the

properties of drugs of abuse, that lead to dependence and addiction, have benefited greatly from genetic manipulations. It has been possible to ascribe specific proteins the site of action of drugs of abuse. For example, it became evident when studying knockouts of the monoamine transporter genes that the rewarding actions of cocaine were not solely through action at the dopamine transporter (DAT) but also at the norepinephrine and serotonin transporters (NET and SERT). It was not until all three transporters were knocked out that cocaine had no pharmacological activity. As with the genetic association studies described above, studying the behavioral profiles of different strains of mice, it is often found that a phenotype may be visible in one strain but not another. For this reason most studies are carried out on mutant mice and sibling control mice, and ideally on mice where the parents have been backcrossed to a specific inbred strain. A mixed genetic background may increase the variability meaning a subtle effect might be lost in the noise or alternatively modifier genes may be present in one of other strain that are needed for the phenotype to be visible and thus in one strain, or in a proportion of siblings on a mixed background, the phenotype will not predominate.

Transgenic Mice

Transgenic mice have new DNA introduced to the genome at a random location. A gene or genetic element is injected into the nucleus of a newly fertilized egg cell and may randomly insert into the genome. It is not targeted, and its expression is dependent on its insertion site. By incorporating specific promoter elements into the transgene, it is possible to direct expression to specific populations of cells. Once inserted into the genome, the transgenic DNA is stable and can be passed from generation to generation in a heritable fashion. Because the random insertion of DNA into the genome may itself disrupt function of a gene at the point of insertion, or it may be differentially expressed due to regulatory elements in the surrounding genome, studies using transgenic mice often require the characterization of more than one founder line of mice. As tools for manipulating gene expression are developed, there are many different ways transgenes can be used to study the function of genes. Gene overexpression, for example, can be driven by simply introducing a gene under the control of its own or other promoter elements. On the background of a knockout mouse (where the endogenous gene has been mutated (see below)), transgene expression can enable behavioral deficits ascribed to the absence of the gene to be attributed to it specifically, presuming that they are restored with transgenic expression. Transgenes with genes encoding dominant negative forms of a protein or micro-RNAs can be used to establish the role of proteins

by blocking their function directly or by reducing their expression in specific neuronal populations respectively. Using the promoters and regulatory regions of genes as vectors for carrying the transgene to be expressed allows targeting of the construct to specific neuronal populations. Bacterial artificial chromosomes (BACs), which can carry large chunks of genomic sequence up and downstream of a gene of interest, have proved especially valuable in increasing the size of transgenes and providing the necessary regulatory components to drive expression in specific neuronal populations. This strategy has been used to generate a library of transgenic mice with green fluorescent protein expressed in the place of thousands of different genes. These BACs are also being used to express Cre-recombinase, an enzyme used to selectively knock-down genes (see below).

Constitutive Knockouts

Rather than random insertion, making knockout mice requires the endogenous gene itself to be mutated. A specific gene is mutated and reintroduced into the mouse genome by homologous recombination (e.g., it is switched for the normal gene) in mouse embryonic stem cells. The embryonic stem cells carrying the mutation are then injected into a blastocyst (mouse embryo at an early developmental stage, a few cell divisions) and divide and differentiate. A chimeric mouse, made up of cells derived from both the host blastocyst and the embryonic stem cells, is born and crossed to a normal mouse. Presuming the gametes were derived from the embryonic stem cells, the mutation becomes heritable and will be present as a heterozygote (one copy of mutant, one copy of wild-type (normal) gene). Crossing these heterozygotes should then produce, by mendelian genetics, 50% heterozygotes, 25% knockouts, and 25% wild-type mice. These offspring can then be phenotyped to determine the consequences of loss of that gene in behavioral tests. This methodology is now commonly used and it is relatively easy to generate knockouts for almost any gene. However, there are issues of this technique both in interpretation and logistics of mutation of certain gene products.

As highlighted at the beginning of this article over 80% of genes in the genome are expressed in the brain. This is not to say that only 20% are expressed elsewhere but that genes may be ubiquitously expressed in all cells or they have multiple roles serving functions during development of tissue and in the mature brain, or be necessary for the functioning of other organs (pleiotropy). Thus, it might be that a gene not only has a specific role in a behavioral trait in the adult but has an essential role in early development as well. In this case the mutant mouse may not survive through development making it impossible to test in adulthood. Genes may have other pleiotropic functions that preclude behavioral profiling,

for example, mice with a neurological impairment might be unsuitable for testing in a complex cognitive task. For this reason, it is also important that new mutants are put through standard neurological tests, to ensure that behavioral impairments reflect a change in the targeted behavior and not an underlying deficit. For example, an impairment in a visual learning task (such as the water maze) may be due to a visual rather than cognitive deficit.

Knock-In Mice

Knock-in mice are generated in much the same way as knockout mice; however, instead of generating a null mutation where the gene cannot be expressed, the mutation introduces a change to the gene that alters its function or introduces new regulatory elements. An example of a way this strategy is used to study human disorders is to swap the endogenous mouse gene for a humanized version of the gene where a genetic variant, that may cause an increased susceptibility to a psychiatric disorder is introduced into the mouse so behavioral changes attributed to the specific polymorphisms of the gene can be characterized. Another manipulation that can be made to genes is to make alterations to the structure of the gene, to alter its function. Examples such as this can be used to make a dominant negative or functionally inactive protein, one with an alteration that changes the function. For example, a key mechanism of action of nicotinic receptors includes both its activation and a subsequent desensitization. A mutation (relating to a naturally occurring polymorphism associated with human epilepsy) that renders the receptor unable to desensitize has been instrumental in elucidating the role of these receptors. Behavioral effects such as locomotor sensitization are seen with much lower doses of the drugs showing the importance of the desensitization in the receptor's normal activity. Drugs with the site of binding of ligands modified have also enabled the study of drug actions. For example, gamma aminobutyric acid (GABA)-A receptor alpha subunits confer binding to benzodiazepine at a site different to binding of their natural ligand, GABA. A mutation at this site altering one amino acid is sufficient to make these receptors benzodiazepine insensitive, but not alter the actions of GABA. These have been used to tease out the specific receptor subtypes mediating the anxiolytic actions of benzodiazepines as opposed to side effects such as sedation and muscle relaxation.

Inducible Expression

Inducible transgenic systems have also been developed whereby the gene can be switched on or off, and its function tested within the same mouse. These systems generally utilize transgenic technologies where regulatable sequences are incorporated into the promoter region

of the transgene. The most common strategy is adapted from a bacterial antibiotic resistance system where the presence of an antibiotic, tetracycline, activates a transcription factor (transactivator) that drives expression of an enzyme that confers resistance to the antibiotic. The transactivator and resistance gene promoter have been adapted and introduced into mammalian systems to enable the switching on or off of a specific gene (behind the tet-promoter) in the presence of antibiotic (delivered to the mouse in drinking water). Using this system, behavioral changes attributed to a neuropathological change in gene expression can be directly tested. By expressing these transgenes on a knockout background, the role of the gene can be tested acutely. Interestingly, on occasion when selective gene expression has been shown to restore wild-type behavior, it has been shown that switching off the gene does not re-instigate the knockout phenotype – pointing toward a developmental role of the gene product in mediating the behavior, not the presence of the gene at the time of testing. The localized expression shows us the importance of genes at particular periods of development. These studies provide important controls for constitutive knockout studies.

Inducible Knock-Downs

To circumvent the issues of epistatic effects of a gene knockout during development (e.g., embryonic lethality), or compensatory changes that may occur during the long-term absence of the gene, several methods have been developed to create inducible knockouts where the gene can be knocked out in specific regions or cell populations at specific timepoints (e.g., adulthood). The most successful strategy has adapted the cre-recombinase system used by bacteriophage viruses to integrate their viral genome into and out of the host bacterial genome. Lox-P sites (specific DNA sequences) are introduced into the gene to be mutated, and the new sequence recombines into the endogenous mouse gene. These two lox-P sites if introduced into noncoding regions should have no effect on their own but, in the presence of cre-recombinase enzyme (not expressed intrinsically in mammalian cells), will join together and the DNA sequence between them will be excised. Thus if the internal sequence contains part of the coding region of the gene, its function will be knocked out. The inducibility of this system comes from the expression of the cre-recombinase, which can be driven either through a transgene where its expression can be regulated by specific promoter elements or by viral injection into a specific brain region. This strategy has been especially useful in looking at the role of genes in specific circuits, where results in a constitutive knockout may be confounded by brain-wide alteration in function. For example, glutamate receptors have been inducibly knocked out in specific hippocampal populations and

striatal medium spiny neuron populations to study their function in specific networks or circuits related to learning and memory, addiction, and schizophrenia.

RNAi

A more recent strategy to downregulate gene expression is the use of small interfering RNAs (RNAi). It has been found that an endogenous method of regulating gene expression is the production of small pieces of RNA that interact with the messenger RNA (transcribed to make proteins) and cause its degradation. Understanding the sequence structure of these RNAs has enabled the design of RNAs to target specific genes. Expression of these driven by transgene or through viral vector expression allows the localized (and potentially reversible) downregulation of expression.

Viruses

A cheaper and faster way to manipulate gene expression *in vivo* has been the use of viruses. Viruses are manipulated so they can no longer reproduce and transgenic DNA introduced. Intracerebral injection of the viral particles to the brain allows a local infection of surrounding brain cells. In this way localized overexpression or knockdown (by shRNA) can be achieved. Common viruses that have been adapted for this purpose include: the Herpes Simplex virus, however, this only confers a short period of gene expression. Alternatively Lentiviruses and Adeno-associated viruses (AAV) which confer long-term expression of the gene of interest, can be used. A caveat of using viruses is that it is difficult to direct the infection or expression to one population of neurons. It is likely all neurons in the vicinity of the injection site will be infected (rather than say just excitatory or inhibitory neurons, for example). Currently, researchers are investigating the selectivity of specific serotypes of AAV vector for specific cell types and this may prove useful for targeting specific cell populations.

Considerations for Interpreting Phenotypic Data

As the targeting of genetic manipulations becomes more precise elucidating the specific contribution of genes to behavior and psychiatric disorders, becomes a more feasible task. Refinements to targeting strategies and the precise localization of genetic mutations to individual cell populations should allow us to construct a picture of what individual pathways and molecules in the brain do in relation to behavior.

The polygenic basis of most psychiatric disorders does not point to simple associations between genes and behavior. Single genes are active in the presence of other genes and it is the combined activity of all these genes that is

measured in behavioral output. A polymorphism in one gene may only show an apparent phenotype in the presence of certain polymorphisms of other genes. The effects of multiple genes (epistasis) on one behavior can confound establishing the role of single genes. Future genetic studies may begin to take this into account, manipulating multiple genes simultaneously.

A factor when considering the pleiotropic effects of genetic mutations is how they might interact with maternal behavior. It might be possible that a knockout mother may show differences in maternal care of her offspring. For this reason it is important that (and often required for publication) that mice of different genotypes are generated from the same matings e.g. heterozygous matings used to make both wild-type and knockout mice. More general environmental factors also need to be considered. In some cases a phenotype may only become visible in combination with manipulations of the environment, for example after introduction of a stressor. This can also account for why the described phenotype of a mutant mouse can vary between laboratories. A phenotypic change in locomotor activity, for example, may be visible in a novel environment but absent in a familiar environment, or in differential lighting conditions.

By recognizing the strengths and limitations of different manipulations of the mouse genome we can interpret behavioral data and begin to understand the complexities of how genes may play a role in psychiatric disorders. In making links from the behavioral phenotyping of mutant mice to the role of the mutated gene in behavior and a psychiatric disorder requires putting together a cohesive picture with parallel pieces of evidence: Is a mutant phenotype carried across more than one behavior associated with the psychiatric disorder? Is it preserved in related mutations? Does it resemble the effect of a pharmacological antagonist? Does the gene appear in human (or mouse) genetic association studies?

Conclusions

There is a place for both top-down and bottom-up approaches in the use of mice to study psychiatric disorders. Gene association studies in inbred strains of mice provide a simpler genetic system to study behavioral variation, than the equivalent human studies where there is more genetic variability and less control of the environment. The tools available to probe the roles of candidate genes (either hypothesis driven or from the association studies) are becoming ever more sophisticated, and provide a powerful way to link gene function to behavior. Though we need to be aware of limitations and pitfalls in analysis of genetically manipulated mice, as new technologies are developed these can be addressed. In combination with lesion and pharmacological studies

which themselves are beset by caveats and limitations, we have a great number of tools that will prove highly valuable in the understanding of how the molecules and circuits of our brains control our behavior, and what the neuropathological changes are that mediate the symptoms of psychiatric disorders.

Neural Bases of Defensive Aggression

A Siegel, S Bhatt, R Bhatt, and S S Zalzman, University of Medicine and Dentistry of New Jersey, Newark, NJ, USA

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Cytokines – Pleiotropic cell-to-cell-signaling proteins or glycoproteins that are produced by different cell types in the periphery and the brain.

Defensive rage behavior – A naturally occurring behavior that takes place in the presence of another animal of the same or of a different species, usually within the domain of its territory; this animal can be of the same or of another species. Basic features of this form of aggression include: flattening of the ears, lowering of the body, drawing in of the head, piloerection, hissing, pupillary dilatation, and stiffening of the tail that becomes motionless.

Enkephalin – A peptide neurotransmitter synthesized in the central amygdala and whose inhibitory actions are mediated upon the periaqueductal gray (PAG) to suppress defensive rage behavior in the cat.

γ-Aminobutyric acid (GABA) – A major inhibitory neurotransmitter in the central nervous system. In the medial hypothalamus and the PAG, GABA inhibits defensive rage behavior by acting through GABA_A receptors.

Glutamate – A major excitatory neurotransmitter of the central nervous system; a principal neurotransmitter of the pathway linking the medial hypothalamus with the midbrain PAG whose functions are mediated through N-methyl-D-aspartic acid (NMDA) receptors.

Hypothalamus – Together with the thalamus, it forms the diencephalon and serves as the primary structure for the integration of defensive rage behavior as well as a variety of other visceral processes.

Interleukin 1 (IL-1) – A cytokine whose actions in the brain serve to facilitate defensive rage behavior by acting through IL-1 β receptors and serotonergic (5-HT₂) receptors both in the medial hypothalamus and PAG.

Interleukin 2 (IL-2) – A cytokine whose actions in the brain serve to suppress defensive rage behavior in the medial hypothalamus by acting through IL-2 and GABA_A receptors and to facilitate defensive rage behavior in the PAG by acting through IL-2 and neurokinin-1 (NK₁) receptors.

Kluver-Bucy syndrome – A disorder associated with lesions of the amygdala or adjoining piriform cortex that is characterized by abnormal docility, hypersexuality, and marked oral tendencies.

Limbic structures – A region of the forebrain consisting of the hippocampal formation, amygdala,

septal area, prefrontal cortex, and cingulate gyrus.

These structures are linked by the fact that they receive cortical and monoaminergic inputs and modulate hypothalamic functions.

Midbrain periaqueductal gray (PAG) – A key structure of the midbrain that receives major output of the medial hypothalamus for the integration and expression of defensive rage behavior.

Monoamine neurotransmitters – These include norepinephrine, dopamine, and serotonin. Both norepinephrine and dopamine facilitate defensive rage behavior by acting through α_2 and dopamine-2 (D₂) receptors, respectively; serotonin facilitates defensive rage through 5-HT₂ receptors and suppresses defensive rage through 5-HT_{1A} receptors.

Septal rage – Marked increase in aggressive behavior following large lesions of the septal area in which the intensity of the aggressive reactions in these animals is so intense that the animals are extremely difficult to handle.

Substance P – A peptide neurotransmitter that powerfully facilitates defensive rage behavior by acting upon NK₁ receptors both in the medial hypothalamus and PAG.

Vasopressin – It acts both as a hormone and as a neurotransmitter. When acting at V₁ receptors.

Overview of the Model of Defensive Aggression

Defensive (aggressive) behavior (referred to interchangeably as ‘defensive rage’ or ‘affective defense’) has been studied most intensely in felines, although varieties of studies have been conducted in other species, including the rodent, dog, and monkey. In addition, there is a close similarity between the characteristics of defensive rage seen in animals and those seen in the human. In the human literature, this form of behavior has been referred to as ‘reactive’ aggression which contains marked impulsivity. It is seen, for example, in certain classes of patients with schizophrenia and borderline personality disorder. An example of this form of aggression in nonpatient populations includes ‘road rage.’ The following discussion concerns research derived from studies conducted in felines.

In the cat, defensive rage is a naturally occurring behavior that takes place in the presence of another animal, usually within the domain of its territory, and involves both defensive and offensive components. This animal can be of the same or of another species. Concerning defensive components, the basic features of this form of aggression include: flattening of the ears, lowering of the body, drawing in of the head, piloerection, hissing, pupillary dilatation, and stiffening of the tail that becomes motionless. Frequently, this pattern of responses serves to cause the opponent (i.e., the threat object) to withdraw from the immediate environment, thus achieving the objective of defensive rage behavior. If the cat decides to attack, its initial response is typically by paw strike, which is a primary means by which it defends itself. However, if the opponent responds to the attack with an aggressive act of its own, the cat will frequently roll over on its back with its anterior surface facing the opponent. With respect to offensive components, the fighting behavior may then result in a change in strategy on the part of the cat attempting to defend itself by exhibiting responses such as scratching and biting of the opponent, which are viewed as offensive. Other elements of offensive behavior that may be present include stretching or extension of the limbs, a hooked-shaped bending of the tail that may change in position to appear erect. Thus, in defensive rage behavior, while the overriding behavior is predominately defensive in nature, this response pattern may be superimposed by components of offense as described above.

Neural Substrates of Defensive Rage

Historical Basis

The first recorded studies of defensive aggression in animals made use of cortical ablations in cats and dogs and took place over the last decade of the nineteenth century and first two decades of the twentieth century. These studies typically demonstrated that such ablations were associated with the induction of marked vocalization, and other indices of rage behavior in response to innocuous tactile stimulation.

While these studies suggested forebrain involvement in aggressive behavior, they provide little information with regard to localization of function. In the 1930s and 1940s, several other approaches were employed to obtain a better estimate of the regions of the brain associated with rage behavior. Three general regions of the brain were the general focus of study. These included the hypothalamus, midbrain PAG matter, and limbic structures.

Hypothalamus

In one approach, decorticate preparations in cats in which the thalami were destroyed but the hypothalamus

remained intact were nevertheless capable of still displaying rage reactions, which suggested the importance of the hypothalamus in the rage process. Other studies attempted to more precisely specify the regions of the hypothalamus involved in rage behavior. Selective lesions of the posterior hypothalamus in the cat or the monkey were shown to reduce activity and eliminate signs of aggression, especially when provoked by tactile stimulation, which appears to underscore the relative importance of the posterior aspect of hypothalamus. Consistent findings were observed following selective lesions in the human where lesions of the posterior hypothalamus had a calming effect upon patients subjected to this procedure. In contrast, selective lesions of the medial preoptico-hypothalamus were shown to block aggressive reactions in mice. These findings may suggest that different parts of the hypothalamus may be species specific. Not all reports of lesions placed in the hypothalamus were reported to block aggressive behavior. In fact, several investigators reported that lesions placed in the ventromedial nucleus of the cat induced rage behavior. Such an effect is similar to reports in the human literature where tumors of the ventromedial hypothalamus were associated with the presence of rage behavior. It is possible that the type of lesions placed in the ventromedial hypothalamus, similar to the presence of the tumors, may have generated an irritative focus and thus served to stimulate the neighboring regions (see discussion of the effects of electrical stimulation below). Alternatively, such lesions may have resulted in the development of a supersensitivity of the descending neurons from hypothalamus that remained intact, which mediated this form of aggression.

Midbrain PAG

The role of the PAG was initially identified by reports that lesions of this region of the midbrain could successfully block the basic features of the rage response, including the vocalization component. Such observations were essential in identifying the PAG as a critical link in the downstream circuit from the hypothalamus for the expression of defensive rage that is described in detail below.

Limbic structures

The limbic system consists of the hippocampal formation, amygdala, septal area, prefrontal cortex, and cingulate gyrus. An extensive literature has emerged from studies of all of these regions, the most notable ones involving lesion and ablation studies of the amygdala, septal area, and prefrontal cortex in various species of animals. In addition, considerable information with regard to the role of limbic structures has been gained through clinical

studies involving the behavioral effects of tumors and seizure activity involving these structures.

One of the earliest and well-known studies involving lesions of the amygdala and adjoining regions of piriform cortex of monkeys described the resulting behavior later known as the Kluver–Bucy syndrome. It is characterized by abnormal docility, hypersexuality, and marked oral tendencies. Other studies involving perhaps regions of amygdala not involved in the induction of the Kluver–Bucy syndrome have produced dramatically different results in which the animals have become hyperaggressive. Later studies involving electrical-stimulation procedures provided new information which clarified the conflict in the literature with regard to the effects of amygdaloid lesions upon rage behavior. In brief, activation of the medial amygdaloid nucleus and adjoining regions potentiates defensive rage behavior, while activation of more lateral regions of amygdala, such as the lateral, central, and lateral aspects of the basal complex, suppresses this form of aggression.

Concerning other areas of the limbic system, studies involving the septal area conducted in rodents have revealed a marked increase in aggressive behavior following large lesions of this region. The intensity of the aggressive reactions in these animals became so intense that they became extremely difficult to handle. The phenomenon was frequently referred to as ‘septal rage.’ With respect to the prefrontal cortex, the first recorded evidence that this region regulated emotional behavior involved the case of Phineas Gage, a railroad worker in Vermont during the early part of the nineteenth century. He was struck by an iron bar that penetrated his brain and damaged parts of his frontal lobe, effectively destroying the connections between the prefrontal cortex and other cortical and subcortical structures. Afterwards, he displayed marked personality changes, such as childlike behavior and the passions of a strong man. Small lesions placed in the frontal lobe of monkeys were reported to result in a more placid animal, while lesions placed in the prefrontal region of rodents resulted in heightened aggressive behavior. Other studies involving electrical stimulation of the prefrontal region of the cat induced marked suppression of aggression and rage behavior.

Neural Circuits Underlying Defensive Rage Behavior

Definition and Properties of Stimulation-Induced Defensive Rage Behavior

Prior to an analysis of the neural circuitry governing defensive rage behavior, it is useful to first briefly describe and characterize defensive rage as induced by electrical brain stimulation in the cat. In this species, brain-

stimulation-induced defensive rage behavior (or affective defense) was originally defined operationally primarily in terms of the defensive elements inherent in defensive behavior by earlier investigators. These properties of the behavioral response are highly similar if not identical to the characteristics of defensive rage which were described earlier in this article with respect to feline defensive behavior occurring in nature. They include flattening of the ears, lowering of the body, drawing in of the head, piloerection, hissing, and pupillary dilatation. With the exception of paw striking, which is present following electrical stimulation, other elements of offensive behavior seen in nature are clearly absent in this model. Thus, defensive rage behavior, as applied in the present context as well as by investigators over the past five decades, reflects a behavioral response that is limited primarily to the defensive components of the overall behavioral repertoire. In spite of the absence of the offensive components, this model has been utilized effectively to provide an understanding of the neural mechanisms governing defensive rage which is the principal focus of this article.

In attempting to understand the nature of the neuroanatomical circuits governing defensive aggression, it is useful to distinguish between two classes of neural structures. The first class refers to structures associated with the elicitation of defensive rage and includes, principally, the medial hypothalamus and midbrain PAG. The second class refers to structures from which defensive rage is not elicited; however, these structures produce powerful modulation (i.e., suppression or potentiation) of this form of aggression, and these regions include the limbic system.

Hypothalamus

Efferent connections

Defensive rage behavior is elicited by electrical stimulation along the rostrocaudal extent of the medial preoptico-hypothalamus. The regional sites within the medial hypothalamus which give rise to the long-descending pathways that project to the brainstem are localized within the anterior third of the medial hypothalamus. Other aspects of the medial hypothalamus such as the region of the ventromedial nucleus associated with defensive rage behavior do not project directly to the brainstem but, instead, project rostrally to the anterior hypothalamus. Thus, neurons within the ventromedial nucleus associated with defensive rage behavior can affect other neurons in the brainstem related to defensive rage through a disynaptic pathway, whose initial synapse lies in the anterior medial hypothalamus. The transmitter released onto anterior medial hypothalamic neurons from the ventromedial nucleus is not known but, since the pathway is excitatory, it is likely that glutamate is a good candidate. The primary target of neurons in the

anterior medial hypothalamus that mediates defensive rage behavior is the dorsal aspect of the midbrain PAG. The neurotransmitter released onto dorsal PAG neurons from the anterior medial hypothalamus mediating defensive rage has been shown to be glutamate which acts through *N*-methyl-D-aspartic acid (NMDA) receptors.

Other projections from the medial hypothalamus project back to limbic structures, such as the amygdala, hippocampal formation, septal area, and even prefrontal cortex, and serve as feedback pathways to regions that significantly modulate hypothalamic processes. An additional important connection links the medial and lateral hypothalamus. Both regions are reciprocally connected. In contrast to the defensive rage response elicited from the medial hypothalamus, the lateral hypothalamus is associated with the expression of predatory attack behavior – a response virtually identical to the predatory (hunting) response seen in nature by felines and related species. Both of these neurons are inhibitory and each of the functions is mediated by γ -aminobutyric acid (GABA) acting through GABA_A receptors. One possible and perhaps likely function of this reciprocal connection is suggested here: namely, when one of these responses such as defensive rage is active, it is essential that other (competing) responses such as predatory attack be suppressed in order for the defensive rage response to be most effective. Therefore, the GABAergic projection from the medial to lateral hypothalamus serves this function.

Afferent connections

The primary inputs to the medial hypothalamus originate from the limbic system. Limbic structures possess the unique properties of receiving inputs from secondary or tertiary sensory sources, inputs from reticular formation monoamine neurons, and, as noted above, they project directly or indirectly to the medial hypothalamus. In this manner, activation of any one or more of these limbic structures by their afferent sources could provide output signals that could powerfully modulate processes associated with the medial hypothalamus, which includes defensive rage behavior. Two of the limbic structures whose effects upon defensive rage behavior have been systematically examined include the amygdala and septal area. Analysis of these regions is considered below along with a brief discussion of the anatomical substrates and role of the prefrontal cortex.

Amygdala. The amygdala – situated in the rostral aspect of the temporal lobe – is composed of a complex of nuclei. Several different projections arise from amygdaloid nuclei that project to the hypothalamus or PAG and provide the substrates for modulation of defensive rage.

One pathway – the stria terminalis – arises principally from the medial nucleus of the amygdala and adjoining regions of the basomedial nucleus. The stria terminalis

projects extensively to wide regions of the anterior-half of the medial hypothalamus, including the ventromedial nucleus. This pathway has a potent excitatory effect upon the medial hypothalamus, in particular, with respect to defensive rage. The potency of this pathway is reflected by the observation that electrical stimulation applied directly to this pathway is sufficient to induce defensive rage behavior. This response is presumed to be the result of massive excitation of the ventromedial hypothalamus by the stria terminalis not unlike the effects seen following direct electrical stimulation of this region of hypothalamus. The facilitating effects upon defensive rage behavior are initiated from substance P neurons of the medial amygdala and are mediated through neurokinin-1 (NK₁) receptors in the medial hypothalamus.

A second pathway arises from the central nucleus of amygdala and adjoining portions of the lateral nucleus and principally supplies the dorsal aspect of the midbrain PAG. These neurons are enkephalinergic, act through opioid μ -receptors in the PAG and powerfully suppress defensive rage behavior. In summary, the opposing effects of lesions and ablations of the amygdala, described above, can be understood in terms of the differential modulatory properties of the amygdala upon defensive rage behavior. Two mechanisms are involved, one facilitatory and the other inhibitory. The effects are mediated from two different regions of amygdala; they utilize two different pathways and the neurotransmitters are clearly different and opposite in function.

Septal area and prefrontal cortex. Parts of the medial septal nucleus and adjoining aspects of the lateral septal nucleus project directly to the medial hypothalamus. This pathway also mediates the potentiating effects upon defensive rage behavior of the medial aspect of the septal area. The far lateral aspect of the septal area appears to suppress defensive rage behavior, and the pathway mediating such effects appears to be disynaptic. The first limb of this pathway projects to the lateral hypothalamus and facilitates predatory attack, which is elicited from this region and is thus presumed to be excitatory to neurons in this region. The second limb represents a short, GABAergic (inhibitory) neuron projecting from the lateral to medial hypothalamus, thereby providing the functional anatomical basis for suppression of defensive rage which is elicited from the medial hypothalamus. The neurotransmitter(s) associated with the pathways arising from the septal area which mediate these effects remain unknown.

The prefrontal cortex produces potent suppression of several different forms of aggressive behavior, which include both predation and defensive rage. There are several possible routes by which such suppression may be manifest. One involves a multisynaptic pathway from the prefrontal cortex whose initial link targets the mediodorsal thalamic nucleus; the additional connections involve several short interneurons projecting from the

mediodorsal thalamic nucleus rostrally to the anterior hypothalamus. A second projection involves a monosynaptic pathway from the prefrontal cortex to the hypothalamus involving smaller quantities of axons arising from the prefrontal cortex. A third pathway is also a monosynaptic projection to the dorsal aspect of the PAG typically associated with the expression of defensive rage behavior. In this manner, activation of these routes to the hypothalamus and PAG endows the prefrontal cortex with significant capacity to modulate aggression and rage behavior. Since all major outputs of the cerebral cortex are believed to utilize glutamate as their neurotransmitter, it is presumed that the outputs of the prefrontal cortex likewise utilize this neurotransmitter, which is excitatory upon its target neurons. The neurotransmitters associated with interneurons passing from the mediodorsal thalamic nucleus remain unknown.

Midbrain PAG

Efferent connections

The dorsal PAG constitutes the most caudal region of the neuraxis of the brain where integration of the defensive rage response occurs. The integrated response involves at least two components: somatomotor and autonomic. The somatomotor components reflect descending pathways from the PAG directly to motor nuclei of cranial nerves V and VII, which govern jaw opening and the vocalization component of the defensive rage response. Other downstream projections reach, directly or indirectly, the spinal cord motor nuclei that control movements of the upper limbs essential for striking at a threatening object in the environment. The autonomic component is subserved through descending fibers that supply either, directly, the preganglionic sympathetic neurons situated in the intermediolateral cell column of the thoracic and lumbar spinal cord or, indirectly, through synapses in the solitary nucleus or ventrolateral medulla. In either manner, activation of the dorsal PAG will result in significant increases in blood pressure, heart rate, and pupillary dilatation which are principal autonomic characteristics of this behavior. The outputs from the PAG for the expression of defensive rage are arranged in neuronal pools, especially within the caudal two-thirds of the neuropil, which are neuroanatomically distinct from other pools of neurons in more ventrolateral and caudal levels of the PAG which are associated, instead, with withdrawal or avoidance of a threatening stimulus.

Afferent connections

At least three different sources of input to the PAG relate to its activation pattern for the expression of defensive rage behavior. A primary source, which was described above, is the anterior medial hypothalamus. It projects in dense quantities mainly to the dorsal and lateral aspects

of the PAG. The largest quantities of fibers terminate in the rostral half of the PAG, while some extend further caudally within the neuropil of the PAG. In this context, the PAG may be viewed as a relay nucleus of the descending pathway of the medial hypothalamus for the expression of defensive rage behavior. Consistent with this view is that, as indicated previously, the excitatory effects of descending fibers from the medial hypothalamus upon the PAG are mediated through NMDA receptors and the transmitter is likely glutamate. The arrangement of this circuit would suggest that the initial integration for the expression of defensive rage takes place in the medial hypothalamus rather than the PAG, where afferent sources of the medial hypothalamus, and, in particular, limbic structures, provide the essential inputs for induction of defensive rage behavior, whose expression is then mediated through the PAG.

A second afferent source includes limbic inputs. These include fibers projecting from the central and lateral nuclei of amygdala as well as from the prefrontal cortex. These afferent sources serve as powerful modulators of defensive rage at the level of the PAG. As noted above, a major enkephalinergic input to the PAG is provided from these nuclei of amygdala and provide significant suppression of defensive rage behavior. While the functions of the prefrontal cortex upon the PAG with respect to defensive rage have not been clearly elucidated, it is likely that this pathway is also inhibitory because the prefrontal cortex, itself, suppresses defensive rage behavior. Thus, the contributions of the limbic system in modulating defensive rage behavior are manifest both at the levels of the hypothalamus as well as the PAG. The principal connections involving the hypothalamus, PAG, and limbic structures are depicted in **Figure 1**.

The third significant afferent source includes fibers such as those contained in the spinothalamic tracts that mediate both tactile and noxious (pain) sensory information. It is well known that collaterals of these tracts supply the PAG. These stimuli may activate neurons in the PAG subserving defensive rage and, accordingly, thus serve to evoke defensive patterns. Such a phenomenon would be particularly true with respect to noxious stimulation, which, when applied to a cat, will evoke a marked defensive reaction that typically includes hissing.

Neurochemical Mechanisms within the Hypothalamus and PAG

Neurotransmitters, Neuromodulators, and Receptors

Both excitatory and inhibitory neurotransmitters in the hypothalamus and PAG play important roles in the regulation of defensive rage behavior. Some of these neurotransmitters have been identified with respect to

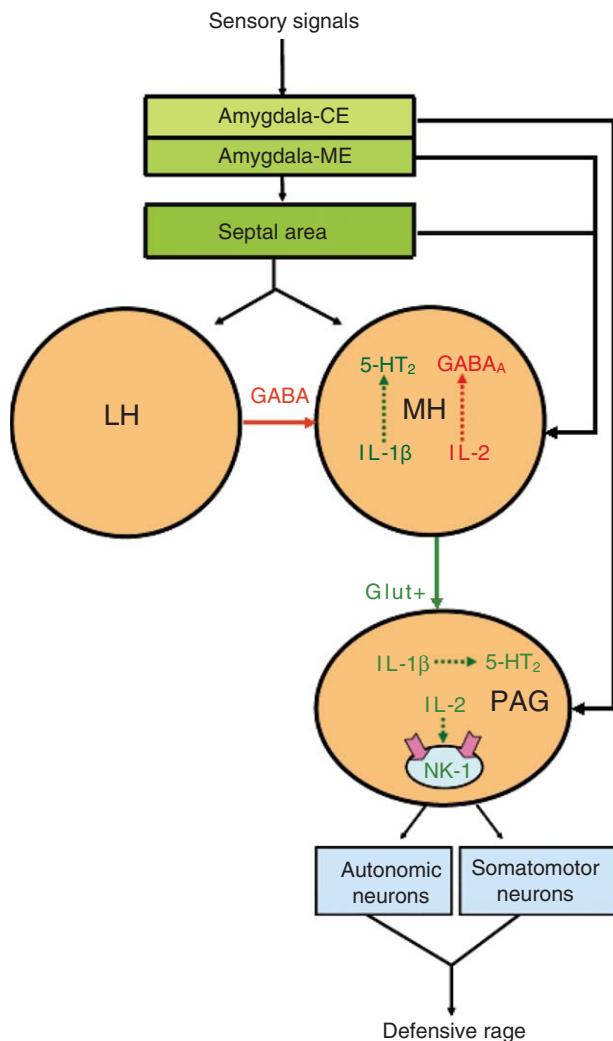

Figure 1 Schematic diagram depicting critical neural relationships and mechanisms involving several limbic structures, the hypothalamus, and the midbrain periaqueductal gray (PAG). Changes in levels of excitability within the septal area and amygdala affect excitability levels and functions of the medial hypothalamus and PAG, which include defensive rage behavior. The expression of defensive rage behavior is mediated through neurons in the medial hypothalamus and a descending glutamatergic pathway to the midbrain PAG. The PAG represents the lowest region of the neuraxis of the central nervous system at which integration of the autonomic and somatomotor components of defensive rage behavior occurs. GABAergic neurons from the lateral to medial hypothalamus provide a major source of inhibition upon defensive rage from a neighboring region of hypothalamus. Also shown in this diagram is the role of several proinflammatory cytokines, IL-1 and IL-2. IL-1 in the medial hypothalamus and PAG facilitate defensive rage and act through 5-HT₂ receptors in both regions. IL-2 in the medial hypothalamus suppresses defensive rage and its functions are mediated through GABA_A receptors. In contrast, IL-2 in the PAG facilitates defensive rage behavior by acting through substance P-NK₁ receptors in the PAG. 5-HT = serotonin; CE = central nucleus of amygdala; GABA = γ -aminobutyric acid; IL = interleukin; LH = lateral hypothalamus; ME = medial amygdala; MH = medial hypothalamus; NK₁ = neurokinin-1.

specific neuronal pathways while others have not. The discussion below (and **Table 1**) summarizes the modulating effects of these neurotransmitters and their receptors upon defensive rage behavior.

Excitatory neurotransmitters and their receptors

Neurotransmitters that have been shown to facilitate defensive rage behavior include acetylcholine, dopamine, norepinephrine, serotonin (acting through 5-HT₂) receptors, glutamate, and the neuropeptides, vasopressin, cholecystokinin, and substance P.

Cholinergic agents, administered systemically, facilitate aggressive responses acting through muscarinic receptors. Moreover, when microinjected directly into the medial hypothalamus, cholinergic agents can induce rage behavior. Norepinephrine and dopamine have similar effects upon defensive rage. The cholinergic pathways over which facilitation is mediated have not been identified. It is quite possible that the pathways involved include local interneurons within the hypothalamus.

Noradrenergic neurons, situated mainly in the locus ceruleus, project widely to the forebrain, including the

Table 1 Effects of neurotransmitters, receptors and cytokines upon defensive rage

<i>Compound</i>	<i>Receptor + anatomical locus</i>	<i>Effect</i>
<i>Monoamines</i>		
Dopamine	D-2, medial hypothalamus	↑
Norepinephrine	Alpha-2, medial hypothalamus	↑
Serotonin	5-HT _{1A} , medial hypothalamus	↓
Serotonin	5-HT ₂ , medial hypothalamus	↑
<i>Amino acids</i>		
Glutamate	NMDA, dorsal PAG	↑
GABA	GABA _A , medial hypothalamus, PAG	↓
<i>Peptides and other classes</i>		
Substance P	NK-1, medial hypothalamus, PAG	↑
Cholecystokinin	CCK-B, PAG	↑
Enkephalin	Opioid- μ , dorsal PAG	↓
Vasopressin	Vasopressin-1A, medial hypothalamus	↑
Acetylcholine	Muscarinic, medial hypothalamus	↑
<i>Pro-inflammatory cytokines</i>		
Interleukin 1	IL-1 + 5-HT ₂ , medial hypothalamus, dorsal PAG	↑
Interleukin 2	IL-2 + GABA _A , medial hypothalamus	↓
Interleukin 2	IL-2 + NK-1, dorsal PAG	↑

Key: ↑, facilitation; ↓, suppression.

hypothalamus. Norepinephrine, acting through α_2 -receptors in the anterior medial hypothalamus, potentiates defensive rage behavior. Likewise, similar functions are mediated by dopamine, arising from the ventral tegmental area, and acting through dopamine D₂ receptors in the same region of the anterior medial hypothalamus. Thus, the catecholaminergic pathways supplying the medial hypothalamus serve a general activating or potentiating function with respect to aggressive behavior. The effects of serotonin differ from catecholamines in that their functions differ in opposite ways, depending upon the receptors through which they act. Serotonin neurons arise from raphe neurons, mainly of the pons and midbrain, and project widely throughout the brain, including the hypothalamus and midbrain PAG. Serotonin, acting through 5-HT₂ receptors in both the hypothalamus and PAG, has been shown to facilitate defensive rage behavior.

Several excitatory neurotransmitters acting at the level of the anterior medial hypothalamus include substance P, which arises from the medial amygdala, (as discussed earlier in this article) and vasopressin, acting through V₁

receptors. While the pathway mediating the excitatory effects of substance P reaches the medial hypothalamus through the stria terminalis, the pathway mediating vasopressin remains unknown.

As noted earlier in this article, the principal descending pathway mediating defensive rage behavior from the hypothalamus arises from the anteriomedial hypothalamus and targets the dorsal PAG. The neurotransmitter released from these neurons is glutamate and their excitatory functions of this pathway are mediated through NMDA receptors in the dorsal PAG. Several peptides, which could either function as neurotransmitters or neuromodulators, also facilitate defensive rage behavior within the dorsal PAG. These include substance P, and cholecystokinin (acting through CCK_B receptors). The pathways associated with these peptides have not been identified.

Inhibitory neurotransmitters and receptors

There are at least three different neurotransmitters that suppress defensive rage behavior. Serotonin, acting through 5-HT_{1A} receptors both in the medial hypothalamus and dorsal PAG, produces powerful suppression of defensive rage behavior. Likewise, enkephalin, whose origin is the central and lateral amygdaloid nuclei, project directly to the dorsal PAG and its powerful suppressive effects are mediated through μ -opioid receptors in the PAG. GABA neurons are found throughout much of the central nervous system (CNS) and, within both the medial hypothalamus and PAG, act through GABA_A postsynaptic receptors to suppress defensive rage behavior. While the GABAergic pathway within the hypothalamus has been identified as a short neuron projecting from the lateral to medial hypothalamus, the origin of the GABAergic pathway within the PAG remains unknown. However, it is suggested that GABA is mediated through a local interneuron within the PAG.

Role of Cytokines

Cytokines may be defined as pleiotropic cell-to-cell-signaling proteins or glycoproteins that are produced by different cell types in the periphery and the brain. While cytokines have typically been studied for the effects on immunity, their relationship to other processes such as development, feeding, and sleep has been described. Cytokines exert their effects by binding to receptors, which may then be followed by the activation of signaling pathways. Cytokines can affect functions of the brain by several routes. Cytokines formed in the periphery may enter the brain through several routes. One involves the blood-brain barrier; and a second may involve entrance to the brain through circumventricular organs or sensory afferents. Cytokine release can also be stimulated by brain endothelial cells and produced by glial and neuronal cells. The discussion below describes

the results of recent studies indicating how cytokines within regions associated with the expression of defensive rage behavior can act as neuromodulators to regulate this form of aggressive behavior.

Evidence of a possible relationship between changes in cytokine levels and aggression has been suggested from studies conducted in the human. A population of normal, healthy adults who were subjected to an enhancement of proinflammatory cytokines displayed elevated hostility scores and, consistent with these findings, a positive correlation was observed between the presence of hostile marital conflict and increased production of plasma proinflammatory cytokines. Moreover, patients with hepatitis C who have been treated with cytokine immunotherapy displayed higher than normal levels of aggression as determined by measures of hostility, anger, and hostility.

Recently, a series of studies have revealed that cytokine-receptor activation within the medial hypothalamus or PAG can powerfully modulate defensive rage behavior in the cat. Activation of interleukin (IL)-1 β receptors in either the medial hypothalamus or dorsal PAG at sites from which defensive rage could be elicited potentiates defensive rage behavior. Further studies revealed that the potentiating effects of IL-1 β are mediated through 5-HT₂ receptors. In contrast, activation of IL-2 receptors in the medial hypothalamus suppresses defensive rage behavior. However, activation of the IL-2 receptors in the dorsal PAG, instead, facilitates defensive rage behavior. The suppressive effects of IL-2 are mediated through GABA_A postsynaptic receptors in the medial hypothalamus, while the facilitating effects of IL-2 in the PAG are mediated through substance P-NK₁ receptors. It is suggested that the difference in effects seen with IL-2 in these two regions can be accounted for in the following manner: in the medial hypothalamus, the epsilon (ϵ) subunit of the GABA_A receptor is absent, which is not the case with respect to the GABA_A receptor in the PAG. In order for GABA to be effective, the ϵ subunit of the GABA_A receptor must be lacking. These findings indicate the following: (1) that activation of cytokine receptors within the CNS significantly modulates defensive rage behavior; (2) that the modulating effects of cytokines are mediated through classical neurotransmitter systems; and (3) the effects of cytokines may possess regional specificity. The effects of cytokines upon

defensive rage within the hypothalamus and PAG are shown in **Figure 1**.

Glossary

Associative learning – A form of learning where an individual learns by temporal or spatial contiguity that two events are related. The association may be further reinforced and enhances future learning experiences by generalization to categories of events that share relevant characteristics with the initial one.

Causal agent – Any entity that produces an effect or is responsible for events or results.

Causal knowledge – A weak causal knowledge refers to a knowledge acquired from associative learning after an individual has been repeatedly exposed to a spatial or temporal contiguity between two events. A strong causal knowledge refers to an immediate or rapid interpretation of how events may relate to each other.

Causal reasoning – Reasoning is the cognitive process by which an individual draws conclusions, makes decisions, or forms judgments based on experiences, events, and observations. When strong causal knowledge emerges from understanding and allows flexible responses to novel contingencies, it becomes causal reasoning.

Inferential reasoning – The process of deriving the logical consequences of assumed premises or the process of arriving at some conclusion that – though it is not logically derivable from the assumed premises – possesses some degree of probability relative to premises.

challenging. When an animal solves a problem, the question is to know whether the animal's response is the outcome of a blind associative learning process, or if the animal recognized certain properties of the relationships between a stimulus and an event, and consequently formulated abstract categories and representations from these associations. In the first case, the animal relies on repeated associations between two events to direct its behavior, which may lead to weak causal knowledge. In the second case, the animal understands how events are related to each other, builds mental representations, and therefore may reason about elements and make inferences on the forces involved. This would be considered as a stronger causal understanding and does not need repeated exposures to the association.

To detect whether animals can reason beyond associative learning, several approaches have been proposed: animals may infer – from observable or unobservable elements – the solution of a problem, they may rely on reasoning to foresee what is to come and prepare their action accordingly, they may build their own hypotheses on what physical forces caused an effect, and they may reason about other individuals from their social world.

Inferential Reasoning

Transitive Inference

Many species are known to be able to match a stimulus with a given reaction. Temporal or spatial proximity between events act as powerful re-enforcers in associative learning. There are reports to support the view that most animals may only solve a task through associative learning and fail to show strong causal understanding of their environment. An approach to explore the reasoning skills of animals has consisted of testing responses of animals during 'transitive inference tasks.' In these tasks, animals first learn the association between a pair of elements. They are then asked to reason about this knowledge and to infer the relative position of pairs compared to each other. In logic, if A is superior to B and B is superior to C, then A is superior to C. Most species – rats, pigeons, crows, New and Old World monkeys, and great apes – have been shown to succeed in transitive inference tasks. In a recent review, a meta-analysis was conducted on responses of animals in inference tasks and different models were created to understand performances of different species. The most robust models – accounting for the

Introduction

In the eighteenth century, the Scottish philosopher Hume concluded that it was vain to search for proof of causality in the universe. Reflecting on causal knowledge, Hume suggested that we can only perceive conjunctions of events. Whatever comprehension we may have of the mechanisms that govern our life, we will never know for certain that our understanding is nothing more than assumptions. Despite this, human beings seek observable or nonobservable explanations for effects, even though they may never prove causal relationships. In nonhuman animals – where the lack of spoken language prevents direct exploring of causal reasoning – assessing what animals understand from their environment remains

performances of most species – were not the cognitive models (inferences via logical reasoning) but were instead reinforcement-based models where associative-learning rules were implemented. It would seem that – by weighing the relative strengths of the learned association against each other – animals could solve transitive inference tasks without calling upon stronger causal knowledge.

Inference by Exclusion

The capacity of animals to infer one element from the presence of another has limits since it may be strongly biased by associative learning. Inferring one solution by using the absence of an element is a more cognitively demanding task, as it requires reasoning about a missing stimulus or event. Vervet monkeys do not infer from a carcass in a tree that a leopard may be close by, and traces left by a snake do not elicit fear responses such as alarm calls in them. One could argue that animals failed to link an observed consequence (the trace) to its causal agent (the snake), but another interpretation would be to consider predatory traces as a poor signal for predatory activity: such traces may be abundant in the wild, preventing potential preys from building strong, accurate, temporal, or even spatial associations between these traces and predators. To explore the extent to which animals might reason about invisible or missing elements, researchers have used approaches based on ‘inference by exclusion’ tasks. In these tasks, animals are given only partial knowledge of where a food reward may be hidden. It is the lack of expected information that cues the animals into choosing an alternative correct option. One version of the task is to detect whether subjects can retrieve the location of a hidden food among two by using the absence of visual cues. Between two boxes A and B, an experimenter displays the content of box A, – the empty one. To solve the task, the subject needs to infer that if A is empty, then B is the box that contains the reward. Another variant is to infer from the lack of auditory cues the position of the reward (**Figure 1(a)**). An experimenter shakes the empty box B, which produces no sound. Subjects need to infer from the lack of sound in box B, that box A contains the reward. These investigations have shown that some animals were inferring the location of the food by exclusion: if not B then A – a process that cannot be solved by associative learning is set up where animals are exposed to a limited number of trials. This line of research has been initially investigated in great apes. Most species of great apes successfully solve these tasks, thereby reasoning about missing information. Other primate species like brown capuchin monkeys show similar responses as well as dogs and to some extent pigeons. This may not be so surprising since some researchers have suggested that animals need to mentally represent food-items hidden inside shells, tree trunks, or piles of leaves,

as they search for them. In fact, this was specifically demonstrated in an experiment with capuchin monkeys, where the monkeys were able to discriminate between an empty nut and a full one based on their weights and the sound produced when shaken. These types of experiments support the idea that animals, in general, can reason about something they do not visually or acoustically perceive.

Inference from the Integration of Multiple Factors

Inferring a correct response by reasoning upon unobserved cues is a capacity that may prove valuable in a species whose access to resources depends on conditions that render the distribution of feeding resources difficult to predict. Foraging behavior has long been assumed to be a random process – based mainly on the shortest route between trees known to potentially bear fruits. Recent studies suggest far more elaborate foraging strategies, for example, primates memorize a network of routes within their home range using landmarks and possibly mental maps of their environment. They are able to modify their foraging route when it becomes inaccessible and use shortcuts. They remember trees they exploited during previous seasons and are capable of generalizing the search to other trees of the same species, which are sometimes not visible from the initial discovery position. In a typical foraging activity, they may have to decide between traveling to a nearby feeding site that may be reduced in size, or, traveling to a distant one that may provide a larger amount of resources. Several decision-making processes may be at stake when foraging and primates might choose their next course of action by reasoning about multiple elements that are not directly visible. When fruits reach maturity, they provide abundant supply but for a limited amount of time. The maturity of fruits may be ruled by seasonal variations but also by less predictable factors, such as local weather conditions. Making accurate predictions about when food will be ready to eat is therefore challenging. Mangabeys from the Kibale forest (Uganda) have been shown to choose the trees they would exploit before even seeing or smelling them. They anticipated the maturational state of the fruits on the trees they visited – a process that could be based on their experience from earlier visits. In addition, they visited and returned more frequently to the trees they knew to be matured, when the sun had been shining (favoring additional maturity of fruits) compared to the days where weather had been fresh or covered. A complete understanding on how weather affects fruits’ maturity is probably not what drove the mangabeys toward the most interesting trees. They may have learned instead that warm-weather periods are associated with faster renewing of food at the feeding sites. In this regard

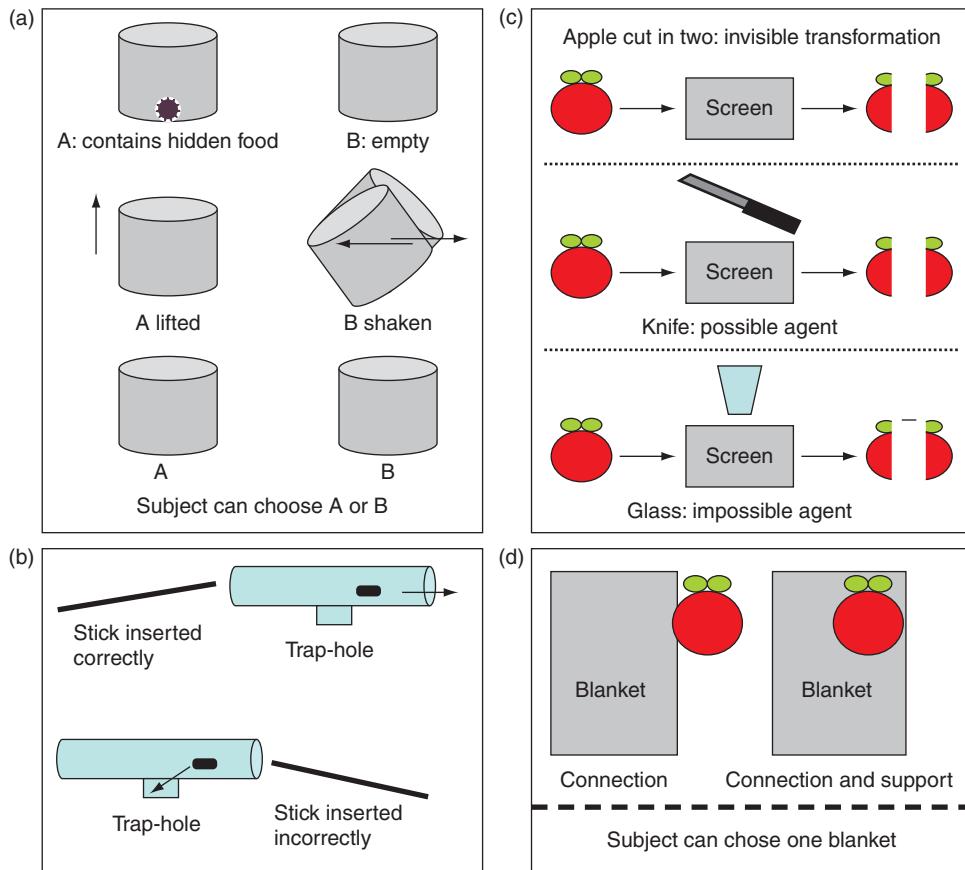

Figure 1 (a) Inference by exclusion. First, the experimenter hides a reward in box A, out of sight. In front of the subject, the experimenter shakes box B (no noise) and lifts box A without shaking it (no noise). The subject can then choose either box A or B. To succeed, the subject needs to infer that the reward is in box A, since no noise was produced when box B was shaken. (b) Trap-tube task. A reward is available if pushed out of the tube with a stick (correct action). However, it can fall into the trap-hole if pushed from the wrong side (incorrect action). Subjects have to foresee the result of the action of the stick on the reward to obtain it. (c) Recognizing causal agents. The experimenter shows an apple before hiding it behind a screen. Then, two halves of an apple are revealed from behind the screen. Objects are then shown to subjects, also from behind the screen: a possible agent of the transformation (knife) or an impossible agent (glass of water). The looking duration toward both possible and impossible agents is recorded. (d) Understanding the role of unobservable forces: Subjects can choose to retrieve one blanket among two. In one case, an apple is left on the blanket and can be retrieved by pulling the blanket. In the other case, an apple is left in contact with the blanket but cannot be retrieved by pulling the blanket. Subjects fail to differentiate between both options and choose equally often the option where the blanket provides connection and support, and the option where it provides only connection.

reasoning is still necessary, since decision making was achieved by weighing different possible options and inferring the best-fruit location, a process that could only rely on mental representations encompassing flexible and complex properties of the environment.

Anticipating Results or Consequences

Reasoning in Relation to Time

Solving problems by relying on anticipatory skills is one of the most recently studied topics in animal reasoning. Individuals may need to reason about missing elements in relation to time – that is, when the solution to a problem is missing now but may be available later. In one study,

orangutans and bonobos were first trained to use a hook to reach for a bottle of juice placed out of their compartment. On following days, individuals were given temporary access to the hooks, but not to the bottles. They were then invited to leave the room and come back 1 h later on the same day. On their return, the bottles were available, but the hooks had all disappeared. To solve the task, individuals had to first collect the hooks before leaving the room, and bring them back later, once the bottles would be set up. In both species, some individuals, but not all, successfully solved that task. In addition, some succeeded with a time interval of one night between the time of collection and return in the bottle room. Experiments with orangutans and chimpanzees have shown similar results for temporal reasoning applying

tool-use tasks. Such planning capacities require reasoning on the mental representation of a need yet to come. Indeed, in most of those studies, researchers controlled the variables such that at the time where subjects had to collect the tools, nothing in their environment could remind them of what would come later on, preventing associative learning from driving the correct behavior. Reasoning in relation to time is also seen in birds. Under experimental conditions, scrub jays are able to adapt their current behavior to solve future tasks. In a particular study, birds flexibly solved planning tasks, relying on anticipatory skills as opposed to hardwired responses. Solving such a task seems possible only if animals use mental representations of what is about to happen; they have to adapt their behavior despite the fact that there is no immediate reason for it. Great apes along with some bird species (corvids) show some similarity with the human in their ability to project future events and organize their responses with regard to future needs.

Foreseeing the Course of Action in Tool Use

Other studies on causal reasoning have addressed animals' understanding more directly of how a present behavior may have future consequences on performances in a task. To do so, these studies have used tool-use-related tasks where animals need to foresee the result of their action on the tool to obtain a reward. One example is the trap-tube task (**Figure 1(b)**), where an animal needs to use a stick to push or pull a reward out of a tube. The tube has an inaccessible compartment, or 'trap,' in the middle of it into which food can fall. The experiment is designed in a way that if the subject does not foresee the correct extractive technique, the reward is lost as it falls into the inaccessible compartment (trap-hole) during the process. Subjects have to insert the stick in the correct side of the tube in order to successfully push the reward outside. Capuchin monkeys generally perform at chance level in this task. One individual was reported to further learn to insert the stick in the hole that was the farthest possible from the reward, suggesting associative learning on how to solve the task, rather than an understanding of causal properties of the relation among the stick, the reward, and the trap-hole. Chimpanzees tested in a similar task succeeded without using the associative rules observed in capuchins, and seemed to accurately anticipate the results of their action on the tool. This may also indicate that they understood better than other primates the role of the tool that could cause either a success or a failure in retrieving the reward. Tests using variants of the trap-tube task have been designed to allow testing of animals that do not usually use tools like rooks. A variation on the trap-tube task was developed with two traps-holes and an inner-pulling system that does not require the insertion of a stick. The task still requires the subjects to foresee the

course of their action and choose from what side to pull in order to retrieve the reward. In this condition, rooks could solve the problem, but no evidence was found that they did so by understanding the causal properties of the task like great apes did.

Understanding Causes

Recognizing Causal Agents

More work has been conducted to explore whether animals recognize the causal agent of a transformation – the tool. Understanding of the causal role of a tool was tested in rhesus macaques. The study consisted in showing an apple before hiding it behind a screen, out of view of the subject (**Figure 1(c)**). The screen was then removed revealing two half apples. The experimenter then took a knife from behind the screen and showed it to the subjects. This computed into a possible transformation – an apple might be divided into two parts under the action of a knife. In additional trials, the experimenter showed impossible transformations, for example, a glass of water was shown to the subject instead of a knife, or two half apples were first hidden behind a screen, and an entire apple was shown afterwards. A comparison between the duration of observation for possible or impossible transformation indicated that macaques looked longer at impossible transformations. The authors interpreted this response as an illustration of the conflict between what macaques expected and what they discovered. This study replicates comparable results previously obtained in experiments with chimpanzees. Rhesus macaques, unlike chimpanzees, are not known for their tool-use abilities; therefore, it is particularly interesting to find evidence for understanding tool-use tasks in this species. Macaques may have recognized the causal role between the knife and the apple by seeing keepers using them – a knowledge not acquired by experiencing the action of the knife themselves. For some researchers, understanding the source of a noise or that a knife is a causal agent reflects causal understanding. Other researchers contest that view. When rhesus macaques identify a knife as a possible causal agent, they would 'only' predict the result of the association (an apple cut in two); there is no proof that any conceptualization of the action itself occurred. For example, they may not understand that the knife works because of a sharpened edge, or because it is held and controlled by a human. The subject does not need to make assumptions about the forces at work to solve the problem.

Explaining and Making Hypothesis

The controversy remains with regard to the animals' capacity to explain how elements are related to each other or why. There is general agreement that animals

can identify the correct solution by reasoning on observable facts – whether visible or momentarily invisible. Animals seem capable of understanding that elements are related to each other; they may also understand that the relationship can have sequential properties – like the fact that one event always precedes another one, or that if a certain element is observed it must have been preceded by another. Therefore, they produce the correct conclusions and anticipate the course of an action accurately. However, it could be that animals cannot conceive the physical forces and theoretical entities which causal explanations rely on. Not all forces responsible for observational events are visible themselves. One of the limits animals encounter is in the understanding that unobservable forces (e.g., gravity) play a causal role. The previously described ‘inference by exclusion’ task is informative in this respect. In such a task the absence of sound when a box is shaken can be used to infer that the alternative box is baited. Different levels of understanding could underlie reasoning processes. First, the correct solution may be reached by reasoning on a well-known association: sound equals presence of food in a container. If there is no sound in box A, then there is no food in box A, thus choose box B. The subjects here infer from the absence of an otherwise ‘observable’ force: the sound. Second, based on their experience that noise always precedes food, animals could also wrongly consider the noise as a causal agent: noise makes food, if there is no noise, then there is no food, thus choose other box. This would be an incorrect assumption but it would still mean success in the response to the task. Third, animals could consider food as a causal agent for the noise and then infer: a food in a box makes noise when shaken, if the box is shaken and makes no noise, then, there is no food and the alternative box should be chosen. Lastly, animals could consider an unobservable force like solidity as the causal agent: both food and boxes are solid elements so that food makes a noise when it hits the inside of the box. If no noise is produced when the box is shaken, there is no food in that box so choose the alternative one. Whatever their level of understanding, apes found the correct box by reasoning about the clues given and made the correct inference. But whether they did so by using the most accurate explanation, the one calling upon solidity, is still open to debate.

For some researchers, proving causal understanding in animals would ultimately consist in showing that they understand that an intermediary nonobservable force mediates the result of an association. In the human, this is referred to as Folk Physics which is defined by Daniel Povinelli as “the kind of understanding of the physical world that develops naturally and spontaneously during the development of human infants and children and later permeates the adult conception of why the world works the way it does.” Researchers have studied the extent to which chimpanzees understood something about physical

laws such as gravity, solidity, or force transmission. For example, chimpanzees do not distinguish between physical contact and necessary connections to make different parts of a tool functional. If chimpanzees have to pull a blanket toward them to obtain an apple, they do not differentiate between the condition where the apple is indeed on the blanket (**Figure 1(d)**), and the condition where the apple is left in contact, but not directly on the blanket. The fact that animals can reason from missing elements does not necessarily prove that they may have a concept of the physical forces at stake. Conceiving an explanation requires more than simply representing what is missing. These studies emphasize the need to distinguish between what is not observed and what is not observable. As put by Daniel Povinelli, “Humans alone think about such things as God, ghosts, gravity and other minds. Animals do not form concepts that refer to merely hypothetical things.” This means also that despite a capacity to represent events from their observable properties and to extrapolate rules from these representations, animals cannot “posit unobservable properties or processes” as mediating variables to explain or to predict observable events or states. Such limitations would also apply toward the social worlds of animals. Animals seem to have representations about the observable properties of their social world, but may not be capable of reasoning about unobservable forces.

Conclusion

The question of how animals reason about their social world was first addressed in the late 1960s by scientists. When people observed that monkeys form coalitions by recruiting support against a third party, they assumed that animals understand something of the relationship between partners and the way they can be manipulated to produce a desired result. Reports about deception also suggested that animals may solve social problems using reasoning. For example, after a fight a chimpanzee would produce an appeasing gesture known to lead the former opponent to approach with peaceful intentions. The chimpanzee producing the gesture would then renew aggression once the former opponent had come close enough. Applying a friendly behavior in a competitive situation may have been a goal-oriented tactic. This would reflect an understanding of others’ mental states, knowledge, or belief. Nonetheless, this behavior might also arise from a single learning process, that is, each time I hold out my hand, my opponent comes closer, where I can attack again. Experimental studies show that most animals possess the skills needed to anticipate others’ behavior, but failing to solve tasks requiring them to attribute mental states to others. As stated by some researchers, cases supporting causal understanding must provide evidence that animals

used previous knowledge and acted in an apparently unrelated way to produce a desire outcome. In most studies assessing social understanding, however, experiments do not succeed into separating causal understanding and potential use of associative learning when solving a problem. When evidences of reasoning about the social world are found, they suggest that reasoning is based on what partners do – observable element – rather than on what partners think – unobservable element. Even if great apes may attribute intention to others, they may not have our ability to infer multiple psychological dimensions. Beliefs and desires play a causal role in behaviors. They are, to the same extent as physical forces, unobservable forces. If they cannot clearly distinguish between thinking, believing, or wanting, primates may not distinguish the causal succession of unobservable thoughts leading to a specific action.

Glossary

Environmental model – A simulation model in which one or more environmental challenges are given to the animal that play (or are hypothesized to play) a role in the human disease.

False negative – A drug which acts like the gold standard in the human condition, but not in the animal model.

False positive – A drug which acts like the gold standard in the animal model, but not in the human condition.

Genetic model – A simulation model in which one or more genes that play a role (or are hypothesized to play a role) in human disease are altered.

Gold standard – In animal models, a gold standard is the clinically successful drug with which all other compounds are compared.

Screening model – An animal model in which the efficacy of an unknown compound is compared to a clinically successful drug.

Simulation model – A model in which certain aspects of a human disease are modeled in an animal species.

in all domains of cognition, schizophrenic patients show more severe impairment in attention, verbal and visual learning, working memory, and executive functioning.

Although schizophrenia is usually diagnosed for the first time between the ages of 18 and 30, several signs and symptoms can already be seen at a much earlier age. Several prospective studies in different countries have shown that, as a group, children that later go on to develop schizophrenia are slower in reaching developmental milestones, such as sitting, walking, or talking for the first time. Together with many other pieces of evidence, this has led most researchers to conclude that schizophrenia has a developmental component.

The etiology of schizophrenia or what causes this disturbance in neurodevelopment is still largely unknown. Family, twin, and adoption studies have clearly shown that genetic factors play a major role in the development of schizophrenia, but concordance rates of about 50% in monozygotic twins is clear evidence that nongenetic factors are also involved. Moreover, although many genetic studies, including large-scale genome-wide scans, have been undertaken, no crucial gene has so far emerged. Although, theoretically, such a gene might still be identified in the future, it seems more likely that several genes contribute to the overall illness. In addition, schizophrenia is certainly a heterogeneous disorder with multiple causes. Nonetheless, some candidate genes have been identified in more than one study. These will be discussed later on in this article. In addition to identifying the gene(s) involved in the development of schizophrenia, much research is also devoted to identifying the nongenetic, environmental factors. This is even more difficult to assess, since it usually involves retrospective interviews, and environmental factors are usually less clearly circumscribed. However, although the nature of the environmental factors is less clear, studies have shown that there are at least two critical periods in which environmental factors may have a major influence on the development of schizophrenia, namely, the perinatal and

Schizophrenia is a severe mental disturbance which afflicts approximately 1% of the population. Patients typically develop schizophrenic symptoms around or after puberty and the symptoms are generally classified into three different categories. Positive symptoms refer to signs and symptoms that are not normally seen in healthy individuals but are produced as a result of the disease, and encompass hallucinations (most often auditory) and delusions (such as paranoid ideation or feelings of being controlled). Negative symptoms, on the other hand, are signs and symptoms that are normally present in healthy individuals but are absent or significantly reduced in patients and encompass social isolation, anhedonia, and apathy. Finally, patients with schizophrenia often show cognitive symptoms. Although they are generally impaired

the (pre)pubertal period. Major life events during these periods increase the likelihood of developing schizophrenia, especially in genetically high-risk individuals, underlining the now well-accepted idea that most major (psychiatric) disorders result from an interaction between genetic and environmental factors. This interaction will be discussed in more detail later on in this article.

Patients with schizophrenia are generally treated with antipsychotic drugs often in combination with certain forms of psychotherapy. Although psychotherapy by itself is usually not very effective, the combination of both forms of therapy has been proven to be more effective than either alone. Antipsychotic drugs belong to a large variety of chemical classes and are often subdivided into classical and atypical antipsychotic drugs. All antipsychotic drugs reduce the positive symptoms but most of them do not have a major influence on either the negative or the cognitive symptoms. Classical antipsychotic drugs, with prototypes such as haloperidol and chlorpromazine, induce major neurological (so-called extrapyramidal) side effects including parkinsonism, akathisia, dystonia, and (tardive) dyskinesia. Atypical antipsychotic drugs, including clozapine, olanzapine, and quetiapine, on the other hand, have been thought to induce much less extrapyramidal side effects. However, recent nationwide studies in the UK and the USA have questioned this. Indeed, a large study in the USA (>1400 patients) was unable to show a major therapeutic advantage of any of the tested atypical antipsychotic drugs over a classical antipsychotic. In this respect, it should be emphasized that clozapine was not included in this study. When the nonresponsive patients were subsequently treated with clozapine, a significant improvement was seen in a large proportion. It would be beyond the scope of this article to discuss the possible reasons for the lack of differentiation between classical and atypical antipsychotic drugs. However, it is a well-known fact that the incidence of side effects depends, to a large degree, on the dose used and there is evidence that previous studies used relatively high doses of, especially, the classical antipsychotic drugs.

Animal Models

Introduction

The development of an animal model for any disease usually starts with a detailed analysis of the symptomatology of the illness as well as an investigation into the pathology and/or etiology of the disease. Once the etiology or pathology of the disease is known, one tries to mimic this in animals and looks for similar symptoms. Such an approach has been quite successful for several neurological disorders such as Huntington's chorea and Parkinson's disease, but is much more difficult for

psychiatric disorders, including schizophrenia, for several reasons.

The symptoms of schizophrenia, with the exception of the cognitive deficits, can only be assessed through a psychiatric interview, making the modeling in animals impossible. In addition, none of the symptoms of schizophrenia is pathognomonic, and all of them can occur in other diseases as well. This implies that a good animal model for schizophrenia should always include more than one symptom, preferably as many as possible.

Another important hurdle in the development of animal models for schizophrenia is the lack of knowledge about the pathology and etiology. Although many studies have investigated the pathological changes seen in the brains of patients with schizophrenia, as with the genetic studies, no clear picture has so far emerged. This again may in part be due to the heterogeneous nature of the disorder, but also indicates that schizophrenia does not result from large structural deficits in one or a few neuronal structures. Indeed, most researches now consider schizophrenia as a disorder of connectivity, thus emphasizing a disturbance in communication between neuronal structures, rather than a localized deficit in one specific brain region. Although such deficits are more difficult to assess, they may have much more widespread functional consequences and might account for the plethora of signs and symptoms.

As with the pathology, little is known about the etiological factors, save that genetic and environmental factors interact, as discussed earlier. This implies that most of the animal models focusing on the etiology are based on a hypothesis rather than on facts. This does not necessarily mean that the animal models are not valid; however, it should be kept in mind when evaluating such models.

Given the relative paucity of hard findings about the etiology and pathology, many researchers have tried to develop alternative models for identifying novel therapeutic agents. Many of these are based on the effects of acute or subchronic administration of psychotomimetic drugs such as amphetamine or phencyclidine. Alternatively, models which are more based on the effects of known antipsychotic drugs, and less on the diseases itself are often employed, especially in the search for novel drugs. These models, often referred to as screening models, will be discussed here briefly, though one can argue whether they really belong to the category of animal models for schizophrenia.

Screening Model

Screening models, also sometimes referred to as animal models with pharmacological isomorphism or with predictive validity, have played a major role in the development of antipsychotic drugs. Indeed, virtually all

antipsychotic drugs currently on the market have been identified using such models. This also explains why the current antipsychotic drugs are all very similar in mechanism of action and therapeutic efficacy (see above).

The development of a screening model usually starts with the (behavioral) effects of a drug with a known clinical profile, the so-called gold standard. In the case of screening models for the treatment of schizophrenia, the gold standard is usually chlorpromazine or haloperidol. In light of the already discussed clinical differences between haloperidol and clozapine, some screening models are based on both haloperidol and clozapine. This gold standard is then given to a rat or mouse, usually a normal, healthy animal and a specific behavior is investigated. This can be a spontaneous or a learned behavior. In some cases, the effects of the gold standard are evaluated on drug-induced behavior. In these latter cases, the distinction between screening models and simulation models becomes less obvious. There is evidence that dopamine hyperactivity and/or glutamate hypoactivity, in part, underlie the symptomatology of schizophrenia. Moreover, schizophrenic patients suffer from stereotyped behavior, deficits in prepulse inhibition and there is even some indication that they have an increased motor activity. Thus, it becomes somewhat arbitrary whether such models are simulation or screening models. However, since we discuss simulation models, especially from the point of etiological similarities, we decided to include these drug-induced models in the category of screening models. **Table 1** gives an overview of the most relevant screening models.

Once the effects of the gold standard are established, the screening model has to be validated. This is the most crucial step in the process of building any animal model, though it often does not receive the attention it deserves. The criteria for validating screening models are directly derived from clinical studies and include the occurrence of false positives (i.e., a drug behaves like the gold standard in the model, but not in the clinic) and false negatives (i.e., a

drug behaves like the gold standard in the clinic but not in the model). Although these two criteria seem to be relatively straightforward, they are nonetheless difficult to evaluate, especially the (non-) existence of false positives. First of all, it is impossible to test all the existing drugs, not used for the treatment of schizophrenia, in a screening model. However, it is even more problematic to answer the question whether all the drugs tested positive in a screening model are true or false positives. Indeed, many compounds have been tested positive in, for instance, the conditioned avoidance response (probably the most widely used screening model for antipsychotic drugs), but a considerable proportion of these drugs never made it to the market. Although one might consider such drugs as false positives, it should be realized that there are many reasons why a drug may not make it to the market, including pharmacokinetic problems, or issues with safety pharmacology or toxicology.

In addition to these general validating criteria, many clinical studies have shown that anticholinergic or chronic treatment with an antipsychotic drug reduces the extrapyramidal side effects but not the therapeutic effect. These latter two criteria thus can be useful to distinguish between the therapeutic and side effects of antipsychotic drugs. **Table 1** gives an indication how well the different models are validated. Once the validation has been established and is acceptable, one can then use such models to test novel compounds, in the hope they may behave like the gold standard and ultimately, after extensive clinical trials, prove to be true positives.

Although such models, as mentioned before, have been extensively used in the development of antipsychotic drugs, they have an important disadvantage. Screening models are based on a gold standard and therefore they will inevitably identify drugs with a similar mode of action, which also explains why the current antipsychotic drugs are all very similar in mode of action and therapeutic efficacy. Since the current generation of medication does not significantly improve the negative or cognitive

Table 1 Screening models and their validation for schizophrenia

Screening test	False positives	False negatives	Potency correlation	Anticholinergic	Chronic treatment

+: there is ample evidence that the criterion is fulfilled; -: there is ample evidence that the criterion is not fulfilled; +/-: there are contradictory results with respect to this criterion; Ø: this criterion has not been investigated in any detail.

symptoms of schizophrenia and therapeutic compliance is usually quite low, we are in need of better animal models with an improved chance of detecting novel therapeutic targets.

Simulation Models

When aspects of a disease are modeled in animals, we usually refer to them as simulation models, though sometimes the term animal models with construct validity is used. As schizophrenia is a disorder of the brain, we need to disturb the normal brain of animals in order to recreate some of the aspects of schizophrenia. Although there are several ways of doing this, we will focus predominantly on etiological approaches, that is, on those models in which genetic or early environmental interventions are used. We mentioned above the use of psychotomimetic drugs, which are sometimes used to model aspects of psychosis. However, since schizophrenia is a chronic illness, such models seem to be less relevant for simulating the disorder. Similarly, given the difficulty in identifying the neuropathology of schizophrenia, such approaches offer limited possibilities for mimicking the pathology in animals.

Genetic Models

Schizophrenia has a strong genetic component, and although the genes that are involved in the etiology have not been unequivocally identified, some genetic changes have been found in several clinical studies. **Table 2** lists the most important genes that have been associated with schizophrenia. Without going into too much detail, it is important to note that for most genes, more than one single nucleotide polymorphism (SNP) has been linked to schizophrenia. A good example is the regulator of G-protein signaling 4 (RGS-4) gene of which four SNPs have been linked to schizophrenia (commonly denoted by 1, 4, 7, and 18). However, in one study, the haplotype G–G–G–G was found to be more common in schizophrenic patients, whereas in another study the haplotype A–T–A–A was seen more often in patients. Another problem is that in most cases, the functional consequence of this mutation is not known, and could represent both gain-of-function as well as loss-of-function mutations. In several cases, increases or decreases in expression of the protein or mRNA of the candidate gene have been found, but it is not clear whether this is really due to the SNP.

Since neither the specific nature of the SNPs nor the functional consequences of those associated with schizophrenia is generally known, it has proven difficult to develop animal models based on genetic mutations known to be associated with schizophrenia. Most studies have therefore been carried out with either homozygous

or heterozygous knockout mice. In particular, the homozygous knock-out animals may not adequately represent schizophrenia as none of the genes so far identified in schizophrenia lead to a complete loss of function. This has led to some intriguing though difficult-to-interpret finding. The schizophrenia-associated neuregulin haplotype, for instance, is associated with increased levels of neuregulin. However, the heterozygous neuregulin knock-out mouse shows some schizophrenia-like features (such as increased locomotor activity and decreased prepulse inhibition).

Environmental Models

Although genetic factors play a major role in determining the susceptibility for schizophrenia, it has long been recognized that environmental factors also contribute to the actual development of the disease. The nature of these environmental factors has proven hard to identify for several reasons. First, as discussed above, the most important environmental factors often antedate the onset of the disease by a long period. In fact, the perinatal period is possibly the most crucial period in which these factors impinge on the disease process. The relative paucity of prospective studies from birth onwards implies that most studies have relied on memories of a relatively distant past. Second, environmental factors are less well circumscribed than, for instance, genetic factors. For instance, the offspring of mothers that were pregnant during the Dutch hunger winter in 1944 have an increased risk of developing schizophrenia. This has been taken to indicate that malnutrition is a possible cause of schizophrenia. Although this may be the case, the hunger winter will undoubtedly also have led to severe stress (as hunger was very uncommon in the Netherlands) and to a change in the nature of the food (many were known to eat tulip bulbs, for instance). Such factors may equally have contributed to the development of schizophrenia. Third, there is increasing risk that schizophrenia results from an interaction between genetic and environmental factors (see below). This implies that studying environmental factors in isolation may fail to identify certain factors.

In spite of these difficulties, several environmental factors can be deduced from the literature that affect children more often who later develop schizophrenia as compared with control children. **Table 3** lists the most important ones and gives some examples. From the table, it is clear that most of the environmental factors so far identified are especially related to the pre- and early postnatal period, which is in line with the idea that schizophrenia is a disturbance of (neuro)development. However, later life stressors or excessive cannabis use around the period of puberty have also been reported to increase the risk of developing schizophrenia.

Table 2 Candidate genes for schizophrenia and genetic simulation models

Gene	Location (human)	Functional consequence of SNP	Animal model	DA resp.	PPI	P50	Memory	Soc Isol	Anhedonia

Peri-pubertal drug use	Excessive cannabis use	Peripubertal cannabinoid agonist	-	+	Ø	+/-	+	+
Peri-pubertal stress	Low socio-economic status Social adversities Severe life events	Isolation rearing None Early ventral hippocampal lesion Prenatal MAM treatment	+	+	+		+/-	+/-

+: the sign or symptom observed in the patients can also be observed in the animal model; -: the sign and symptom observed in the patients was not observed in the animal model; Ø: the sign or symptoms has not been investigated in the animal model. Abbreviations: DA resp.: hyper-reactive response to dopamine agonists; PPI: deficit in prepulse inhibition; P50: deficit in P50 auditory gating; memory: deficit in memory tests; Soc Isol: social isolation.

Based on these environmental factors, such as the prenatal stress, prenatal immune challenge, maternal deprivation, and isolation rearing models, a large number of animal models have been developed. In addition, the early ventral hippocampal lesion model has to be mentioned. In this model, the ventral hippocampus of 7-day-old rats is lesioned with an excitotoxic compound. Although, strictly speaking, this is not an etiological model (i.e., there is no evidence that the ventral hippocampal region is lesioned in children who later develop schizophrenia), it has been a very successful model and the lesioned animals show (in adulthood) a number of similarities to schizophrenic patients.

The Symptomatology of Schizophrenia

In spite of the apparent lack of knowledge about the etiology of schizophrenia, quite a number of genetic and environmental factors have been identified that play a role in its development. As discussed in the previous sections, many of these can be modeled in animals. However, the question remains whether such modeling leads to comparable symptoms in animals. Since most symptoms are difficult to assess, even in humans, much research is devoted to identifying signs and symptoms that are more objectively measurable. In this context, much experimental work has, in recent years, focused around the concept of endophenotypes. In order to be called an 'endophenotypes' a sign or symptom should be heritable, co-segregate with the disease and also occur in healthy siblings. Moreover, it should be state dependent, that is, it should also occur in patients in remission. The idea of endophenotypes is that they are more easily quantifiable (using specific cognitive or electrophysiological tests) and more related to specific brain regions or neurotransmitters, and thus more accessible for studying in animals, thereby increasing their translatability.

Several endophenotypes have so far been identified for schizophrenia, though in some cases there is still some doubt as to whether they fulfill all the requirements. These include smooth pursuit eye tracking, P50 sensory gating, prepulse inhibition, sustained attention, and working memory. Most of these relate to the cognitive symptoms of schizophrenia and several of these can also be assessed in animals. In addition, patients with schizophrenia also suffer negative symptoms such as anhedonia and social isolation. Even though several models for anhedonia have been developed in animals, such as decreased sucrose preference and increased threshold for brain self-stimulation, these have not been studied very often in relation to schizophrenia. Social behavior, and more specifically social isolation, on the other hand, has been studied in many animal models for schizophrenia. Finally, patients with schizophrenia show prominent

positive symptoms, which are generally impossible to assess in animals (see discussion at the beginning of this article). One possible biomarker (though it is still unclear whether this is a true endophenotype) is the hyper-reactive dopaminergic state. Several challenge studies have shown that patients with schizophrenia show an increased sensitivity of the dopaminergic system to psychostimulants such as amphetamine, especially in the striatal complex. Since antipsychotic drugs block the dopaminergic transmission and reduce positive symptoms, this increased dopaminergic state may well represent a biomarker for this group of symptoms.

Tables 2 and 3 summarize the main findings of the various animal models in relation to the signs and symptoms discussed here. It is important to realize that this table can not give full and detailed account of each model, and sometimes studies from different laboratories come to different conclusions. Whether this represents true differences, or are due to slight changes in the methodology, or the use of different mutant animals is still unclear. Nonetheless, the tables clearly show that much more work has been done using environmental manipulations than genetic ones. The tables also show that certain symptoms or endophenotypes (such as prepulse inhibition) are much more often studied than others (such as anhedonia).

Validating Simulation Models

In contrast to the screening models for schizophrenia, much less work has been done in trying to validate the simulation models. Since such models are based on the disease itself, they aspire, in addition to predictive validity, also face and construct validity. Although most models show some face validity, most of the manipulations shown in **Tables 2 and 3** also show behavioral abnormalities not seen in schizophrenia, which decreases their face validity. Further, with respect to the predictive validity, most of the simulation models lack in-depth analysis, including the effects of chronic treatment or the influence of anticholinergic drugs. Moreover, with respect to assessing the predictive validity of these models, we have to realize that much is still unknown about the clinical effects of antipsychotic drugs. For instance, whereas cross-sectional studies have provided some evidence that antipsychotic drugs may reduce prepulse inhibition (PPI) and gating, some longitudinal studies have suggested that the effect of both classical and atypical antipsychotic drugs is rather limited. Similarly, as discussed in the beginning of the article, there are, so far, no drugs effective against the cognitive and negative symptoms of schizophrenia, suggesting that the validity can only be assessed by the lack of effect of antipsychotic drugs.

Summary and Outlook: Gene–Environmental Models

In order to develop novel drugs for schizophrenia, we were restricted, for a long time, to screening models, based on known effective drugs such as haloperidol or chlorpromazine. This has certainly hampered the development of really innovative treatments. Fortunately, our increased knowledge on the role of genetic and environmental factors in the etiology of schizophrenia and the identification of specific biomarkers and endophenotypes has led to a wide range of novel simulation models for this severe psychiatric disorder.

These novel models are capable of capturing a number of aspects of schizophrenia. Although their validity has not been assessed in great detail yet, they already have proven to be of great value. In order to further improve the modeling of schizophrenia, interest should now turn to the integration of the two types of models. It is becoming more and more evident that schizophrenia is due to an interaction between genetic and environmental factors. It is therefore not so surprising that many of the genetic models listed in **Table 2** do not show overt schizophrenia-like abnormalities. As in patients, these genes are susceptibility genes, increasing the risk that, upon an environmental challenge, such abnormalities can occur.

Thus, it would be interesting to investigate the effects of stressors in animals with a different genetic background. Some studies have already been done, and it has been shown, for instance, that in contrast to Wistar or Sprague Dawley rats, Lewis rats are more or less resistant to the effects of early maternal deprivation, isolation rearing, and early hippocampal lesioning. It is to be hoped that within the next decade the various environmental manipulations described in **Table 3** will be applied to several of the genetic models displayed in **Table 2**, in order to further improve the simulation models for schizophrenia. At the same time, a better understanding of the clinical pharmacology of the biomarkers and endophenotypes will certainly be beneficial for improving the validity of the simulation models.

Conclusions

The rational development of etiology-based simulation models for schizophrenia has greatly increased over the last two decades. This is mostly due to an increased knowledge of susceptibility genes and environmental risk factors. Further, the identification of specific

endophenotypes and/or biomarkers has increased the translational power of the current generation of animal models. The next steps should now focus on further improving the models by focusing on the gene–environmental interaction, that is, by combining specific environmental manipulations displayed in **Table 3** with some of the genetic models displayed in **Table 2**. In addition, more knowledge of the clinical pharmacology of the various endophenotypes would be very helpful in assessing the validity of the different models.

Glossary

β-Amyloid Protein – A form of amyloid protein which is commonly found in abundance in the brains of Alzheimer's Disease patients.

Amyloid Precursor Protein (APP) – The precursor to the β-amyloid protein. The gene associated with APP has been linked with Alzheimer's disease.

Long-term Potentiation (LTP) – A form of synaptic plasticity that requires conjoint pre- and postsynaptic activity. LTP is often asserted to underlie memory formation.

Presenilins – A family of transmembrane domain proteins widely expressed in the brain. Missense mutations in genes coding for two of these proteins (presenilin-1 and presenilin-2) have been linked to a familial form of Alzheimer's Disease.

Reactive Gliosis – The neuroinflammatory response of glial cells to brain tissue insult.

Senile Plaque – Abnormal extracellular deposits of β-amyloid protein commonly found in the brains of patients diagnosed with Alzheimer's disease.

Tau Protein – A microtubule-associated protein found in neurons throughout the central nervous system. Abnormal, hyperphosphorylated, Tau protein is associated with the formation of the neurofibrillary tangles commonly seen in the brains of Alzheimer's Disease patients.

Transgenic animal – An animal which carries an exogenous gene deliberately inserted into its genome.

strategies to assess the biological basis of memory as well as neurodegenerative diseases that impact cognitive processes across the lifespan. However, the molecular genetics revolution brought with it both great expectations as well as questions that pervade colloquial discussions until this day. The belief that dementia and other devastating disorders of the mind could be explained by simple (or even single) gene mutations became pervasive in popular parlance. Furthermore, the expectation that these genes could be manipulated to modulate cognitive function became common place. As a particularly striking example, in the preface of a text summarizing a three day symposium on the chemistry of learning, Corning and Ratner wrote that one impetus for the symposium was the frequent request by nonscientists that they be provided "memory molecules" ... to help some senile relative." Despite the optimism of the early 1960s, progress in satisfying these goals has been slow. Nevertheless, experiments using transgenic animals, when properly conducted and interpreted have been shown to be a useful technique in behavioral neuroscience. In what follows we highlight some of these techniques in order to illustrate how transgenic animals can be effectively used to further our understanding of dementia and other disorders of the mind. To exemplify this approach, we focus on the usefulness of transgenic animal models in behavioral neuroscience by examining the advances made in the study of senile dementia. We hope to demonstrate both the usefulness of this technique as well as its potential pitfalls.

Introduction

Watson and Crick's description of DNA fostered a torrent of new strategies to address the mechanisms of genetics, and subsequently, ushered in a new interest in the role of genetics in brain disorders. By 1960, the laboratory of Francois Jacob had developed new methods to locate specific genes on chromosomal material, and moreover, a process by which genes could be excised or added into the DNA of single cells. These methods were the precursors to modern transgenic science, an approach that has revolutionized

Transgenic Animal Models: Advantages and Disadvantages

Transgenic mice are generated in a process that begins with the injection of a DNA strand fragment (representing a gene) into the male pronucleus of a newly fertilized mouse embryo, after which the DNA is incorporated into a random site on one of the chromosomes. Since the embryo is at the single-cell stage, the newly incorporated gene is replicated and ultimately is expressed in all of the animal's cells,

including its germline. This heterologous expression of a DNA fragment is commonly referred to as a transgene and the gene's product is made in addition to the endogenous gene expression pattern.

The manipulation of embryonic stem cells may be used to induce more specific genetic modifications. When introduced into a host embryo, stem cells can contribute to all cell types as the embryo develops. By homologous recombination of stem cells maintained in culture, modifications can be introduced into specific genetic loci and introduced into the mouse germline to promote mutations of preexisting proteins. Depending on the nature of the recombination and its location on the DNA strand, these mutations can effect deletions (i.e., knockouts) or modifications of existing genes and the expression of novel proteins. Since the engineered strand of DNA replaces a strand that had been endogenously expressed, the effects of the new gene are pure, that is, they are not the summed product of the endogenous gene and the transgene.

Since their introduction, transgenic strategies have been employed to generate mice that lack, or express in a modified form, genes that contribute to molecular and biochemical processes that have been asserted to contribute in various ways to the induction, storage, and expression of memories in the mammalian brain. This approach may be recognized as a modern variant of more widely used pharmacological strategies that for many decades served as a mainstay in the arsenal of tools employed in attempts to elucidate the biochemical substrates of memory. Despite their wide use, pharmacological manipulations were generally acknowledged to be inadequate, owing to the lack of specificity of most (or all) pharmacological agents, the lack of agents for many targets, and the difficulty associated with specifying or restricting the site of action of a pharmacological manipulation. However, although the transgenic and pharmacological approaches are conceptually related, many of the complications incurred with pharmacological manipulations are circumvented with modern genetic techniques. In particular, for every gene there exists a specific target protein, and any protein of interest is coded for by a specific gene.

While superior in many respects to their pharmacological counterparts, the use of transgenic animals is not itself free from interpretative difficulties. First, genetic alterations depending on a transgene are often expressed throughout an animal's development and can adversely impinge on a cascade of developmental processes. Thus, any unique properties of the adult phenotype (for instance, its capacity to learn) might reflect an acute influence of the genetic manipulation, or possibly, a consequence of an abnormal development of the nervous system and/or compensatory effects promoted by the gene deletion. In this regard, it should

be noted that many gene deletions produce gross abnormalities (e.g., neuroanatomical or morphological) and, in many instances, are lethal. Thus, even transgenic animals which appear to be nominally normal (at a behavioral or neuroanatomical level of analysis) can reasonably be expected to be abnormal at levels that escape detection. Second, a transgene is often expressed in every cell in the organism, thus confounding attempts to interpret the effect of the alteration in any specific brain region. Each of these first two complications has been at least partly overcome with newer techniques. Specifically, recent advances in transgenic models have led to the ability to create conditional transgenic animals that express genetic alterations only in specific brain regions and/or only after certain developmental points. Third, the production of a mutant mouse requires several generations of inbreeding, and the inbreeding may introduce uncontrolled mutations that may themselves impinge on the target behavior. Lastly, the genetic approach suffers from a major interpretative difficulty endemic to traditional pharmacologic manipulations. Specifically, a genetic mutation may impinge on a target behavior for reasons unrelated to that which was intended. To illustrate the analogy, a drug that impairs learning may do so via its disruption of a specific component of the learning mechanism, or may do so as a secondary or unintended effect of the drug, for instance, on the animal's state of alertness or its sensory acuity (as but two of many possibilities). Thus while the transgenic approach has certain definite advantages over more traditional pharmacological interventions, the interpretation of results based on these genetic manipulations is not uncomplicated. Overcoming these interpretive difficulties requires a close attention to the issues of experimental design and behavioral methods (an issue that we will return to below).

Alzheimer's Disease: Example of Advances Made through Use of Transgenic Models

With the exception of some primates, Alzheimer's disease (AD) is not known to spontaneously occur in nonhuman animals, making it an ideal target for transgenic models.

AD is the most common form of senile dementia, affecting an estimated 40% of all people over the age of 80 (although this estimate is complicated by comorbid states and imprecise diagnostic tools). The initial symptoms of AD include poor memory of recent experiences, and consequently, an impairment of new learning and the ability to recall that which had been previously learned. While AD is typically diagnosed with

behavioral and cognitive tests, it can only be confirmed upon autopsy by the presence of senile or neuritic plaque – areas of dead tissue containing among other things large deposits of beta-amyloid ($A\beta$) protein. Senile plaque is most commonly seen in the hippocampus and its afferent cortical structures, and until recently, laboratory studies of AD were largely limited to pharmacological manipulations of these structures and their synaptic integration, both in attempts to produce animal models of the disorder, and to assess the efficacy of treatment strategies. Although fruitful, this approach has had limited success in describing the etiology or pathology of AD, or as a tool for the development of effective treatments. However, recent advances in genetics and the development of transgenic technologies have made it possible to study alterations in brain morphology, synaptic transmission, and learning in strains of mice that carry genes associated with the human dementias characteristic of AD. Specifically, transgenic mice have been created to investigate the role of three of the genes (APP, presenilin-1, and presenilin-2) associated with familial forms of AD.

The amyloid precursor protein (APP) is the precursor to the β -amyloid peptide, the principal constituent of the senile plaques that are prevalent in the brains of human AD patients. To determine the action of APP in presenile animals, Zheng *et al.* produced mice lacking the gene that codes APP. During early adulthood, a marked increase in reactive gliosis was observed in the brains of the transgenic animals. Behaviorally, the animals exhibited reduced locomotor activity and grip strength, as well as deficits in spatial water maze learning and a reduced capacity for hippocampal long-term potentiation (LTP; a form of synaptic plasticity that is often asserted to underlie memory formation). This set of results indicates that under normal conditions, APP plays an essential role in the development of the nervous system and its regulation of behavioral function, suggesting that a disruption of APP function may underlie or contribute to the expression of AD. However, although APP deficient transgenic mice exhibit hippocampal neuron loss and declining synapse density in adulthood, only a subpopulation of these transgenic animals display lethargy or learning deficits, suggesting that APP function or expression may alter the susceptibility to neuronal loss and dementia, but may not itself underlie the behavioral or cognitive deficits that characterize AD. This latter caveat highlights the necessity of attending to the performance of individual experimental subjects.

Other APP transgenics have been generated that express mutations associated with early-onset familial AD, and these strains are characterized by accelerated deposition of β -amyloid protein (the constituent of senile plaques), a reduction in neuronal density in the

hippocampus, and often, an impairment of LTP induction. Similarly, these mice often exhibit severe impairments in the rate at which they acquire escape responses in the spatial version of the water maze as well as impairments in other cognitive tasks. For instance, Kelly *et al.* compared the performance of transgenic mice that expressed a human AD-associated mutant form of APP to wild-type controls in the water maze and in passive avoidance. They demonstrated that APP mutant mice showed age-related decline in performance in both of these tasks that were not related to changes in sensory or motor impairments. Furthermore, they (as well as others) reported that the emergence of these learning impairments correlate with the development of plaque formation. However, in other instances, the development of plaques appears to be unrelated to learning deficits or impairment of *in vitro* indices of learning-related synaptic plasticity, such as LTP. In all, variations in the expression of APP appear to be related to neuroanatomical abnormalities and behavioral deficits associated with AD, but its exact role in promoting these abnormalities is unclear and it does not appear sufficient in itself to underlie the dementia.

The early-onset familial form of AD is more highly correlated with mutations in one of two genes known as presenilins (PS-1 and PS-2) than with the APP gene itself. Proteolysis of presenilin proteins in turn stimulates the proteolysis of the APP, and down regulation of PS-1 is associated with a decrease in β -amyloid production. Moreover, overexpression of the PS-1 gene leads to the overproduction of β -amyloid. Thus variations in PS expression may precede irregularities in APP function and thus may be better suited as the determinant of the emergence of AD.

Targeted ablations of the PS-1 gene are lethal during development and are associated with abnormal development of the nervous system, and thus electrophysiological recordings from mice lacking the PS-1 gene have been rare. In contrast, transgenic mice that overexpress the PS-1 gene have been developed, and these mice are amenable to electrophysiological and behavioral characterization in adulthood. In all such lines, increased levels of β -amyloid have been observed during middle adulthood. To examine whether the overexpression of PS-1 influences electrophysiological properties of the hippocampus implicated in learning and memory storage, Parent *et al.* measured field excitatory postsynaptic potentials (EPSPs) at the Schaffer collateral-CA1 synapse in hippocampal slices. Although basal indices of synaptic efficacy (e.g., EPSP slope and amplitude) were unaltered in the transgenic animals, input-specific LTP was more easily induced and was more persistent in the transgenic animals than in the respective wild-type control subjects. Thus if LTP is a substrate mechanism for memory storage, it is difficult to reconcile these results with the proposal that

PS-1 expression contributes to the learning deficits that are characteristic of AD. Even more problematic, Janus *et al.* found that expression of the human PS-1 gene was associated with a significant improvement in the performance of mice in the spatial version of the water maze task. Furthermore, Chui *et al.* showed that mice that expressed the human form of PS-1 failed to develop senile plaque. Based on this pattern of observation, it seems that mutant PS1 alleles may require coexpression of human versions of other AD-associated genes in order to promote a behavioral phenotype indicative of AD.

Thus far, mice expressing single AD-related transgenes have been less than adequate as models for the elucidation of AD, prompting several attempts to generate mice carrying mutant APP and PS-1 genes. This double-transgenic approach has begun to yield promising results, including a line of mice that expresses neuropathologies in early adulthood (3 months), as well as a concomitant emergence of impaired choice performance in a t-maze. However, even at 9 months of age, these same mice exhibit no impairment in spatial water maze learning, suggesting that even this double-transgenic manipulation is inadequate to capture the fundamental essence of the Alzheimer's pathology, even though it may more adequately model the etiology of the disorder. However, Puolivali *et al.* reported significantly impaired retention in the spatial water maze in these mice by 11–12 months. Furthermore, these impairments correlated with the total amount of A β . The failure to capture the full range of AD symptoms in double-transgenic mice have led researchers to create so-called triple-transgenic mutant mice (3xTg-AD) which express APP, PS-1, as well as Tau. This final gene is associated with the formation of neurofibrillary tangles, a neural pathology also seen in AD. 3xTg-AD mice develop AD-like plaques and neurofibrillary tangles in the hippocampus, cortex and amygdala in a hierarchical fashion that mimics the progression of AD. Unlike the double-transgenic mice, 6-month-old 3xTg-AD mice showed impaired memory retention in the spatial version of the water maze as well as contextual fear conditioning. However, memory retention was unimpaired in young 3xTg-AD mice, at an age at which AD-like pathology is not yet present. These findings demonstrate the usefulness as well as the difficulties in the use of transgenic animal models in behavioral neuroscience.

Conclusion

The great expectations that arose after the advent of the genetic revolution and transgenic technologies in particular remain to a degree unrealized. Nevertheless, these genetic tools have proven to be of great use in behavioral neuroscience. The ability to selectively over-express or

under-express genes has allowed for modeling of disorders in animals that otherwise would not be possible. However, great care must be taken when interpreting the behavioral results from such animals, as manipulating individual genes can cause cascading effects that have far reaching influences. This is especially true when the genes are altered during or prior to development. As mentioned earlier, a genetic mutation may affect a behavior for reasons unrelated to that which was intended. To some extent these drawback can be overcome by using animals whose gene mutations are present only in certain brain subregions or are only present during adulthood. However, even in these cases behavioral results must be interpreted with some caution. For these reasons using only one behavioral paradigm is not ideal (it is noted that in the majority of studies described above, the spatial water maze served as the sole index of cognitive performance). A clear picture of the effects that a gene mutation has on behavior can only emerge after observing behavior across a wide battery of tasks. A recent study by Matzel *et al.* investigating the role of the cell adhesion molecule Nr-CAM demonstrates this nicely. Nr-Cam is thought to be involved in susceptibility to addiction in humans. Matzel *et al.* found that mice deficient in this adhesion molecule showed no overall learning deficits across four distinct learning tasks (including the water maze). However, these animals did display impaired performance in a fifth cognitive task that was based on learned passivity (passive avoidance). These same animals also exhibited increased propensity to enter stressful environments and a higher sensitivity to heat and shock. Taken holistically, a picture emerges from this study which demonstrates that Nr-CAM deletion may increase impulsive behavior in animals that are hyper-responsive to aversive stimulation, a characteristic thought to underlie a susceptibility to drug addiction. If these various performance measures were assessed only in isolation, no such overall conclusion would likely have emerged. So while transgenic mice have been a boon to understanding brain systems and impairments, like any other tool they are best applied in conjunction with comprehensive testing and analytic strategies.

Quanti exempla animalium valeant in morbis mentalibus humanis tractandis

Glossary

Biomarker – An indicator of a normal or pathological biological process based on scientific evidence and can be objectively measured. They can provide information regarding the health status of the subject, the degree and progression of the abnormality, and response to a pharmacological treatment.

Clinical endpoints – A potential drug must be shown to be safe and effective, that is, to be of clinical benefit to the patient. They may be defined as the absence of a pathogen, the reduction or disappearance of an abnormality, or reduction in the physical or behavioral manifestations of the disease/disorder, including survival and/or quality of life.

Construct validity – Closely related to the pathology and the underlying biology of the disorder, and the accuracy with which changes in the model organism reflects that in the human.

Endo and exo phenotypes – Terms defined originally by John and Lewis and later developed by Gottesman and his colleagues for heritable characteristics of a disorder present primarily in affected individuals as well as in family members regardless of whether the disorder is active or not. The complexity of the endophenotype increases as a function of distance from the gene and gene product.

Ethological validity – The use of natural or species-relevant stimuli for manipulating behavior in animals, or the approximation of the natural environment of the model organism.

Etiological validity – Etiology refers to the causes or origins of pathology. When etiology of a disease can be established, as say, for example, a viral or fungal infection, modeling the effects of such an infection in animals can be extremely useful to discover and develop antiviral or antimyotic agents to combat the infection.

Experimental medicine – Studies in human volunteers or specific samples of a patient population to (1) obtain mechanistic and pharmacological information of compounds entering into development, (2) explore and define biological markers with which the state and progress of a disorder can be monitored, as well as the effects of pharmacological interventions on its progress, and (3) establish models and procedures with which to obtain initial signals of efficacy.

Face validity – The phenomenological similarity between the behaviors exhibited by the animal model and the specific symptoms of the human condition.

Forward genetics – The process by which the genetic basis of a phenotype is investigated (phenotype to gene).

Good laboratory practice (GLP) – Principles that provide a standard for planning, execution, reporting, and archiving of laboratory studies. GLP studies are mandatory for safety and toxicological assessment of a new chemical entity (NCE). GLP, however, is not a Food and Drug Administration (FDA) requirement for preclinical studies to characterize the NCE.

Nonetheless, it is a common practice within the pharmaceutical industry to require preclinical researchers to conduct their experiments in as close a GLP fashion as possible.

Investigational new drug (IND) – The first stage of seeking approval for the marketing, use, and distribution of an NCE in the United States is the application for an IND in which the sponsoring company presents a document detailing the proposed clinical studies with the NCE, the chemistry, manufacturing, and control information of the NCE; and a summary report of the preclinical studies carried out with the NCE describing the pharmacological effects of the NCE, mechanism of action and the absorption, distribution, metabolism, and excretion (ADME) of the NCE; if these effects are known.

Model – A model of a human disorder attempts to recapitulate its aspects in a simpler organism, or in different species. A model is based upon the inducing conditions thought to reflect the etiological sources of the disorder. These inducing conditions may be genetic, ethological, developmental, mechanical, or pharmacological, and the establishment of the model depends on different levels of validity. Once a model is established reliably and is shown to be valid, it serves as an extremely important tool with which to study normal and abnormal human functions. Models of disorders are also important tools with which the effects of pharmacological or behavioral interventions can be assessed.

New chemical entity (NCE) – A potential drug with a novel chemical structure. An NCE is also referred to as an NME or new molecular entity.

Pharmacological isomorphism – In terms of drug development, a special condition of predictive validity is usually determined through pharmacological validation, that is, a comparison of the normalization of abnormal or impaired biology/behavior in animals by the NCE following application of clinically effective drugs used in the treatment of pathology in humans.

Predictive validity – The ability to predict changes in the human subject based upon changes in the model. No common underlying mechanism is assumed.

Procedures – The experimental manipulations by which a model of a human disorder is established and its effects can be measured. Procedures are not necessarily synonymous with the model. For example, aspects of state anxiety in humans can be ethologically modeled in rodents by taking advantage of the rodents' preference for dark, sheltered places; presumably as a defense against predators. Various procedures such as placing the rodent in a light-dark environment and observing behaviors such as the exploration of the light areas can be used to measure this experimental state anxiety. On the other hand, some procedures can be synonymous with the model. The effects of prolonged and chronic stress on physiology and behavior can be modeled directly by subjecting a rodent to an unpredictable series of mild stressors over a period of time. While the individual stressors chosen, frequency of appearance, and unpredictable nature of their application are procedures, chronic mild stress can be reasonably considered as a model of aspects of environmental stress in humans.

Proof of concept – Demonstration that the IND has therapeutic activity through the hypothesized mechanism in a target indication.

Proof of mechanism – Demonstration that a novel molecule is able to interact with the desired target and produce a desired functional effect through the hypothesized mechanism.

Proof of principle – Demonstration that a hypothesis is validated. This hypothesis may or may not be the ultimate therapeutic activity of the IND.

Proofs of mechanism, principle, and concept – Drug targets are continuously subjected to examination to determine whether the theoretical relationship of the target and associated lead molecules to the human disorder can be supported and sustained. Consequently, throughout the drug discovery and development process, objective proofs are considered milestones and the criteria with which further progression of the lead molecule are judged.

Reverse genetics – The process by which function is ascribed to a gene or gene product through the manipulation of that gene through deletion, silencing, or overexpression (gene to phenotype).

Translational research – The process through which information and insights flow from clinical observations to refine the development of animal models as well as the complementary flow of information and insights gained from animal models to the clinical setting, be it through improved diagnosis, disease management, or treatment; including pharmacological treatment.

Value and Validity: Two Sides of the Same Coin?

When first approached by the Editor to write this commentary for the *Encyclopedia of Behavioral Neuroscience* on the topic of the value of animal models for human mental disorders, I was slightly nonplussed by the choice of the word *value* in the title that I was assigned. Value implies economic or moral worth. According to *Merriam-Webster's Dictionary*, value is a noun defined, *inter alia*, as being "... a fair return or equivalent in goods, services, or money for something exchanged," or having "...relative worth, utility, or importance." Indeed, even as a transitive verb, value denotes "...the estimation or assignation of monetary worth, or the high consideration of something." Throughout my professional career examining the validity of the animal models to study the neurobiological substrates of behavior and the probable therapeutic utility of a novel molecule or new chemical entity (NCE), it never seriously occurred to me that I was not doing something of value. Nevertheless, perhaps value is a correct term to use when considered in the context of the pharmaceutical industry, the ethical use of animals for biomedical experimentation and especially the present re-examination of reasons for the apparent lack of novel therapeutics to be used in the treatment of central nervous system (CNS) disorders.

The present controversy regarding the presumed value of animal models for CNS disorders has its origins in the publication of a short, but very influential white paper on innovation or stagnation in the discovery and development of drugs by the US Food and Drug Administration (FDA) in 2004. This document analyzed the growing expenditure of medicinal research and development coupled with the parallel decrease in the number of submissions of NCEs registered from 1993 to 2003. Animal models in general were singled out as a point of concern. In addition to the more obvious reasons for registration failure, such as unexpected toxicity, lack of efficacy, that is, lack of therapeutic action has been cited as the most frequent reason for failure. NCEs submitted for the treatment of CNS disorders, in particular, have seen some of the worse attrition rates of 50–60%. This depressing picture was not helped by notable failures of NCEs with novel mechanisms of action such as Glaxo's serotonin 5-HT₃ receptor antagonist ondansetron (cognitive disorders) and Merck's NK1 receptor antagonist, aprepitant (MK-869 for the treatment of depression). Both these INDs suggested therapeutic potential from their effects in preclinical models. Subsequent examples of novel targets that failed to live up to their clinical promise include Pfizer's CRH-1 receptor antagonist CP-316,311, also indicated for depression, Pharmacia's dopamine D₄ receptor antagonist antipsychotic soneprazole (PNU-101387G). Potential drugs for the treatment of neurological disorders have also been withdrawn from further development for lack of efficacy in clinical trials. These include Novartis' antiparkinson compound TCH346 or AstraZeneca's antistroke compound NXY-059.

This climate and apparent lack of efficacy of potential CNS therapeutics have helped to reinforce a negative attitude toward the value of animal model use in CNS drug research in general and within psychiatric research specifically. This is not a new phenomenon. Louis Lasagna, one of the founders of controlled clinical trials for example, recalls a Merck executive's lack of confidence in animal models to predict what a drug would be good for. This attitude is very much alive today. Indeed, within the biopharmaceutical industry, one could even question the necessity for preclinical demonstrations of efficacy. When an IND is filed, the FDA only requires a summary of preclinical data, if available. On the other hand, the FDA is very specific on the type and detail of safety and toxicological studies that have to be done under certified GLP conditions. Though it is very unlikely that a sponsor would advance an NCE to the IND stage without a preclinical dossier that includes studies of mechanism of action and potential clinical efficacy, it is actually not required.

Validity, on the other hand, also implies worth, but with quite a different emphasis. Validity refers to

something being "...well-grounded or justifiable: being at once relevant and meaningful <a valid theory> b: logically correct <a valid argument> <valid inference>;" as well as "conforming to accepted principles of sound biological classification." Animal models for CNS disorders are endowed with different degrees of validity, of which face, construct, and predictive validity are the most common. In addition, ethological and etiological validity are increasingly important considerations, especially in view of the emerging greater concern with gene and environmental interactions in the development and manifestation of behavioral disorders.

Face validity of an animal model is mainly an intuitive criterion of the reasonableness of the model and is characterized by analogy with human behavior. Models with high validity can be very persuasive on a surface level. Feelings of defeat and worthlessness associated with depression can be modeled, for example, by the immobility developed by rodents when placed repeatedly in a cylinder of water from which there is no escape. One could intuitively argue that, "Yes, I too would feel depressed if all my efforts to change were useless." However, it can also be argued that immobility rather than being a manifestation of defeat could also be a very effective adaptive strategy.

Face validity is neither necessary nor sufficient to establish a model. Other forms of validity such as etiological, construct, and ethological validity are essential to raise an experimental manipulation of animal behavior from a reasonable and analogous description of abnormal human behavior to a more powerful heuristic and predictive tool with which to study the neurobiology of behavior and help predict the potential therapeutic effects of novel drugs. Etiology refers to the causes or origins of pathology, and ideally, if one knew the causes of psychiatric or neurological disorders and could reproduce them in an animal, the discovery and development of novel therapeutic agents would be a much more straightforward endeavor. Unfortunately, the causes of complex behavioral disorders are unknown. Indeed, even within neurological indications where the causes of neurodegeneration are better, though incompletely understood, causal relationships between neurodegenerative factors and behavioral changes, including cognition, are not clearly established.

Although the etiology of complex disorders is poorly understood, one could argue that one of the great strengths of animal models of human mental disorders, and hence their great value, is their ability to associate biological processes with changes in behavior. Though variously defined by various investigators, construct validity deals with the consistency or the relationship of a given psychological construct, such as intelligence, anxiety, and depression, with scientific rationale thought to reflect the construct. Construct validity is closely related to the concept of behavioral homology, which is the

commonality of animal and human behaviors dependent upon similar molecular, cellular, and system biology. For example, schizophrenia is associated with abnormalities in dopaminergic, serotonergic, glutamatergic, and nicotinic function. These functions can be measured in man and in animals neuroanatomically, biochemically, electrophysiologically, and behaviorally and can be subsequently or contemporaneously associated with changes in behavior in schizophrenic individuals. An animal model that recapitulates these biological changes reliably can be said to be a model endowed with increasing construct validity.

Predictive validity of an animal model of a behavioral disorder, as discussed above in the context of clinical pharmacological efficacy, has lately become an unknown quantity. It has not always been so. The major pharmacological interventions for depression and schizophrenia may well have been discovered by serendipitous observations of clinicians of the effects of drugs had on the mood or behavior of their patients. However, knowledge of and subsequent examination of the mechanism of action of these drugs established the importance of the role of the monoamine neurotransmitters, dopamine, norepinephrine, and serotonin in the expression and treatment of these disorders. The biogenic amine theory of mood disorders proposed by Schildkraut and Kety in 1967 was based upon the mechanisms of action of drugs such as iproniazid and imipramine, which potentiate the effects the monoamines dopamine, serotonin, and norepinephrine. The dopamine-blocking properties of antipsychotics such as chlorpromazine and haloperidol are related to the positive, that is, hallucinations, illusions, and delusions, symptoms of schizophrenia. Having clinically effective drugs and knowledge of their mechanism of action provide the basis of the major tool to test the predictive validity of animal models for predicting CNS therapeutic activity of NCEs. This process of validation is called pharmacological isomorphism, and it consists of the comparison of the effects of an NCE with that of a clinically effective drug. Pharmacological isomorphism validation takes place throughout the drug discovery and development process from first establishing a proof of concept showing similarities in outcome in an animal model of a disorder of the NCE compared with the clinically effective drug to clinical trials of the IND where its effects upon clinical endpoints are always compared to the clinical golden standard.

The Drug Discovery and Development Process: Where Animal Models for CNS Disorders Add Value

In many ways, drug discovery is the process of describing function to a novel molecule, the ultimate function being that of efficacy in the treatment of the disorder for which the NCE is intended. Drug discovery and development

can be usefully described as a linear process illustrated in **Figure 1** through which a suitable molecular target is first identified and chosen, a lead compound from many that interact with this target is characterized and progressed for safety and toxicology studies and then submitted to regulatory authorities as an IND for entry into humans. There is a continual process of validation that takes place from the moment that a drug target is identified and selected to well beyond a drug candidate being finally registered and is in clinical use. Animal models add value to this process by intervening at various points. Furthermore, animal models and procedures are not static. As more information about the drug (and the disorder the drug is designed to treat) becomes available, this information feeds back to preclinical drug discovery and associated academic collaborators to help develop new, or refine existing, procedures in a reiterative process.

Target Identification

Drug targets are primarily proteins or protein products associated with a disease and with which a small molecule interacts to produce a beneficial effect. For a target to be druggable, a molecular target should be associated with disease and capable of interacting with the potentially therapeutic NCE. Drug targets can be chosen on the basis of literature, location in target organs, and the presumed relationship with the disorder. In addition, the selection of a particular target by a pharmaceutical company is also dependent upon strategic and economic considerations.

Traditionally, drug targets have focused on G-protein-coupled receptors, enzymes, and ion channels, and these comprise more than 80% of marketed drugs. The publication of the human genomic code plus molecular biological tools, such as microarray technology, gene deletion, and overexpression, or random mutagenesis, all contribute to the identification of novel targets. High-throughput screening methods are now commonly used to provide the initial hits or suitable starting compound(s) for the medicinal chemist to start a synthesis program. Many hundreds of molecules from propriety and/or public compounds are screened for affinity with the molecular target of interest (protein, RNA, or DNA), and those molecules that satisfy the physicochemical criteria imposed upon them are then progressed for validation.

Animal models and procedures developed over the past five decades can play an important role in the identification of novel targets. Forward genetics is the process by which the genetic basis of a phenotype is identified and investigated. Environmental or developmental models of abnormal behavior are being used successfully to induce reliable behavioral phenotypes to which genetic techniques such as qualitative trait locus analyses can be applied to identify and study the genetic and environmental basis of such phenotypes.

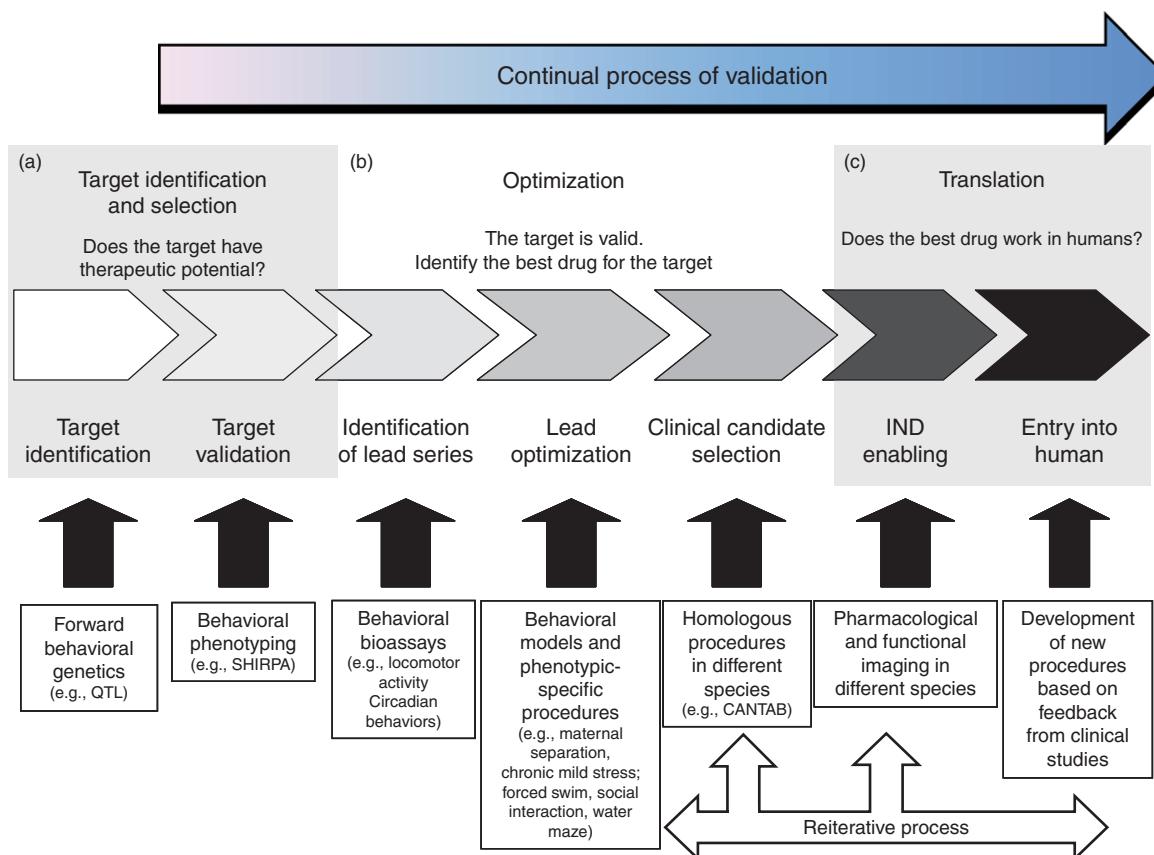

Figure 1 Points of intervention of animal models and behavioral procedures that add value to the drug discovery process during stages of drug target identification and validation, lead compound optimization, and translation. Adapted with permission from an unpublished slide provided by Dr. Guy Higgins.

Target Validation

Early target validation is essentially an interaction between the medicinal chemist and *in silico* and *in vitro* biologists, who will work together to identify the most promising lead series upon which to base the drug discovery efforts. Important activities at this stage include receptor-binding studies, interactions with relevant intracellular messengers, *in vitro* responses in isolated organs, etc. Animal models, particularly genetic models, play a very important role during this early stage of target validation. Once a gene or gene product is identified as a drug target, it is almost canonical that a mutant mouse will be engineered that will have the gene either deleted or over-expressed, and a process of reverse genetics of ascribing function to a gene is started. Gene-deleted mice, or knock-outs, have posed interpretational problems as compensatory changes can develop throughout the life span of the mouse. Technical modifications such as conditional knock-downs or the use of gene silencing through RNA interference have emerged as powerful tools to understand the contribution of that gene to behavior. Random mutagenesis is another technique through which changes in behavior are produced and need to be related to normal

behavior. Regardless of the molecular biological technique used to produce the mutant animal, behavioral procedures are used to identify and characterize the putative function of the gene. This process is known as behavioral phenotyping, and various protocols such as SHIRPA have been developed to standardize this process. A couple of words of caution, however, regarding the predictive ability of either the forward or the reverse behavioral techniques used for target identification or early validation. The background strain of the species used is a very important factor in determining the type and strength of the phenotype produced, and the behavioral specificity of the changes must be carefully evaluated. This latter caveat is particularly germane in assessing cognitive function as apparent cognitive impairments may be more parsimoniously ascribed to behaviors other than cognition that may also be modified by the mutation.

Animal models of function or behavioral bioassays are used in close cooperation with biochemistry and electrophysiology to identify the most promising chemical series to work on and to optimize one or two lead compounds that will eventually be proposed for further progression.

Certain pharmacological experimental manipulations can produce very clear and consistent functional consequences in behavior. For example, stimulation of locomotor activity can be used as a read-out of molecules interacting with the dopaminergic or serotonergic systems. Behavioral bioassays are routinely incorporated into the screening cascade of drug discovery projects. They are devised to measure the behavioral effects of an experimental molecule and help establish *in vivo* proof of mechanism. Bioassays are also extremely useful for revealing unexpected changes in behavior that could affect how the experimental molecule could affect the results of more complex models later on during optimization of a lead compound. For example, long-term recording of circadian behaviors such as feeding, drinking, locomotor activity, sleep-wake cycles, and their modification by drugs can be extremely informative. Bioassays therefore complement *in vitro*, *in vivo*, and *ex vivo* preparations; provide important information for structure-activity relationships of the molecule; and reveal potential side effects or alternate indications.

Lead Optimization

Once a promising lead is identified, the role of *in vivo* animal models assumes a more prominent role in characterizing function to the molecules followed by early examination of potential efficacy in a therapeutic indication. These models include early ADME studies to ensure that the lead compound is optimized in terms of getting to the right place, at a suitable concentration, for an appropriate amount of time, and that the metabolic fate of the compound is understood before it goes into man. It is also at this point that the animal models for CNS behavioral disorders are used intensively to provide the first evidence not only of mechanism, but also of potential therapeutic efficacy. It is very unlikely that model development and testing of lead compounds are done without reference to neurological and molecular correlates. Consequently, experiments are routinely planned to include imaging, biochemical, or electrophysiological measures hopefully on the same animals that have been assessed behaviorally.

As indicated previously, there is considerable controversy as to the predictive value of these animal models. Others and I have argued that some of this disillusionment is due to the siren call of models and procedures with high face value; added to this are the very clear differences in measures of outcome between animal and human testing. Clinical outcomes are measured in terms of reductions in the physical or behavioral manifestations of the disease/disorder. Clinically meaningful changes are usually measured by scales of clinical impression. Preclinical endpoints are typically alleviation or reversal of abnormal behavior or neuropathology by the NCE

compared to a clinically active standard. There is no way that we can get our animals to speak, but we are striving to find measures of behavioral change that are comparable across species.

A major change in biomedical research of mental disorders is the revision from syndrome-based to etiological and pathophysiological criteria. As part of this move away from syndrome-based criteria is the focus of identifying reliable phenotypes that underlie many types of behavioral disorders and can even be shared among them. This endophenotypic approach is helping to break down complex disorders into more manageable parts that can be studied and manipulated. Consequently, it is nonsense to speak of an animal model of a particular behavioral disorder, but rather one should consider these experimental manipulations as modeling homologous behavioral phenotypes. Behaviors indicating social withdrawal, lack of pleasure, or avolition are not only characteristic of depression, for example, but also of schizophrenia. The construct of anhedonia can be modeled, for example, in animals through the following prolonged experience of mild stressors (environmental model of depressed-like behaviors) or by neonatal hippocampal lesions, or juvenile social isolation; these latter considered neurodevelopmental models of schizophrenic-like behaviors. Changes in preference for sweetened solutions, rates of electrical self-stimulation, social interaction, or anticipatory hyperactivity are common readouts measured in these experiments.

In furthering the construct validity of these models, it is not enough to have analogous changes in behavior between the model organism and human. Ideally, these behaviors and underlying neurobiological substrates should extend across various species, from rodents, non-human primates to humans, and that the behavioral procedures used to measure changes should be tapping into the same processes across species. A clear example of the systematic development of procedures through which cross-species comparisons can be made has been provided by Robbins and his colleagues. Building upon the long tradition of modelling the effects of human brain lesions in primates they developed cross-species procedures using nonverbal stimulus modalities such as the presentation of geometrical shapes and use of touch-screen responses that enable the measurement of the effects of these manipulations. These procedures have been subsequently adapted for rodents, making them excellent translational tools as the independence of language based testing allows for meticulous cross-species studies of biological correlates and the effects of drugs on cognitive behavior. Furthermore, these procedures have been instrumental in tracking the course of disease progression in a number of neurodegenerative disorders such as Alzheimer's and Parkinson's, as well as providing preliminary indications of clinical efficacy.

Imaging and Biomarkers

The search for cross-species biomarkers is a major focus in translational research as these can be used to direct pre-clinical and clinical studies and to give early indications of potential clinical efficacy as well as potential toxicity of candidate drugs. Noninvasive imaging techniques such as positron emission tomography (PET) or magnetic resonance imaging (MRI) have become leading translational tools providing *in vivo* information about brain areas that are activated in response to mental states and processing. Imaging techniques can also provide information about disease state and progression. Wherever possible, once a lead compound is identified, PET radioligands are developed to investigate CNS penetration, target exposure, and occupancy *in vivo* and to relate this information to biological function. PET studies are also used in microdosing studies in which minute amounts of the radiolabeled compound can be administered in humans, and valuable cross-species relationships between animals and humans can be established such as dose adjustments and early ADME information. PET studies can also provide a proof of concept for novel targets.

In vivo imaging studies indicating the availability, distribution and exposure of an IND can be of immense help in deciding whether a compound should be progressed for further clinical testing, or in retrospect, exclude reasons for a clinical lack of efficacy. There is a high failure rate in psychiatric clinical trials due to response variability and placebo responses. It is not clear from these failed clinical trials whether the failure of the IND is truly lack of efficacy, or other factors such as whether target exposure had been achieved to exert a biological effect. For example, aprepitant was associated with a failed trial in which the active comparator, paroxetine, was not significantly different from the placebo. This lack of separation from placebo made it difficult to determine the true efficacy of aprepitant. The NK1 radioligand [¹⁸F]SPA-RQ was used to measure NK1 receptor occupancy in various species and eventually in human. These latter studies confirmed that the doses of aprepitant used in the clinical studies were sufficient to reach the brain, displace [¹⁸F]SPA-RQ, and block the receptor. These results indicated conclusively that the aprepitant was able to interact with its drug target and that this interaction was insufficient to produce an antidepressant effect. Aprepitant was subsequently withdrawn from further clinical development as an antidepressant.

Parallel to the advances being made in human imaging, small animal imaging studies are being conducted. Imaging studies reveal changes in brain structure and function underlying neurological and psychiatric disorders in humans that can be translated back in animal models. Small animal brain imaging can be used to examine the effects of drugs on brain structures or provide pharmacodynamic information of drug action. These effects can be related to the behavioral,

physiological, and temporal changes in the animal models and thus providing further construct validity. One major caveat, however, is those animals need either to be anesthetized or fixed in position during the procedure. Consequently, the results are influenced either by a pharmacological background or stress. Another caveat for both human and animal studies is that the observed changes in blood flow are only a poorly understood indirect measure of neuronal activity. With proper controls, however, small animal imaging studies are proving their worth in many phases of the drug discovery and development process.

The establishment of experimental medicine units within biopharmaceutical companies is providing an interface at which preclinical and clinical researchers interact. Biomarker development is an important activity that can involve both preclinical and clinical investigators. For example, imaging techniques are being used as possible biomarkers of neurological and psychiatric progression of disorder. Small animal imaging has been used in conjunction with genetic models of amyloidosis in order to observe the development of amyloid deposition in the brains of these animals, for example. These same animals could conceivably be used to track behavioral impairments as well as the effects of novel pharmacological interventions that can subsequently be related to changes in man. Another example of close collaboration between investigators is in the early detection of behavioral impairments or other forms of toxicity due to the novel compound. For the past decade, there has been considerable interest in the possibility of using immunological interventions for the treatment of disorders ranging from tobacco addiction to Alzheimer's disease. Initial enthusiasm for an active immunization approach targeting brain amyloid clearance that will maintain, or hopefully improve, cognitive function in Alzheimer patients was dampened by the development of meningoencephalitis in some patients. This has led to developing passive immunization approaches that should minimize this risk. However, immunological studies of passive anti-amyloid immunization in an appropriate genetic animal model indicate that meningoencephalitis can also develop in these mice.

Pharmacogenetics, or the individual responses to drug treatment, is a serious concern (but also an opportunity) to the medical community as well as the biopharmaceutical industry. Aside from the fact that some patients may not benefit from particular pharmacological treatment, individual responses during a drug trial may provide such variance as to suggest that the IND has no efficacy and consequently had be dropped from further clinical development. The recent phase II clinical trial of rosiglitazone (Avandia[®]) in Alzheimer's patients is an oft-cited example. This antidiabetes drug showing promise in a genetic model of amyloidosis, including improved cognition, failed to show any overall significant effect on ADAS-Cog scores. However, following stratification of the subjects according

to their APOE4 genotype, very clear improvements in ADAS-Cog were observed in APOE4-negative subjects. These results have justified further development of this drug in phase III clinical trials due for completion in 2009.

Established behavioral animal models of depressed-like behaviors such as the forced swim test, tail suspension, social defeat, and suppressed responding have been instrumental in identifying candidate genes, including *TREK1* (*KCNK2*), for antidepressant drug activity. It is significant that initial confirmation in a patient population is providing forward genetic validation of these models and the use to which they are put. Indeed, to quote the authors, "... this study is one of the first to examine candidate genes derived from mouse models of antidepressant response, validating the utility of such models for understanding the genetic basis of human antidepressant response" (Perlis *et al.*, 2008:2816).

It is apparent throughout this article that the topic of the value of animal models for predicting therapeutic action has focused strongly on animal models for behavioral disorders to the exclusion of neurological disorders. This is not to say that animal models for behavioral disorders have any more or less value than those for neurological disorders. Neurological animal models for symptoms of neurological disorders have been crucial for the discovery and development of pharmaceuticals for their symptomatic treatment. One can cite numerous examples of novel treatments for the control of seizures in the epilepsies, dopaminergic-based treatments for the tremors associated with Parkinson's, or cholinergic treatment for treatment of Alzheimer's disease. Nevertheless, the relief of these symptoms is transitory and can be related to side effects that limit their usefulness. Neurological disorders are closely related with neurodegeneration, and animal models, mostly genetic, have contributed greatly in the understanding of neurodegenerative processes. However, the clinical efficacy of novel treatments developed following activity in these models is still to be demonstrated.

In posthumous answer to the apocryphal Merck executive, and in response to the very present and concerned present day executives of biopharmaceutical companies, one would be hard pressed to demonstrate any real value of animal models based on the criteria of ultimate therapeutic activity outlined above. Nevertheless, a straight yes or no answer would be facile as there are many reasons why an IND fails to show efficacy in clinical trials. In a recent analysis of the apparent lack of congruence between pre-clinical and clinical outcomes of efficacy, using depression as an example, Borsini and I were able to identify at least six factors that can account for INDs being withdrawn from further development. These include an overreliance in the face value of behavioral models and lack of internal replication of results, design of clinical trials, placebo responses, genetic variations in response to drugs, and species differences in bioavailability and toxicology. Furthermore, at

least two further factors can be considered to account for the disappearance of INDs from the development pipeline: (1) lack of interest of pharmaceutical sponsors to continue developing certain drugs and (2) the reluctance or lack of interest in publishing negative results by the sponsors. Publication bias and the reluctance of pharmaceutical companies to disclose the reasons for withdrawal of individual INDs make a thorough analysis of the true predictive ability of preclinical animal models and clinical efficacy virtually impossible.

I hope, therefore, to indicate in this overarching commentary on the use and value of animal models that animal models have and have always had a very valuable and valid role in the drug discovery and development process. Without indication of *in vivo* function, it would be extremely difficult for novel compounds to be identified and optimized. Activity of a novel compound in animal models of abnormal behaviors provides an indication of the potential therapeutic activity of the compound, and as models simulate aspects rather than the totality of poorly understood disorders, it would be nonsense to suggest that activity in one test, or even five, guarantees activity in heterogeneous population of patients. What one can say with certitude, however, that without a much closer interaction between preclinical and clinical investigators sharing their expertise in a continuous process of model validation, the predictive power of any model will not improve.

One could conclude, therefore, that invalid models have no value at all, but that valid models have their limited value, and that is determined by the purpose to which they are being used.

Plus ça change, plus c'est la même chose.

(Alphonse Karr, 1808–90)

Summary

The value of animal models for predicting CNS therapeutic action has been questioned on the basis of a lack of clinical efficacy of potential drugs with novel mechanism of action despite promising preclinical activity. The causes of psychiatric and neurologic disorders are poorly understood, and models that attempt to simulate an uncertain etiology are imperfect at best. Animal models are being redefined in terms of genetics and phenotypes rather than syndromes. Within their limitations, the reliability and validity, particularly construct validity of animal models, are demonstrating their value by identifying novel targets and validating targets throughout the drug discovery and development process. Closer ties between clinical and pre-clinical investigators ensure the continual refinement of animal models not only in describing function to novel compounds, but also in the establishment of biomarkers and the study of pharmacogenetics.

Glossary

Abnormal spindle-like microcephaly-associated (ASPM) – A gene involved in neurogenesis that regulates brain size.

Developmental dyslexia or reading disorder (RD) – A disorder in children characterized by deficiencies in decoding written language.

Forkhead box P2 (FOXP2) – A gene that encodes a regulatory protein belonging to the Forkhead box group of transcription factors. Mutation of this gene has been implicated in an inherited speech disorder and anomalies of brain development.

Klinefelter's syndrome (KS) – A syndrome related to an extra X chromosome (47,XXY) in which the behavioral phenotype is characterized by language-based learning difficulties.

Microcephalin 1 (MCPH1) – A gene implicated in neurogenesis that regulates brain size.

Specific language impairment (SLI) – A neurodevelopmental disorder characterized by problems in understanding or producing language in the absence of causal factors such as hearing impairment, mental retardation, neurological deficits, primary emotional disorder, or social deprivation.

Speech sound disorder (SSD) – A neurodevelopmental disorder marked by developmentally inappropriate errors in speech production caused by articulatory and phonological processing impairment and resulting in significantly reduced intelligibility.

Williams syndrome (WS) – A genetic disorder caused by a rare spontaneous mutation affecting chromosome 7, associated with mental retardation but spared language function and verbal short-term memory.

languages, and the fact that language is acquired with such remarkable facility and regularity in children without explicit instruction. More recently, psychologist Steven Pinker has suggested that natural selection might have shaped the evolution of a human's 'innate grammar' and posited that this knowledge must be represented in the microcircuitry of the brain. According to this strong 'nativist' viewpoint, other animals do not have the capacity for language, and therefore language marks a preeminent trait of human evolution.

Opposing 'emergentist' views contend that many of the same observations attributed to innate knowledge of language can be observed in a system which is not innately structured. Proponents such as Elisabeth Bates and colleagues underscore the remarkably plastic and experience-dependent nature of cortical microcircuitry development and specialization, particularly with regard to language. For example, 95–99% of right-handed individuals are genetically predisposed to left cerebral hemisphere dominance for language, yet infants and young children who sustain damage to left hemisphere language areas succeed in developing normal or near-normal language in the right hemisphere of the brain. From an evolutionary standpoint, it has been argued that the qualified successes by Sally Savage-Rumbaugh and colleagues in teaching symbol-based communication systems to Bonobo chimpanzees (who share 98% of the same genes with humans) suggest that the divide between humans and our closest primate relatives may not be as wide as some believe, but rather reflect a gradation of communicative skills.

Models of the relationship between genes and language must make sense of a complex and temporally dynamic interaction between the genotype, environment, and epigenetic factors and must do so with reference to their influence on the brain. Conservative estimates have suggested that 40% of all genes in the genome are expressed in the brain; hence, thousands of genes may have direct or indirect functional implications on various aspects of language development. While a wealth of new information has emerged in recent years, our understanding of genetic factors that influence language and its development remains rudimentary, related in part to the complexity of language itself, as well as to changing tides in our understanding of how genes influence human behaviors. In the following sections, we review current evidence suggesting that genetic factors may play a significant role in the ontogeny of language in humans.

Background

Discussions of the genetics of language can be traced to Charles Darwin, who in 1871 remarked that "Man has an instinctive tendency to speak, as we see in the babble of our young children, while no child has an instinctive tendency to bake, brew or write." Advancing this notion nearly 100 years later, the linguist Noam Chomsky claimed that humans are born with an innate or hardwired knowledge of grammar that is apparent in observations that common grammatical principles are shared by all

Specific Language Impairment

SLI and the Genetics of Language

A prevalent approach to understanding genetic contributions to language has involved the identification of genes associated with disturbances of language development in children. Approximately 5–7% of school-aged children are designated as having a clinical condition known as SLI. This developmental disorder is characterized by problems in comprehending or producing language that occur in the absence of clear causal factors such as hearing impairment, mental retardation, gross neurological deficits, primary emotional disorder, or social deprivation. Although a broad consensus on standardized diagnostic criteria for SLI is currently lacking, the disorder has been a focal point for discussions of the genetics of language because of the relative specificity of the disorder to language development. This interest is based on the following rationale: if anomalies in a gene or a set of genes can be associated with SLI, which by definition implies normal cognitive development in other domains, then this provides some evidence that these genes are particularly important for language. However, the relevance of this approach to elucidating the genetic contribution to normal variation in language function remains open to question.

SLI: Heredity Studies

A first step in establishing whether or not genetic factors are involved in SLI requires establishing the heritability of the disorder. Several decades ago, Eric Lenneberg and others noted that delayed or deviant language development tended to run in families. Subsequent family studies have suggested that 24–63% of children with SLI have at least one family member who is also affected. While the familial occurrence of language impairment may reflect genetic influences, it may also be due to shared environment. A commonly used method to tease apart the relative contribution of genetic or environmental factors in language acquisition is to ascertain whether monozygotic (MZ) twins, who share 100% of their DNA, are linguistically more similar to one another than dizygotic (DZ) twins, who share only 50%. If MZ twins are more similar in language ability than DZ twins, then it can be inferred that this may be related to their greater genetic similarity.

When applied to SLI, the approach has typically involved examination of whether or not concordance rates for SLI differ between MZ and DZ twins. Twins are concordant if both have SLI, and are discordant if only one twin is language impaired. Comparing concordance rates provides an estimate of the contribution of genetic factors to the emergence of SLI. Theoretically, if SLI was

completely determined by genetic factors, MZ twins would have 100% concordance while DZ twins would have 50% concordance. Twin studies of SLI to date have almost uniformly indicated higher concordance rates for MZ twins compared to DZ twins. A metaanalysis by Karin Stromswold showed that for spoken language disorders, concordance rates averaged around 84% for MZ and 50% for DZ twins. The resulting overall heritability estimates from these and subsequent studies have ranged from 0.5 to 0.75, indicating a moderate to strong genetic contribution to risk for SLI. In general, concordance is higher the more severe the disorder although moderate heritability (39%) has also been observed for language ability in the normal range. Concordance is significantly higher for males compared to females.

While twin studies have proven to be a powerful technique, the heritability estimates derived from them are susceptible to a broad range of methodological issues (e.g., methods of ascertainment, diagnostic criteria, and definition of ‘impairment’) and theoretical assumptions. For example, twin studies assume equal exposure to environmental influences. However, some evidence suggests that MZ twins may have greater similarity of experience than DZ twins, potentially biasing estimates of the genetic contribution. Heterogeneity in the phenotypic manifestations of language impairment in children is a major complicating factor in their interpretation. Binary classification of ‘affected’ or ‘unaffected’ does not adequately reflect phenotypic variations since some siblings may fail to meet the criteria or cutoff for a diagnosis of SLI, yet demonstrate subthreshold disturbances of speech and language development.

The extent to which aspects of language (phonological, lexical, semantic, syntactic, and pragmatic) are compromised in individuals with SLI can vary. Recent studies suggest that genetic factors may not exert a general influence on language development but instead may play a role in the emergence of specific forms of language impairment that differentially involve distinct components of language. For example, reports suggest that language impairment associated with speech deficits of sufficient severity to warrant clinical referral may involve a stronger genetic component than language problems with preserved speech. Some aspects of language development appear more influenced by environmental factors than shared genetic influences. For example, data from the Twins Early Development Study (PI: Robert Plomin) suggest that at 2 and 3 years of age, vocabulary development and grammar share genetic influences but variation is more strongly accounted for by environmental factors.

In attempting to provide a more precise characterization of the SLI phenotype, some researchers have found it helpful to forego the use of global measures of language to define SLI and instead examine endophenotypes using biological or cognitive markers of vulnerability to the

disorder. This approach assumes that a complex behavior such as language may reflect the influence of genetic factors on one or a number of elemental abilities or neural processes that are more directly related to genetic influences and thus serve as better indices of the genetic risk of developing the disorder. Theoretical accounts of the essential problems underlying SLI have emphasized deficits impacting phonological and morphosyntactic development. These are evident in difficulties repeating meaningless but phonotactically legal words (e.g., 'perplisteronk'), deficits in auditory perception of rapid changes in speech signals, problems producing verb inflection, and errors in comprehension of marked syntactic structures such as passive voice phrases. Using such an approach, Dorothy Bishop and others have highlighted deficiencies of phonological short-term memory and processing of grammatical inflections. Both appear highly heritable but are subject to genetic influences that do not overlap significantly.

SLI: Karyotype Analysis

Karyotype analysis is used to detect specific chromosomal deletions, duplications, or translocations that may be associated with language impairment. Classic karyotype analysis can detect anomalies in the order of 10 megabases in size, while fluorescence *in situ* hybridization (FISH) can detect smaller anomalies in the order of 100 kilobases or less. In 2001, scientists at the Institute for Child Health in London reported that karyotype analyses (using FISH) in three generations of a British family (the KE family) with an inherited speech disorder disclosed an autosomal-dominant mutation in half of the members. The 15 affected individuals presented with verbal dyspraxia, an impairment in the ability to produce the coordinated oromotor movements required for speech. Their speech was effortful, inflections marking tense or number were often incorrect, and word order was commonly confused. In addition, they demonstrated poor comprehension of syntactically complex structures and performed poorly on a lexical decision task. The mutation involved a single gene in region 7q31 referred to as FOXP2, which stands for Forkhead box P2.

This first account of an association between a specific speech/language disturbance and an identified genetic deficiency created tremendous excitement in the scientific community, and it was argued that the finding was strongly supportive of the existence of a 'language gene.' However, subsequent investigations have discounted these claims. The apparent language problems appeared closely tied to their poor neuromotor control of facial muscles and difficulty pronouncing words. In addition, observations of nonverbal learning disabilities and significantly lower IQ in affected members compared to

unaffected members suggested that the effects of the mutated gene were not specific to speech or language.

The significance of FOXP2 mutations to understanding the genetics of SLI has also been questioned because it is relatively rare in the broader population of SLI children. Moreover, the affected members had structural brain abnormalities that are not normally seen in SLI and may even preclude the diagnosis. These anomalies involved portions of the left inferior frontal gyrus (Broca's area, a classic language center), the caudate nuclei, and cerebellum. Nonetheless, FOXP2's probable role in determining variation in oral facial skills required for articulate speech has been supported by findings that mutations of FOXP2, somewhat different from those observed in the KE family, also result in verbal and orofacial dyspraxia. Overall, current evidence suggests that FOXP2, like other FOX genes, may regulate the transcription of target genes (essentially turning other genes on or off), particularly genes involved in normal brain development. Mutations may indirectly cause a form of speech and language impairment because of resulting abnormalities in the development of frontostriatal and frontocerebellar networks required for speech production.

Consistent with this, the normal human-specific variant of the gene has been observed in Neanderthal DNA and thus dates to an evolutionary period associated with primitive vocal communication systems and the appearance of a human-like vowel space. In animals, disruption of copies of FOXP2 affects cerebellar development and vocalization. However, FOXP2 is active in several regions of the CNS and in other aspects of embryogenesis and neurogenesis (e.g., developing lung, and cardiovascular/intestinal and neural tissue). Vernes and colleagues have recently suggested that FOXP2 may downregulate CNTNAP2, a gene that makes a protein that enables intercellular interactions during brain development. Other genes relevant to language development that are active during neurogenesis and are developmental regulators of brain size are the MCPH1 (Microcephalin 1) and ASPM (abnormal spindle-like primary microcephaly-associated) gene.

SLI: Genetic Linkage and Association

Large research studies use a method known as genetic linkage analysis to determine which chromosomal regions contribute to the development of language impairment. In these studies, genotypes from multiple members across several generations of affected families are examined in an attempt to identify a genetic 'marker' that segregates with the disorder. A marker is a fragment of DNA sequence at a unique location in the genome that shows variation within the population. Markers commonly involve differences in single bases called single nucleotide

polymorphisms (SNP's). If linkage studies succeed in implicating a chromosomal region in a disorder, then genetic association studies are used to compare the frequency of specific markers in samples of affected individuals to the frequency of those markers in matched but unaffected controls. The goal of this comparison is to identify those markers that are more frequent in affected individuals.

The first genome-wide screen of SLI, completed in 2002, studied 98 families and found evidence for linkage of SLI phenotypes to 16q24 and 19q13. These findings were confirmed in a replication study in 2004 involving 86 new families. In a separate study with five extended families with SLI, evidence was found for linkage to 13q21. However, this localization was based on the analysis of reading discrepancy assessments in these families rather than a language-impairment phenotype.

Related Disorders

Speech Sound Disorder

Speech sound disorder (SSD) frequently overlaps with SLI and affects approximately 4–16% of children between 3 and 6 years of age. The condition is marked by developmentally inappropriate errors in speech production caused by articulatory and phonological processing impairment and results in significantly reduced intelligibility. These errors occur despite a well-formed oromotor tract, normal intelligence, and intact hearing, and are distinct from problems associated with mutism or stuttering. Synonymous terms for SSD have included articulation disorder or, more recently, phonological disorder. Quantitative measures of SSD symptoms are often based on assessments of consonant articulation, and repetition of nonsense and complex multisyllabic words. Recent genetic studies have linked SSD to 6p22 and 15q21. The linkage peak on chromosome 15 was located in region 15q14, adjacent to regions such as 15q11–13 that have been implicated in the Prader–Willi syndrome and in Angelman's syndrome. Both of these disorders are associated with articulatory difficulties and poor oromotor skills, but also include impairment in other domains. Other studies have shown linkage to a chromosome 3 locus (3p12–q13) which had previously been implicated in RD.

Developmental Dyslexia

Developmental dyslexia, also commonly referred to as reading disability (RD) or specific reading disorder, has a prevalence of 5–10% in school-aged children and has long been regarded as a familial and heritable disorder of neurological origin. Often related to SLI, multiple deficits have been proposed to underlie the disorder, the most

common involving: (1) deficits using grapheme-phoneme (letter-sound) rules (phonological decoding) or (2) deficits recognizing words by letter patterns or lexical units (orthographic decoding). Broadly, deficiencies in phonological decoding correspond to a type called 'phonological dyslexia' and orthographic decoding problems are characteristic of 'surface dyslexia'. Like SLI, heritability estimates differ according to how the phenotype is defined. Heritability is higher for phonological than for surface dyslexia. Genetic contributions to performance on tasks sensitive to problems with phonological processing (e.g., phoneme awareness and nonword repetition) are about 60–70% across different measures, with 30–40% accounted for by environmental factors.

Phonological processing problems have been most closely linked to a region on the short arm of chromosome 6. At least four other areas have been implicated in the genetic transmission of risk for dyslexia by genome-wide linkage studies. The first of these candidate genes was identified in 2003 on chromosome 15q21 and titled *dyslexia susceptibility 1 candidate 1* (DYX1C1, also referred to as EKN1). In 2005, three new candidate genes were proposed: ROBO1, DCDC2, and KIAA0319. DYX1C1 is expressed in several tissues in the brain, including cortical neurons and white matter glial cells. Beyond this, the function of DYX1C1 remains unclear. ROBO1 was discovered by serendipity in an individual with RD who demonstrated a translocation involving the 3p12–q13 region. This region is involved in the guidance of dendritic connections and interhemispheric axons. DCDC2 and KIAA0319 are located in the region of 6p22. They are thought to have a role in neural migration, and are expressed in brain areas that have been implicated in reading, particularly frontal, temporal and inferior parietal cortex in the left hemisphere. Overall, disruption to normal patterns of regulation of these genes, through deletion or duplication, appear to result in inadequate guidance of cortical neuronal migration as well as the development of axonal and dendritic connections during brain development.

Language Disorders in Genetic Syndromes

In addition to genetic studies of SLI and related conditions, advances in our understanding the genetics of language have emerged from studies of *de novo* occurring genetic variations. Specific genetic anomalies or syndromes, where language development has proceeded along a different developmental trajectory than other aspects of development, provide important opportunities to study the effects of genes on structure and function of the brain. Among these, Klinefelter's syndrome (KS) and

the Williams syndrome (WS) have been especially informative.

Klinefelter's Syndrome

KS is a relatively common genetic disorder (1/1000 males) defined by the abnormal chromosome karyotype 47,XXY. In contrast to X-linked conditions such as fragile X or Aarkog syndrome, which can result in mild to moderate mental retardation respectively, KS results in rather selective cognitive impairments particularly involving language-based learning difficulties. Delays in language and speech development are often detected by age 2–3 years as difficulties in articulating and structuring language output. These difficulties remain evident in some form at all ages. Later in development, significant impairments are frequently observed in higher-order aspects of expressive language, particularly in deficits with word retrieval, expressive grammar, and narrative formulation. Problems with receptive processing of language are evident in relative deficiencies in phonemic discrimination and in comprehension of syntactic and morphological aspects of language, as well as slow verbal processing speed. These early language impairments tend to predict language-based learning disabilities, including problems with reading, spelling, and writing.

Behavioral studies suggest that individuals with XXY show reduced hemispheric specialization for language, and recent structural neuroimaging studies have shown cortical thinning in left inferior frontal as well as temporal regions of the brain. Functional neuroimaging studies have revealed decreased asymmetry in activation of the superior temporal gyrus (STG) and the supramarginal gyrus (part of Wernicke's area). Such findings have suggested that genes on the X chromosome may be involved in hemispheric specialization for language.

Williams Syndrome

WS is caused by a rare spontaneous microdeletion affecting chromosome 7. It is often included in discussions of the genetics of language because, at first blush, it appears to constitute the opposite pattern to SLI. Children with WS have relatively spared language function and verbal short-term memory, in the context of manifest impairments in visual-spatial and social-pragmatic skills, attention deficits, and heightened anxiety levels. Yet, analyses of the linguistic and cognitive capacities in WS have revealed a more complex picture. While children with WS learn to speak fluently and with rich grammatical structure, their lexicon may be somewhat restricted to simple, concrete expressions (i.e., significant reduction in use of abstract relational terms), suggesting that cognitive impairment is also reflected in their language development.

Evolutionary Considerations

Grammatical language is thought to have its origins in genetic changes that influenced brain development between 100 000 and 50 000 years ago. A 'macro-mutational' viewpoint suggests that changes in a single gene less than 100 000 years ago may have resulted in a cascade of neurological changes in the brain that culminated in the emergence of modern language capacities. Alternatively, micro-mutational theories suggest that a series of small or gradual genetic changes resulted in alterations in brain function (e.g., increased computational efficiency) that cumulatively allowed for encoding of human-specific behaviors such as language. Language came about when speech and syntax were added to older communication systems and putatively emerged in the left cerebral hemisphere from a disposition towards right-handedness and the use of gesture.

Interestingly, a new sign language created by deaf Nicaraguan children over the past 25 years has provided an opportunity to examine the inception of universal hallmarks of language. Researchers found that in creating the language, children analyzed complex events into basic elements, which they then sequenced into hierarchically structured constructions according to principles that were apparently independent of gestures accompanying speech produced by hearing individuals in their surrounding environment. Successive learners adopted and extended this procedure, ultimately transforming the signs from a gestural form of communication into a linguistic system.

Contemporary studies suggest that differences in recently evolved versions of two genes may influence preferences in how humans code language in speech. Broadly speaking, 'tonal' languages such as Chinese use pitch changes to convey differences in the meaning of words, while nontonal languages such as English are more dependent on cues present in vowels and consonants and their arrangement to signal comparable changes in meaning. Mutations in genes called ASPM and Microcephalin that began to appear roughly 37 000 years ago and believed to affect brain development (discussed earlier) were more frequent in populations using nontonal languages. As this difference could not be explained by historical or geographic factors, the direction of this effect suggests that tonal languages may have older origins.

Conclusion

Significant advances in genetics coupled with improvements in understanding language and its disorders have together revolutionized our understanding of the genetics of language in the last two decades. The evidence for a moderate to strong genetic contribution to speech and

language development is overwhelming, although recent studies suggest that this may overlap significantly with genetic influences on nonverbal cognitive abilities. As the field rapidly evolves, it is likely to transform our current understanding of these relationships in the coming decade.

Human Evolution: Biological and Cultural

Human evolution starts about 6 million years ago, the approximate estimate of our separation from the line leading to chimpanzees, the nearest primates. The first important difference seems to have been the bipedal stance, perhaps accompanying descent from the trees to the savannas of Central Africa. The immediate advantage may have been that of giving higher running speed, useful for catching prey and flying away from dangers, but the freeing of hands it permitted helped greatly a major exaptation (a secondarily appearing adaptation): tool making. The oldest tools collected by archeologists are stones modified by breaking them so as to use the cutting edge thus produced for various purposes, for example, opening bones of dead animals and eating their bone marrow, which is considered a delicacy still today. They are at most 3 million years old. However, tools made of wood and other less durable material could not survive. There were, however, other signs of heightened intelligence: the increase of brain size was already on its way. Starting from 350 ml, which is still standard in all the nearest primates, it increased to the present value of 1300 ml in perhaps irregular ways (e.g., Neandertals, now extinct, had bigger brains than modern humans). There were physical signs that language was already beginning: at the time the first tools were made, five out of six skulls had a larger size on the left side of the brain, in the Broca region. The biological basis of language must have anyhow progressed over a long time, and perhaps the final major steps took place in the small East African tribe that was responsible, before it started for the Out of Africa spread that began 60 000 years ago. The main evidence for this is that any living human population can learn without difficulty any other existing human language, and therefore the necessary biological machinery was already present in basically all members of the founder population before it spread. However, language evolves much faster than genes and the 6000 or so languages in existence today may be the last remnants of the societies (the tribes) that were generated during the great demographic expansions. The first was between 60 000 and 10 000 years ago, at which time most of the world had been settled under an economy of food collection (hunting-gathering), and saturation with that economy had been reached. The world was then populated by roughly 1000 times more than the initial East African tribe that started

and produced the Out of Africa expansion. Demographic saturation of some especially rich areas (Middle East, China, Mexico, West Africa, and New Guinea) stimulated the development of food production (the agro-pastoral era). From these centers the new economy spread around at a rate about double that of the Out of Africa expansion, and today we have reached another saturation level, with a population size roughly another 1000 times greater than that when domestication of animals and plants began.

Language

Language was probably fully mature at the time of the origin of modern humans, and certainly had a fundamental place in the evolutionary success of our species. It would seem that another neurobiological function was also more highly developed in humans than in the other primates: the form of imagination that can lead to inventions that, if accepted, can rapidly change individual and social life. Communication permitted by language increased the efficiency of cultural transmission, the transmission of knowledge, and especially new knowledge created in every generation, and today the rate of spread of new information has practically the speed of light.

It may be useful to specify that the term 'culture' is used to indicate whatever knowledge and behavior is learnt from any sources during life, and thus includes also the novelties that are generated and transmitted. This is basically the simple idea that Lamarck used for explaining evolution, but today we know that biological evolution depends on transmission practically limited to that from parents to children, and therefore it takes many generations before a biological novelty (generated by genetic mutation) can spread to the whole population. While biological change deals with chemical, very simple changes of DNA, which are rare, spontaneous, and random, the cultural hereditary patrimony consists of novelties in our knowledge and behavior, that we can simply call, somewhat vaguely, 'new ideas,' and take, in cultural evolution, the same place that genetic mutations have in biological evolution. A first difference is that, unlike genetic mutations, new ideas are not random but aimed to give a specific result, which is hopefully useful to the people being taught, and/or (perhaps) to the inventor.

The other major difference between cultural, and biological evolution, is transmission. Biological evolution does transfer knowledge only from parents to children;

in culture the same mechanism has an honorable place (vertical transmission). When it is the only cultural transmission mechanism for specific traits, it may prove as conservative as biology. Certain types of information, for example, the religious one, and many other behavioral customs are learnt and more easily accepted more or less irreversibly during early ages of life. However, culture is transmitted also from anybody to anybody (horizontal transmission) irrespective of relationship, age differences, etc. Moreover, there are social institutions like schools or governments that impart instruction to large groups of individuals, and teachers or leaders of great influence because of intelligence, activity, power, or simply charm of the teacher/leader. Technologies such as writing invented between six and thousand years ago, has greatly increased the power of past knowledge: we still learn directly from Aristotle or Moses, but the ease of printing and using other mechanisms of transmitting information like radio and television have enormous power to influence large masses of people.

Natural Selection

The human species, like all others, is under control of natural selection, that is, it is governed by demographic laws such as survival and fecundity: individuals who create more of the next generation are those who survive more easily until maturity and/or are more fecund. The rate of evolution under natural selection depends on the variation of individual reproductivity (darwinian fitness, a measure of the adaptation of an individual, or of a genetic trait), which is a function of survival and fecundity of individuals. Natural selection thus adapts automatically a population (and the ensemble of populations forming a species) so as to guarantee optimal reproduction: living organisms are mechanisms capable of reproducing themselves, and their capacity to prosper is tantamount to their capacity to reproduce, that is, generate descendants that look like the parents in essential traits. For traits that are not affected by natural selection, the rate of evolution is equal to the mutation rate, and mutation is a rare, spontaneous, random event that is mostly neither advantageous or disadvantageous but selectively neutral. Under biological evolution alone, corrections and improvements take place by mutation and natural selection, but today we try to correct with our own medicines and decisions the problems that we can diagnose, and therefore we evolve mostly by cultural evolution. We also produce new problems for ourselves by cultural evolution. The corrections we try may produce benefit but, like any change, they will also have costs. Eventually, also cultural changes fall under the sickle of natural selection, if they decrease survival or fecundity.

A paradigmatic example is a problem called lactose intolerance, that is produced by milk consumption in

adults. Milk contains a sugar called lactose that babies of all mammals can digest and use to exploit a fair amount of the energy contained in milk. This is made possible by an enzyme called lactase that all babies produce, but after weaning everybody stops producing. Animal domestication of mammals by humans has stimulated also adult humans to use milk produced by domesticated mammals, but like all mammals humans do (did) not produce lactase after weaning. It happens that the indigestible lactose contained in milk taken by adults produces medical symptoms of a condition called 'lactose intolerance.' However, genetic mutations have arisen that repress the stopping of lactase production after weaning, and therefore make individuals lactose tolerant for all their lives. One of these mutations originated in the Ural mountains about 6 thousand years ago, in a population of reindeer shepherds who had developed the use of milk as food by adults. In a cold region it was a great benefit to be able to use the extra calories of milk without medical problems, and therefore natural selection greatly favored the custom arisen by mutation and transmitted to direct descendants of the original mutant. Practically all the reindeer shepherds thus became tolerant in a reasonable time because of natural selection, and the adult lactose-tolerance mutation spread to neighboring countries by mixed marriage. Today almost all Scandinavians show lactose tolerance, which is common also in most northern Europe, but is less and less common if we study the rest of Europe. Diffusion takes time and moreover in the south of Europe natural selection in favor of the mutant is not so impressive: in south Italy tolerance is 25%, in Sardinia 20%.

This is an example of biological and cultural coevolution with a relatively uncomplicated interaction. In animals like mammals which live on lactose containing milk lactase, at least in their junior years, production may have lasted all life. However, there is an economic advantage in general by not producing something that is not needed (and may even be disadvantageous). Thus, biological evolution of the mutation determining 'lactase production after weaning' may have spread early enough in the origin of mammals hundreds of million years ago. But cultural evolution generated the use of milk by human adults as a secondary effect of the domestication of medium size animals, a custom which had benefits (continuation of the greater energy production permitted by lactose use, especially in the cold); but also costs (lactose intolerance) for the rest of the population. It could be later eliminated by further genetic evolution. There are probably many other similar examples, and a fundamental cultural process, the introduction of agro-pastoral economies, was probably a major factor in determining genetic or cultural processes, or mixed ones like lactose tolerance, with increasing benefits and decreasing costs. They must have been quite different in the different areas of agro-pastoral economies.

The Four Major Factors of Biological Evolution

All novelty in biological evolution is determined by mutation: natural selection is the key to adaptation and therefore the maintenance of life through survival and fecundity, but there are two other major factors of evolution which also depend on demographic quantities: random genetic drift (or simply drift) and migration. Natural selection is the only source of adaptation, which is formally measured by darwinian fitness, but biologically we are also interested in knowing the specific anatomical and physiological mechanisms that are responsible for greater or lesser reproduction of individuals possessing given traits. Thus, a dark skin color helps resisting higher temperatures determined by more solar radiation, because where the amount of ultraviolet radiation is increased, skin cancer is also increased. Therefore, skin color is darker where latitude is lower. However a peculiarity, white skin, is another case of natural selection due to a cultural novelty. Skin is white in Europe because wheat, the major food of Europeans, introduced somewhat before 10 000 years ago in a small village at the boundary between Turkey and Syria, does not contain vitamin D. Wheat became a major food with agriculture. If vitamin D is not contained in sufficient proportions in the diet, bones do not grow properly, and serious, life-limiting rickets is generated. But wheat does contain a precursor which can be transformed into vitamin D under the skin, under irradiation by enough ultraviolet. A dark skin prevents the sun ultraviolet (UV) from reaching the derma under the skin where the enzyme is found, and mutations to white skins have been formed and spread where they are useful, in the north of Eurasia for wheat eaters.

Drift

Drift is the consequence of statistical fluctuations of gene frequencies due to the finite size of populations. It is measured by the number of reproducers per generation, N , which is about one third of the population census for human populations. The smaller is N , the greater is the genetic variation among populations, estimated by variance measurements, and the smaller that within populations. Variation within one population is also measured in a very simple way also by another quantity called genetic diversity, which is the estimate of heterozygosity of the individuals forming the population, averaged over all genes.

Migration

Migration among populations reduces diversity among populations, that is, it has the same effect as increasing N , and therefore one often considers these two factors together by uniting them into the quantity Nm . When

Nm is high, genetic diversity among individuals of a population is high, and that among populations low.

Founders' Effects

The greatest effects of drift are seen for rare recessive genes. The most famous is Tay Sachs disease, which causes blindness, dementia, and death in the first year of life in children born perfectly normal. Healthy carriers of the disease (heterozygotes) are 1/25 among Ashkenazi Jews in New York, and the incidence of Tay Sachs is one in 2500 births. The disease is absent or extremely rare elsewhere, and also in other Jewish ethnic groups who, after the Jewish diaspora, peopled world parts other than N. Europe. There were many millions of Ashkenazi Jews in N. Europe before the Holocaust, but they probably originated from a very small group that migrated from Rome to N. Europe in the Middle Ages. Fifty percent of them descend from just four women, but there was very substantial growth that generated the several millions of Jews living in N. Europe before the Holocaust. One founder of Ashkenazi Jews, or more probably one of their descendants not many generations after the founding, was a heterozygote for a mutation of the Tay Sachs gene that, being recessive, multiplied undisturbed in children and later descendants of the mutant. Under these conditions, if a heterozygote marries a fully normal individual, their children have a 50% chance of being heterozygotes. At some later stage two heterozygotes may marry with each other and, according to Mendel's expectations, one out of every four of their children is expected to show the disease.

Today this terrible disease has practically disappeared, thanks to prophylactic abortion of fetuses diagnosed as diseased. Conservative rabbis who do not accept prophylactic abortion suggest that heterozygotes should take a DNA test before marriage, and avoid marrying together if they are both heterozygotes. Many other rare genetic diseases can be diagnosed by simple DNA tests. Two populations – Quebec in Canada, and Capetown in S. Africa – were generated by a relatively small number of founders. Both colonies started approximately around 1650, by numbers of colonists of order of 2000. Records of marriages of their descendants exist for both. Among descendants a few genetic diseases or minor traits are found that are very rare or unknown elsewhere. The founders or early descendants who carried the mutants have been identified by the reconstructed genealogies.

Worldwide Phenomena Showing the Quantitative Importance of Drift

Drift is not noticeable only for these observations on rare genetic diseases, but is responsible for much more general phenomena. An effort of whole word analysis of human

populations, the Human Genome Diversity Project, has generated a collection of cell lines totaling about 1000 individuals, coming from 52 aboriginal populations of the five continents. It is deposited at the Fondation Jean Dausset of Paris (HGDP-CEPH). DNA produced from the cell lines is available to research workers. In order to avoid DNA patenting that would hinder research, pharmaceutical factories have not access to these DNAs, and all results must be published. One very clear result obtained with 783 micro-satellite genes, and confirmed with 650 000 single nucleotide polymorphisms of the Illumina microarray is that there is a very regular linear fall of genetic diversity, measured as heterozygosity, as a function of geographic distance from the likely place of origin of the population of ~1000 East African hunter-gatherers that started the Out of Africa expansion and occupied the whole world. The most likely explanation of this fall of genetic diversity is a phenomenon called the serial founder effect. It is assumed that the expansion occurred as a sequence of steps, each of which consisted of the foundation of a small colony of the furthest population, farther away from origin. The number of steps between the East African origin and the most extreme periphery occupied (in Chile) must have been in the hundreds, on the basis of simulations that used demographic data in agreement with archeology and anthropology information. Each step must have determined an episode of founder effect, as the numbers leaving the mother colony for founding a daughter colony in unsettled territory in the immediate neighborhood were probably small.

Migration Rates during the Recent Expansions of the Human Species

The migration m mentioned earlier refers to the proportion of population exchanged between two neighboring colonies. Another migration rate, that of expansions of the human species, can be estimated. The first is the hunter-gatherers (HG) expansion from East Africa to the furthest place, Chile, passing through the Bering strait. This distance is $c.$ 25 000 km, and was covered in 50 000 years, i.e. 0.5 km per year. When the world was settled and the hunting-gathering economy was replaced by at least four independent developments of agro-pastoral (AP) economy (in the Middle East, E. Asia, Mexico and West Africa, in order of time, from 11 000 to 4000 years ago) the rates of migration of km/year of these farmers expansions was greater (1 km a year and more). At the time of the agricultural expansions all technologies were more refined, and movement was not in an essentially unsettled territory like the HG expansion (at that time the world outside Africa was occupied by *H. neanderthalensis* in Europe, and very sparse *H. erectus* and *H. flores* in Asia, which must have had very low population densities. It

seems in both cases there was no sign of conflict or admixture of *H. sapiens* with the earlier inhabitants, in agreement with the hypothesis that they all belong to different species that developed after a very first diaspora from Africa of the genus *Homo* some two million years ago. The farmers' expansions were in territory previously settled by hunter-gatherers, but there was probably frequent intermarriage between the new settlers and the residents, generating a peculiar admixture with a gradient of relative frequency.

The same microsatellite and the 650 000 Illumina data used for the serial founder effect were also analyzed for the correlation between genetic and geographic distance of population pairs. The latter are estimated as the crow flies (but via Bering for comparison between an American and a non American individual). The correlations (0.89 and 0.91) are among the highest observed in any biological phenomenon. Simulations showed they could be interpreted assuming that quantitatively the major evolutionary factors were drift, migration, and mutation, and that the effect of natural selection determining differences among populations was rather modest. Selection examples have been shown to be present but are mostly relatively local events. The adaptive reason of most remains to be explained.

Evolution of Major Neurobiological and Sociobiological Traits and Syndromes. General intelligence

Most normal and pathological traits do not behave as simple mendelian traits, but nevertheless many and perhaps most have at least some partial genetic component. A measure called 'heritability' has been introduced to indicate the percentage fraction of variation of the trait that can be due to genes. It is usually calculated on the basis of correlations between relatives of various degrees, from twins of various types to parent-child, sib-sib, and less close relatives. A simple classical theory shows the expected quantitative relations between these correlations and helps to give a rough analysis of the accuracy of the heritability estimate.

An analysis of the intelligence degree, originally suggested to help the discovery of presumably retarded children needing education in special schools, has later been further developed in the idea that it can evaluate 'general intelligence.' The quantity measured is called IQ (intelligence quotient), and a large number of testing methods were advanced, which tend to give similar results and are correlated with success in schools, as judged by scholastic performance. The IQ test has been widely developed and standardized for age, and also for sex, since girls tended to give higher average scores (perhaps because of higher precocity). Correlations of high IQ

and success in various professions gave rise to over-interpretations, and excessive confidence that it might measure genius. In reality, most interesting geniuses have rather a highly specialized intelligence (e.g., in music, mathematics, philosophy, various forms of science, art and literature, and even politics) and are often pathological in other respects (being schizophrenic, or autistic, or having other behavioral abnormality). One of the two men who revolutionized genetics by discovering DNA structure gave a serious blow to the idea that all geniuses have extremely high IQ, by making it known that his IQ did not even reach the 5% upper level. IQ is correlated clearly with reasoning ability and capacity to learn, but exceptional success in life depends more often on exceptional ability in some specific direction, rather than in the average skill needed in scholastic work.

Study of the heritability of IQ gave very high values, especially if based on data of identical twins. However, the extension of studies showed that socio-cultural inheritance has considerable importance, also for identical twins. Trials to answer this objection were made by testing identical twins reared apart, but they are very few and often far from answering the conditions necessary to accept their validity (e.g., many of those reared apart actually lived in the families of close relatives). The extraordinary interest of identical twins to keep close ties leaves a feeling of doubt that the results are somehow influenced by the desire, probably subconscious, that the resemblance is very high. More accurate tests of the environment and statistical analyses using many degrees of relationship concluded that three causal factors have about equal power in IQ: (1) genetics, (2) socio-familiar environment, (3) special unpredictable events of various nature in individual lives. It is interesting that in the beginning two very high quality research groups who analyzed a vast body of published data with the most advanced methods came to quite different estimates of heritability. Later one group withdrew its conclusions and replaced them with results very near to those of the other group, which are those summarized very concisely above. Very few other intellectual skills were examined so extensively, but the most serious and common psychiatric diseases like manic-depressive syndromes, schizophrenia and autism do certainly have both genetic and socio-cultural components. It may be that in all very common disorders and physical and intellectual traits causal factors may turn to give not very inspiring results similar to the above ones. These methods however rely on one simplifying assumption that may obscure or cancel many real and interesting complications: they assume all factors interact additively. One sobering consideration comes from results in the study of a measurable quantity in yeasts: temperature resistance, which can be important

for the pathogenic effects of individual strains. In an organism genetically as malleable as yeasts, in which all possible combinations of genes can be artificially created and their phenotype tested, it was found that different sites even within one gene can have oppositely interacting, reciprocally neutralizing effects. In the human species, in which experimentation of the same kind would be required, one is obviously more limited to carrying out certain types of analysis at a high genetic resolution. Such complicated interactions will probably be studied also in humans, but will be limited to traits that can be studied *in vitro*, in practice only on human cell lines, or *in vivo* using animals in which one can transfer human genes.

In spite of all these difficulties, in the case of some of these highly polygenic diseases which have strong cultural and environmental components, when the DNA of each individual was analyzed, it was possible to identify some DNA segments that have partial but reproducible phenotypic effects. In this genome era one can expect that progress will be rapid, but the analysis is very expensive and is time consuming even with very powerful computers, because of the number of interacting factors, and of the number of DNA units involved and their size. It will also most probably require large numbers of patients for each disease. Nevertheless, a new field is open for the brave.

Glossary

Gene polymorphism – A variation in the DNA sequence that occurs in more than 1% of the population.

Although quantitative behavioral genetics has long established the heritability of personality traits, the underlying mechanisms responsible for individual differences across a broad set of complex behaviors have been poorly understood. Starting with molecular genetic discoveries in the 1990s, and the advent of genomic imaging or imaging genetics in the early years of the new millennium, these mechanisms are now accessible to study. In this article, we give a broad overview of how molecular biology and neuroimaging have advanced our understanding of the biological basis of personality, and briefly discuss our view of the future direction of the field.

Genetic studies of personality traits have to address four concerns. First, most conceptualizations of traits, for example, impulsivity, are not rooted in biology. Second, any one trait may be affected by multiple genes with small effect sizes quantitative trait loci (QTLs), as illustrated by studies of intelligence and neuroticism, and any one gene may participate in more than one trait. Third, gene expression can be regulated by environmental variables, including life experience, and may involve epigenetic or other regulatory mechanisms that are still poorly understood. Fourth, the scale of these regulatory changes may be very large, affecting multiple hundreds of genes that participate in complex molecular signaling pathways, posing analytical challenges that can only be addressed with advances in bioinformatics. These four concerns are central to the emerging field of ‘molecular psychology,’ which focuses on the molecular mechanisms underlying complex behaviors. In the remainder of this article, we highlight the current state of molecular psychology with respect to the study of personality.

Associations between Personality Traits and Individual Genes

Molecular psychology’s birth year may be 1996, when a set of studies was published that first reported significant associations between specific gene polymorphisms and personality traits. The first study reported an association

between a common variation within the promoter region of the serotonin transporter gene (5-HTT) and the personality traits of neuroticism and harm avoidance. In this study, higher levels of self-reported harm avoidance or neuroticism were associated with the presence of the short allele, caused by a deletion polymorphism that is located in the 5' promoter region of the gene (5-HTT linked polymorphic region, 5-HTTLPR). Functionally, this short allele is associated with reduced levels of 5-HTT, suggesting that the genetic regulation of serotonergic tone is associated with these personality traits. A large number of replication studies have produced conflicting results, but two meta-analyses concluded that the evidence supports a small but significant association between the 5-HTTLPR polymorphism and neuroticism. Indeed, even the original study found that this polymorphism could account for only 3–4% of the total variance, suggesting that many more genes may be involved in the regulation of this personality trait.

Also, in 1996, two other studies reported associations between a common variation in the dopamine D4 receptor gene (*DRD4*) and the personality traits of extraversion and novelty seeking. The polymorphism was a variable number tandem repeat (VNTR) located in exon-III of the gene, with the most common variants being 2-, 4-, and 7-repeats. Functionally, these repeats differ in their efficiency in response to dopamine. The 7-repeat allele was shown to be less efficient than the 2- and 4-repeat alleles and the 10-repeat allele was shown to be more efficient than the 2-repeat allele. The 7-repeat allele, in particular, was associated with elevated levels of extraversion and novelty seeking. In addition to the VNTR, the *DRD4* was also shown to have a single nucleotide polymorphism (SNP) (C-521T) in its promoter region, which causes a 40% decrease in the transcription of the gene with the T allele compared to the C allele. Presence of the C allele was associated with higher extraversion and novelty-seeking scores. Subsequent replication studies produced conflicting results and two meta-analyses concluded that there was no association between extraversion and either of these *DRD4* polymorphisms. However, one of these meta-analyses did conclude that there was evidence for a significant association between novelty seeking and impulsivity traits and the *DRD4* C-521T polymorphism. Similar to the 5-HTTLPR polymorphism, the gene accounted for only a small fraction (about 3%) of the total phenotypic variance, suggesting the involvement of many other genes in these traits.

The search for novel candidate genes for complex traits continues. For example, a SNP within the gene that regulates catechol-O-methyltransferase (COMT), which degrades catecholamines (including dopamine), may be associated with extraversion and/or neuroticism. The SNP is the Val¹⁵⁸Met polymorphism, which results in an amino acid change from Valine to Methionine and a 75% decrease in the enzyme's ability to degrade dopamine. Individuals with the Val–Val genotype were reported to have significantly higher extraversion scores, although no association with neuroticism was reported. However, another study, conducted on a female sample, reported a significant association between harm avoidance (a trait conceptually similar to neuroticism) and presence of the Met allele. Another study is consistent with this association, reporting a higher frequency of the Met allele in highly neurotic females, but not males, suggesting that sex is a critical variable.

Although other polymorphisms have been investigated, the discovery of single polymorphisms that show a consistent association with specific traits remains elusive. What is clear now is that the genetics of personality traits is complex, and likely to be affected by large number of genes and gene networks, any one of which may further interact with other genes or be modulated by environmental stimuli. Thus, researchers are increasingly looking for technological breakthroughs that will allow them to query very large numbers of genes, moving the field from individual candidate genes to whole-genome association studies.

Associations between Personality Traits and Whole Genomes

By current estimates, human genetic variation is about 0.5%, and studies devoted to cataloging and data-basing this variation are being conducted. Technological advances in gene microarrays are fast: in 2007, it was possible to probe for 500 000 SNPs at a time; by 2008, that number had doubled. To date, the cost per array is still relatively high, making it too expensive to use in very large-scale genetic studies. To address this problem, some investigators have used a method that involves pooling DNA samples from individuals that share a characteristic of interest, and compared the results of whole-genome analysis for this pooled DNA with that of a control group. In one such study, pooled DNA from about 2000 individuals (selected out of a cohort of more than 88 000 subjects) was used in a whole-genome association study of neuroticism. Surprisingly, this study failed to identify any SNPs that account for more than 1% of the variance. The paucity of positive results for whole-genome associations with personality traits gives us pause. As is always the case with null results, many reasons come to mind. We

listed four possible reasons in the introduction of this article. Even larger sample sizes, and even more sophisticated bioinformatics and data reduction approaches may be needed to identify relevant gene candidates. In addition, the choice of phenotype measures and the possibility of interactions with environmental variables may be significant factors that obscure a simple gene–trait association that many have sought. We turn to a discussion of these two factors next.

Endophenotypes and Imaging Genetics

The reliance on self-report has been a weakness in single-gene and whole-genome association studies of personality traits. The need for more objective phenotypes that can be linked more closely to genotypes was fulfilled by the use of endophenotypes such as cognitive-affective processes or localized brain measures. The power of the endophenotype approach is illustrated by the rapidly growing literature of functional brain imaging studies of individuals genotyped for the 5-HTTLPR polymorphism, beginning with a study by Hariri and colleagues, in which they reported a significant association between the short allele and increased amygdala activation in response to negatively valenced faces. While the interpretation of this observation continues to be debated, the basic phenomenon is very robust, and has been replicated consistently across many imaging studies, and recently confirmed by a meta-analysis. One reason for such consistency is that the effect size is much larger when genetic variation is mapped onto an endophenotype (which is closer to the level at which a gene operates) than a more distal phenotype, such as self-reported behavior.

Gene x Environment Interactions

In the first molecular genetic study to report a gene x environment interaction (GxE), Caspi and colleagues discovered that a common variation within the gene that codes for monoamine oxidase A (MAOA) moderates the effects of childhood maltreatment on aggressive behavior later in life. It was reported that maltreated children with the genotype that results in relatively low levels of MAOA are more prone to exhibiting antisocial behavior and conduct disorder, and are more involved in violent behavior. A meta-analysis confirmed these results, although the debate on the implications of this finding continues.

Paralleling the findings on early adversity and monoamine oxidase-A (MAOA) genotype affecting later behavior, it was reported that the effects of life stress on later depression are moderated by 5-HTTLPR genotype, such that carriers of the short allele have twice the level

of depressive symptoms, diagnosed depression, and suicidality than noncarriers do. Another study replicated this association finding, although later studies suggest additional moderating factors, such as social support, age, or sex. Indeed, a recent meta-analysis concluded that the GxE interaction may not be valid for studies using clinical phenotypes of depression. We think that endophenotypes, such as those based on imaging genetics, may provide more reliable measures of GxE effects.

A GxE interaction for 5-HTTLPR genotype was reported in an imaging study, which reported that carriers of the short allele exhibited greater activation in the amygdala (and elsewhere in the brain) as a function of life-stress experience. In these same individuals, more life stress also correlated significantly with higher levels of rumination, a risk factor for depression. Interestingly, noncarriers exhibited the opposite pattern: more life stress was associated with reduced amygdala activation and less rumination. The data illustrate that both carriers and noncarriers of the short allele may respond to life stress, but in opposite directions.

An attractive candidate for a molecular mechanism of these GxE interactions is ‘epigenetic programming,’ which causes changes in gene activity (turning on or off genes, altering their expression levels) that does not involve DNA sequence alterations. One such epigenetic mechanism involves DNA methylation, in which methyl groups are added to the cytosine bases on DNA, with the functional consequence of reducing or silencing gene expression. Indeed, there is now preliminary evidence for methylation differences as a function of 5-HTTLPR genotype. However, the best evidence for a GxE interaction to date comes from rodent studies that have shown that early maternal experience alters methylation of the glucocorticoid receptor gene in a manner that affects later stress reactivity and that is reversible through cross-fostering or through chemical agents that reverse gene methylation.

Conclusion

In this very brief survey of molecular psychology studies of personality, we present the evolution of a field that has moved from a search for simple associations of single candidate genes toward a search for whole-genomic variation and identification of interacting variables, as well as their underlying molecular mechanisms. Building on a decade-long and rich literature from behavioral and quantitative genetics, the first molecular psychology studies of 1996 and thereafter focused on discovering associations between single-gene polymorphisms and self-reported personality traits. Although there are some successes (most notably the discovery of the 5-HTTLPR polymorphism and its association with neuroticism,

which remains to date the strongest candidate gene after more than a decade of searching for other genes) in this endeavor, it is now clear that the use of endophenotypes may be better suited to discover associations between gene variants and individual differences in behavior or in the neural substrate that regulates these behaviors. We still await breakthroughs in the discovery of more candidate genes by way of whole-genome association studies, but results so far are disappointing.

Attention is now increasingly directed at more complex interactions between genes and other variables that may affect personality traits and individual differences in other behaviors. This is particularly true with respect to the potential role of epigenetic mechanisms, which may regulate gene expression through exposure to life stressors. Exactly how life stress alters epigenetic programming will undoubtedly become a major theme of future genetic studies. Given this focus on reductionistic explanations, we need to remind ourselves that genetic regulation through environmental influences need not be a passive event: the individual too plays a role in shaping an environment as an active agent. It is possible that an individual’s agency may ultimately affect his or her gene expression, closing the circle between nature and nurture.

Role of Gene Transcription in Long-Term Memory Storage

J Hawk and T Abel, University of Pennsylvania, Philadelphia, PA, USA

Glossary

Central Dogma of Molecular Biology – First articulated by Francis Crick in 1958, it states that biological information flows from deoxyribonucleic acid (DNA) to ribonucleic acid (RNA) to protein. This hypothesis has been a cornerstone of biology for the past 50 years, yet recent findings have challenged the absolute hegemony of this view. For instance, epigenetic modifications represent a mechanism by which environmental information interfaces with DNA to restrict the information flow out of the genome.

cAMP-response element (CRE)-binding protein (CREB) – A transcriptional activator that binds to CRE sites (consensus: TGACGTCA) in genomic DNA. CREB is a basic leucine zipper (bZIP) transcription factor that is phosphorylated at residue serine-133 in response to activation of cAMP-dependent protein kinase (PKA) and mitogen-activated kinases (MAPKs). Phosphorylation-dependent interaction with the co-activator CREB-binding protein (CBP) strongly enhances transcription of CREB target genes.

Epigenetics – DNA-encoded genetic information is identical in the vast majority of cells in the metazoan body, yet a variety of distinct cellular properties are required to generate the multitude of cell types that make up the body. This paradox led C.H. Waddington to propose in the late 1950s that mechanisms other than genetic information can mediate and maintain cell fate decision. A number of developmental epigenetic markers have been defined such as post-translational modification of histone proteins and covalent modification of DNA. Recent research suggests that these epigenetic mechanisms are used in the mammalian brain to guide transcription during memory formation.

Hippocampus – Nestled under the medial temporal lobe of the neocortex, the hippocampus is critical for the formation of spatial and contextual memory. In humans, the hippocampus is required for the formation of episodic memories, a type of autobiographical memory about events set within time and place often summarized as ‘what-where-and-when.’

Histone – The four core histones (H2A, H2B, H3, and H4) form the basis of DNA packaging. These proteins, each in duplicate, are encircled by 146 bp of DNA to form the nucleosome. The amino-terminal tails of histone proteins extend out of the nucleosome and are

sites for post-translational modifications that form the basis of epigenetic information storage. A number of histone amino-terminal tail residues are sites for specific types of modification; for instance, particular lysine residues can be acetylated or methylated to modulate gene expression.

Memory consolidation – The process by which an initially labile short-term memory is converted into a long-term memory in the hours following learning.

Messenger ribonucleic acid (mRNA) – These processed RNA molecules are transcribed from genomic DNA and read by translation machinery into proteins. This biopolymer is the key mechanism by which information is transferred from DNA to protein in accord with the Central Dogma of Molecular Biology. In eukaryotes, sequence-specific transcription factors recruit DNA-dependent RNA polymerase (RNAPII) to genes, which produces precursor RNA (pre-mRNA) copies of DNA. Mature mRNA is produced by removing intronic sequence (splicing), 5' capping with 7-methylguanosine, and 3' poly-adenylation.

Transcription – The process of producing a ribonucleic acid (RNA) copy of a deoxyribonucleic acid (DNA) template sequence. RNA is generated using complementarity of base-pair interactions to specify the appropriate ribonucleotide that is inserted into the growing chain of RNA by the enzyme RNA polymerase (RNAP).

Transcription factor – Broadly defined as any protein required to initiate or regulate transcription. Often, as in this article, this term refers to sequence-specific DNA-binding proteins that bind to regulatory regions of specific genes where they control the efficacy of transcription. By contrast, general transcription factors are required for the transcription of the majority of eukaryotic genes.

Transgene – A gene that is derived from one organism and introduced into another. As with any gene, the transgene includes DNA sequence that is to be transcribed and regulatory elements that control transgene transcription.

Translation – The process by which mRNA is used to guide the production of a protein by the ribosome. The incorporation of each amino acid in a protein is specified by a sequence of three nucleotides referred to as a codon.

Introduction

More than 100 years ago, the psychologists Georg Müller and Alfons Pilzecker discovered that, shortly after learning, memories are unstable and sensitive to retroactive interference from new learning, but with time these labile short-term memories are converted into stable long-term memory through a process that became known as consolidation. Since that time, research in organisms ranging from sea slugs to mice has shown that this consolidation process involves the activation of neuronal signaling cascades that result in the production of new RNA and protein. This *de novo* transcription and translation after learning is a hallmark of the consolidation process that distinguishes long-term memory from short-term memory. Our understanding of the molecular mechanisms of memory formation has evolved considerably over the past few decades largely due to the development of genetic and molecular strategies to study memories, especially those memories known to require specific neuronal circuits, such as hippocampus-dependent spatial and contextual memory.

Stages of Memory: Acquisition, Consolidation, and Retrieval

Long-term memory formation proceeds through three distinct phases: acquisition, consolidation, and retrieval. Acquisition is the process of learning information about the world and initially produces a labile short-term memory that can be disrupted through interference by new learning, seizure, or inhibition of a variety of cellular and molecular processes. Consolidation occurs with time after learning to confer resistance to disruption, thus converting a short-term memory into a long-term memory. Once information has been stored, it must be retrieved to guide behavior. The specific processes that are required for the formation of long-term memory provide insight into the mechanisms responsible for each of these phases. For instance, disruptions that selectively affect long-term memory without impairing short-term memory provide knowledge about the consolidation process. The earliest of these studies showed that pharmacological inhibition of transcription or translation blocks long-term memory, while leaving short-term memory intact. In the 1960s and 1970s, researchers working on organisms ranging from goldfish to mice established that shortly after acquisition there are windows after learning during which transcription and translation are required to consolidate memory. These early pharmacological studies have been substantiated by genetic approaches that demonstrate a critical role of transcription factors in memory consolidation after learning.

The Hippocampus is Critical for Spatial and Contextual Memory

In 1957, the pioneering studies of Scoville and Milner first suggested that damage to medial temporal lobes structures, especially the hippocampus, causes an inability to form new episodic memories in humans. Since that time, experiments in rodent models have substantially advanced our understanding of the role of the hippocampus in memory formation. Two behavioral paradigms, contextual fear conditioning and spatial learning in the Morris water maze (**Figure 1**), have been particularly useful for understanding the role of the hippocampus in memory. The Morris water maze, first developed by Richard Morris, has become the archetypal measure of spatial learning and memory. Rodents are naturally good swimmers but will seek escape from water when placed in a pool. In the Morris water maze, this tendency is used to motivate rodents to find an escape platform submerged below the surface of water that has been made opaque. With repeated training, the rodents find the platform more quickly in a manner that depends on distal cues. Performance in this task can be measured in a probe test in which the platform is removed and the search pattern of the swimming rodent is examined for a bias toward the region that previously contained the platform (**Figure 1(b)**). Hippocampal lesions block acquisition in this measure of spatial memory but leave intact the ability to swim to a visible platform. Because rodents require repeated training sessions to learn the platform location, it is often difficult to dissociate the effect of manipulations on acquisition and consolidation. The contextual fear conditioning task provides an opportunity to disentangle these two processes by producing a robust long-lasting memory in only a single training session with the added benefit that the biochemical consequences of learning can be precisely related to the time of learning. Contextual fear conditioning involves quantifying a species-specific, stereotyped fear response, including activation of the sympathetic nervous system and a characteristic freezing posture, to measure the retention of an associate between a footshock and a particular context (**Figure 1(c)**). Measuring short-term memory in this task provides a key control in consolidation studies by determining whether learning is possibly impaired. Contextual fear conditioning is disrupted by lesions of the amygdala and the hippocampus, but the closely related cued fear conditioning task, in which freezing is measured in response to a discrete cue, is affected by lesions of the amygdala but not the hippocampus. Therefore, cued fear conditioning serves as a control task to suggest hippocampal specificity when using contextual fear conditioning, providing critical information about whether observed changes in contextual memory are likely due to changes in hippocampal function.

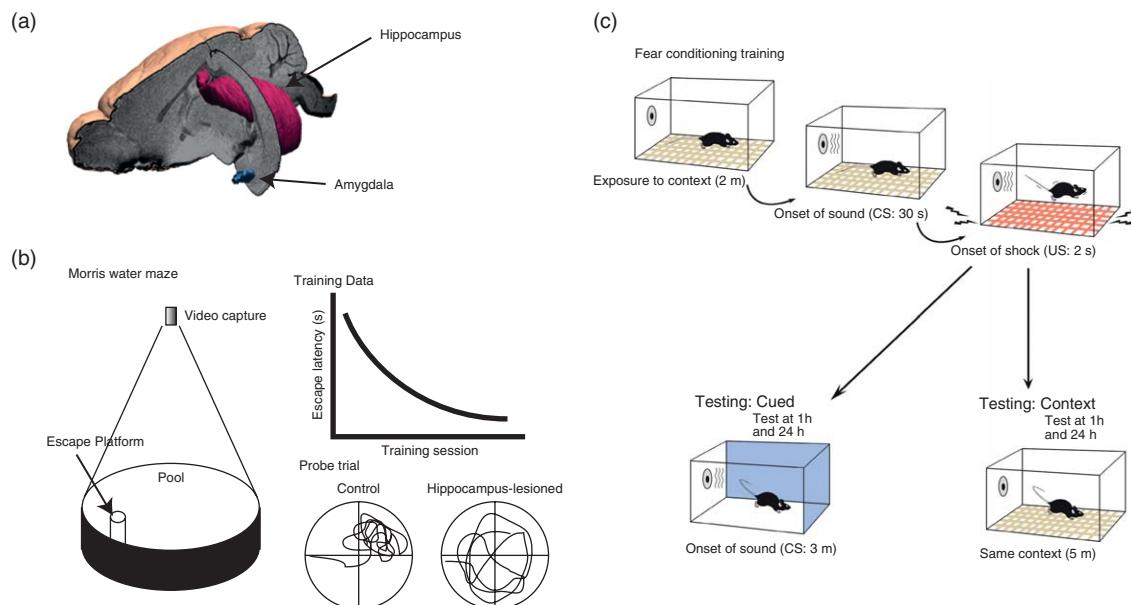

Figure 1 Hippocampus-dependent memory tasks. (a) The hippocampus and amygdala, located in the medial temporal lobe of the cerebral cortex, play critical roles in memory formation. (b) The Morris water maze is a spatial learning and memory task that requires the hippocampus but not the amygdala. In this task, mice learn the position of a hidden escape platform during repeated training session, as measured by a reduced time to find the platform (escape latency). Memory for the platform location is assessed in a probe trial in which the platform is removed. A trained mouse will search extensively within the quadrant that formerly held the platform, whereas a mouse with hippocampal lesions will have no spatial bias to its search for escape. (c) Fear conditioning is an associative memory task that typically involves the pairing of a shock with a novel context and a cue, such as a white noise or tone. During training, a mouse is placed in a novel context and allowed to explore briefly. After the exploration period, a sound is played that co-terminates with a footshock. This training paradigm produces both context-shock and cue-shock associations that can be measured by quantifying a stereotyped and species-specific fear response characterized by immobility, or freezing. The freezing response upon reexposure to the cue in a distinct context measures cue-shock association, while freezing upon reexposure to the training context measures context-shock association. Both of these forms of associative memory require the amygdala, but cued fear conditioning does not require the hippocampus. (Source: Memory, Kandel).

Hippocampal Synaptic Plasticity as a Model for Memory

The existence of well-controlled, hippocampus-dependent memory tasks has been instrumental in establishing a role of individual molecules in memory formation, but another key factor in driving the study of molecular mechanisms of hippocampal memory has been the development of *in vitro* paradigms to examine the changes in synaptic strength after electrical stimulation of neurons, termed activity-dependent synaptic plasticity (Figure 2). The discovery by Bliss and Lomo in 1973 that high-frequency stimulation of connections between neurons in the hippocampus leads to a long-lasting increase in the strength of those connections, termed long-term potentiation (LTP), provided powerful experimental support for Donald Hebb's earlier prediction that learning could emerge from the selective strengthening of connections between neurons firing simultaneously, a key principle of Hebbian learning theory that is often paraphrased as "Neurons that fire together wire together." The initial work by Bliss and Lomo was followed by a flurry of research into the molecular mechanisms of

synaptic plasticity at specific hippocampal synapses using *in vitro* preparations. For instance, a single high-frequency burst of stimulation to the Schaffer collateral pathway from CA3 to CA1 of the hippocampus (Figure 2(a)) produces a relatively short-lived and protein synthesis-independent form of LTP known as E-LTP (Figure 2(b)), but repeated tetani induce a much longer lasting form of LTP (L-LTP) that requires protein synthesis and transcription. The knowledge gained from studies of these and other forms of LTP continue to guide learning and memory research.

Signaling Cascades Involved in Synaptic Plasticity and Memory Formation

By the late 1980s, pharmacological and physiological experiments had paved the way for genetic approaches to study memory formation by suggesting key molecular players in synaptic plasticity and memory formation, such as the *N*-methyl-D-aspartate (NMDA) receptor, calcium/calmodulin-dependent kinases II (CaMKII), and cyclic AMP (cAMP) signaling (Figure 3). For instance, the

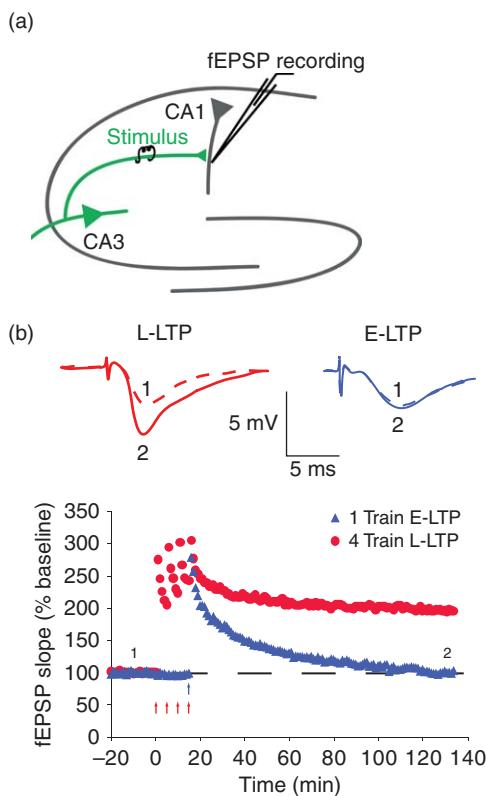

Figure 2 Hippocampal synaptic plasticity. (a) The most heavily studied synapses in the brain are those of the CA3-CA1 Schaffer collateral pathway. This connection is commonly examined using *in vitro* hippocampal slice preparations as illustrated here. A stimulating electrode is placed in the CA3 axon bundles projecting to CA1, and a recording electrode measures field excitatory postsynaptic potentials (fEPSPs) in the synaptic layer of CA1. (b) Representative fEPSPs are illustrated before potentiation with dashed lines (1) and 2 h after potentiation with solid lines (2). Sample fEPSPs are measured by stimulation at 1-min intervals throughout the recording and the initial slope of the fEPSP is plotted relative to baseline fEPSPs prior to potentiation. The slope of the fEPSP increases after both a single 100-Hz tetanus (blue) and four 100-Hz tetani (red), producing long-term potentiation (LTP). LTP induced by a single tetanus, which dissipates more quickly, is referred to as early-LTP (E-LTP), but LTP produced by four tetani, which persists much longer, is called late-LTP. Both E-LTP and L-LTP require NMDA receptor and CaMKII activity, but only L-LTP requires PKA activity.

induction of LTP at CA3 to CA1 synapses, the Schaffer collateral pathway, depends on the activation of NMDA receptors, a type of ionotropic glutamate receptor that requires both the presence of glutamate in the synaptic cleft, glycine binding, and depolarization of the postsynaptic neurons, which releases a voltage-dependent magnesium blockade of the channel pore. Thus, NMDA receptors act as molecular coincidence detectors between pre- and postsynaptic activation, a property that is an important component in the Hebbian theory of associative learning. Unlike other ionotropic glutamate receptor, the NMDA receptor fluxes large amounts of calcium into

neurons. Once inside neurons, calcium activates signaling cascades through calcium-bound calmodulin ($\text{Ca}^{2+}/\text{CaM}$), including type I adenylyl cyclase and CaMKs. Subsequent pharmacological studies showed that inhibitors of CaMKII block the induction of LTP at the Schaffer collateral pathway. Although CaMKII is required for the induction of both E-LTP and L-LTP, cAMP-dependent kinase (PKA) activity is required only for the long-lasting transcription-dependent phase of L-LTP, providing the first suggestion that the PKA pathway may be responsible for initiating the transcriptional program that mediates long-term changes in synaptic strength. Behavioral studies have shown striking co-incidence between the molecular mechanism required for synaptic plasticity and memory formation. For instance, inhibitors of PKA cause long-term memory impairments but leave short-term memory intact. In fact, these deficits emerge several hours after training, paralleling the memory deficits induced by transcription inhibitors. Pharmacological studies provided a critical step in the process of identifying the molecular mechanisms guiding memory formation, but drugs often have off-target effects and only a few of the molecules involved in memory are likely to be good drug targets. Further, pharmacological agents have an impact on glia as well as neurons. Reverse genetic approaches, on the other hand, can readily target an individual gene and can manipulate specific aspects of protein function, even in defined cell types, to elucidate the genetic basis of memory.

Genetic Approaches to Examine the Molecular Mechanisms of Mammalian Memory

The advent of knock-out mice in the late 1980s opened entirely new avenues for the study of mammalian learning and memory. With this technique, the role of an individual gene or isoform in memory formation could be examined without the limitations of drug specificity. Knock-out mice are produced using gene-targeting techniques developed by Cappucci, Evans, and Smithies, for which they won the 2007 Nobel Prize in Physiology or Medicine. This process involves the careful selection of homologous recombination events in mouse embryonic stem (ES) cell lines, which are subsequently injected into developing blastocysts (Figure 4(b)). Homologous recombination, the swapping of DNA between identical DNA sequences, occurs at very low frequency, but a resistance marker in the gene-targeting construct is used to select the few ES cells that undergo recombination for injection into a developing embryo. In addition to allowing for selection, the resistance marker replaces an exon, a piece of the gene coding sequence, leading to elimination of any proteins

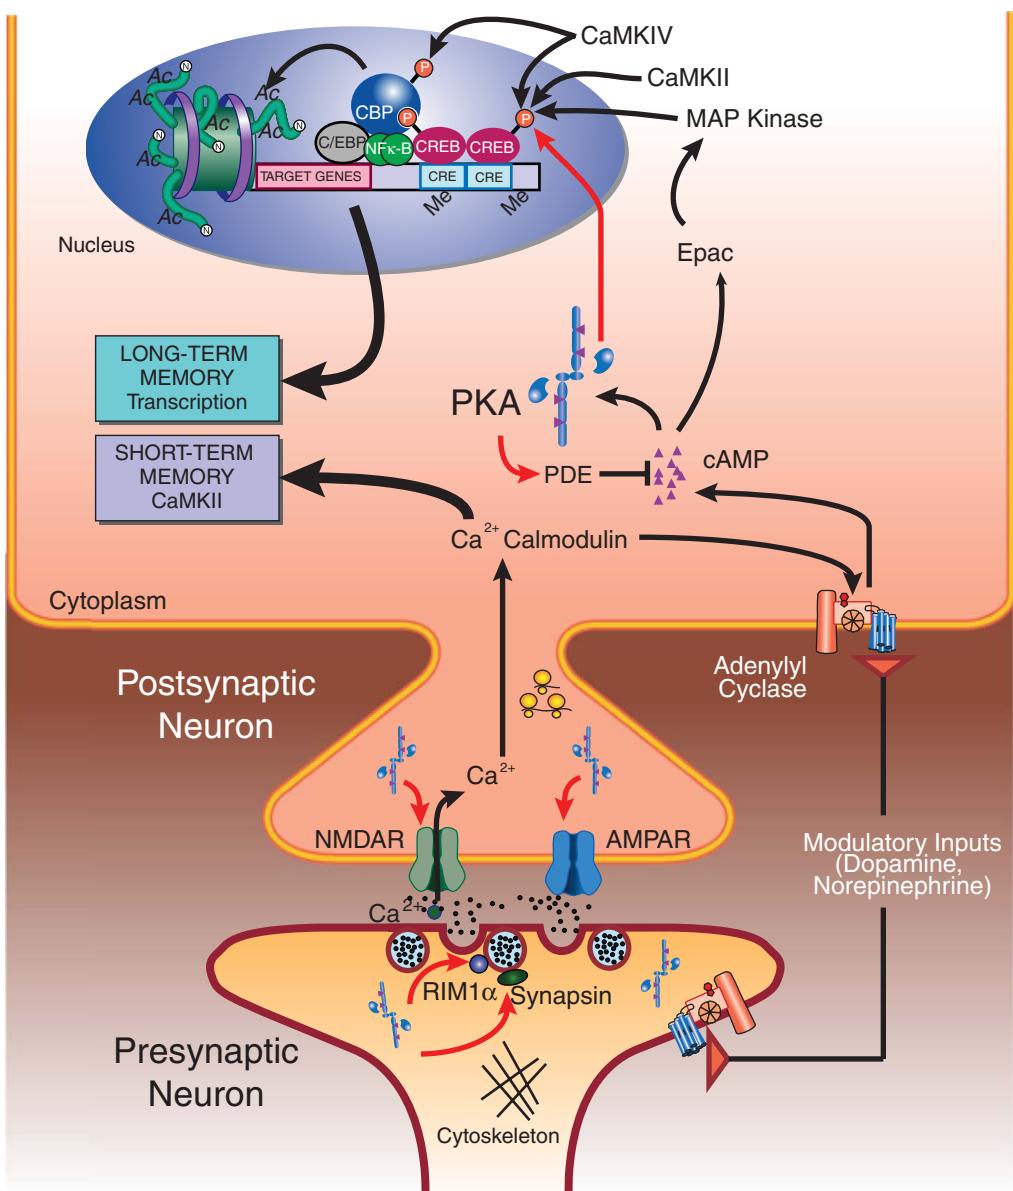

Figure 3 Signaling cascades in memory formation. Many of the signaling cascades that regulate short-term and long-term memory formation have been identified using genetic approaches to study mouse memory. Calcium ions (Ca^{2+}) enter neurons through NMDA receptors and bind calmodulin, which activates kinases including CaMKII to mediate changes in neuronal physiology that underlie short-term memory. Ca^{2+} -calmodulin also activates type I adenylyl cyclase to increase intracellular cAMP levels, which activate protein kinase A (PKA) directly and MAP kinase pathways through exchange factor activated by cAMP (Epac). Signals converge to recruit enhanceosomes consisting of transcription factors (such as NF κ B, CREB, and C/EBP) and transcriptional coactivators (CBP) to cause histone acetylation and transcription. These transcriptional processes are thought to mediate the long-term stabilization of memory that occurs during memory consolidation.

produced from transcripts that include this exon. These conventional knock-out mice have been used extensively to test the requirement for specific genes in learning and memory.

An individual protein is typically composed of multiple functional domains, each of which carries out a specific biochemical function. Because gene knock-out removes all of these functions simultaneously, this

technique is unable to address the role of particular protein domains or biochemical activities in learning and memory. Yet, with a few modifications, the gene-targeting technology used to create knock-outs can generate mice with mutations in individual amino-acid residues, called knock-in mice. The process of producing knock-in mice requires the same homologous recombination process as knock-out, but includes an additional replacement exon

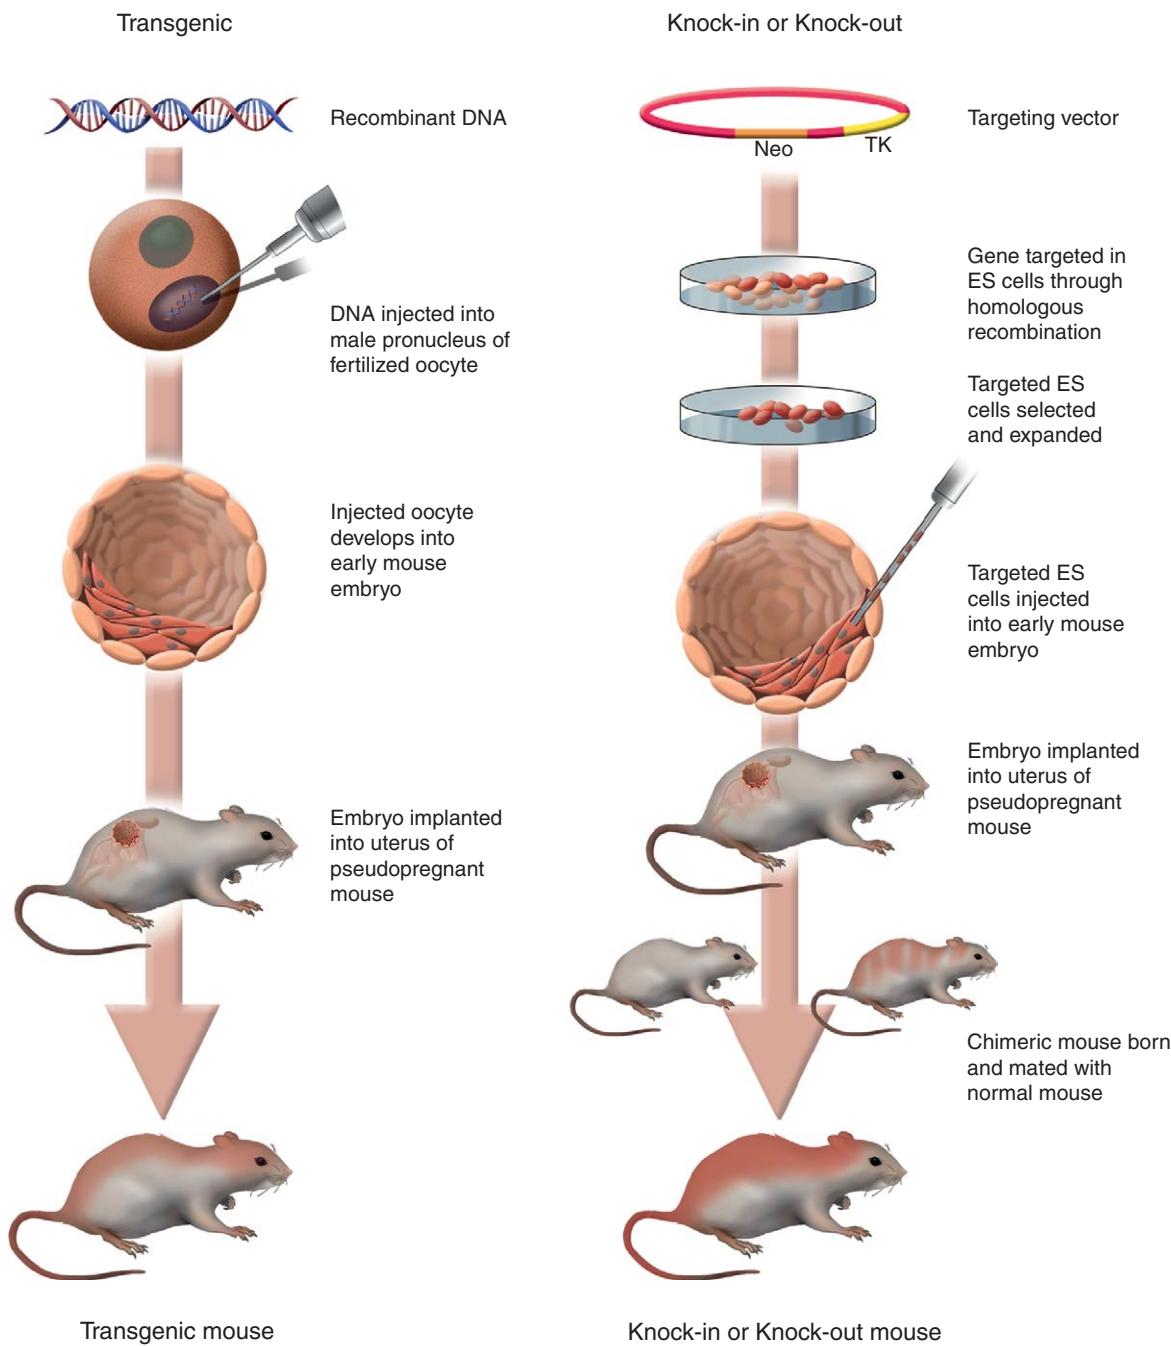

Figure 4 Generation of mutant mouse lines. (a) Transgenic mice are produced by injecting transgene DNA into the pronucleus of recently fertilized oocytes, which integrates into the genome without site specificity. The oocyte develops into an early stage embryo, which is then implanted into a pseudopregnant host female mouse. The offspring of host female are genotyped to identify founders that have incorporated the transgene into their genome. Each founder may have distinct transgene expression patterns, presumably due to the site of transgene insertion. (b) Gene targeting approaches rely on homologous recombination in embryonic stem (ES) cells to knock-out a gene with a selectable marker or knock-in an excisable selectable marker along with the allele of interest. Selection using these markers and a marker against random insertion, typically thymidine kinase (tk), allows purification of only those ES cells that have undergone homologous recombination. The ES cells are injected into a developing mouse embryo from a mouse line with a coat color distinct from the coat color of the mice used to produce the ES cells, and the embryo is implanted into a pseudopregnant female host. The resulting chimeric offspring are derived partly from the original embryo and partly from the ES cells leading to diverse coat color patterns that can be used to assess the contribution of the ES cells to the mouse. These chimeric mice are mated to a mouse with a recessive coat color. If the ES cells have contributed to the germ line of the chimera, some offspring will have the ES cell-derived coat color. These mice will contain the knock-out or knock-in mutation.

bearing the mutations that are to be knocked-in. The selection cassette is then removed in the ES cells by site-specific recombinases prior to injection of the ES cells into the embryo, leaving only the mutated exon in place of the normal exon. The knock-in approach has allowed researchers to go beyond identifying genes that are necessary for memory and to test hypotheses about the biochemical role of particular gene products or protein domains in the machinery of memory.

A major limitation of both knock-out and knock-in mice is that the gene is mutated throughout development and throughout the body. Transgenesis, an approach developed by Palmiter and colleagues, can circumvent these concerns by allowing regulation of transgene expression with a specific promoter, a region of DNA that recruits transcriptional machinery to genes through transcription-factor-binding sites. A transgene consists of a promoter regulating expression of an RNA that encodes a relevant protein. Often, this transgenic protein is a mutated form of a naturally occurring protein designed to interfere with the function of the endogenous protein, such as a dominant-negative or competitive inhibitor. Production of a transgenic mouse lines consists of injection of transgenic DNA into the male pronucleus of fertilized eggs, which leads to random integration of transgene-encoding DNA fragment into the embryonic genome (**Figure 4(a)**). The site of transgene insertion can affect the transgene expression pattern, a finding that has been exploited to identify mouse lines with very refined transgene expression patterns. Because specific protein domains can be mutated in the transgenic protein, this approach often allows identification of the role of specific biochemical functions. Two major caveats of the transgenic approach are that transgenic protein must compete with the wild-type protein and that high levels of transgene expression can interfere with proteins other than the wild-type version of the one that is transgenically expressed. Thus, it can be difficult to determine whether the wild-type gene is required during normal learning and memory.

A substantial advance in gene knock-out technology has been the development of conditional knock-outs using the Cre/LoxP system, which allows the deletion of an individual gene in specific cells and at specific times. This technology was made possible by the discovery of recombinases, enzymes that catalyze the exchange of DNA at specific sequences, particularly the Cre recombinase from bacteriophage P1 that targets the 34-bp LoxP sequence. Using the previously described knock-in strategy, gene exons can be flanked by these LoxP sites. In mice containing two LoxP-flanked (floxed) copies of a gene and a transgenically expressed Cre recombinase, the floxed gene is deleted in cells with Cre expression. The ability to regulate gene deletion through transgenic Cre has been a tremendous boon to learning and memory

research, but there are several major concerns that should be considered when using the Cre/LoxP system. First, with the Cre/LoxP system all deletions are final, so if the Cre transgene is expressed in early development all subsequent cells will lack the gene. This consideration is especially important as some Cre transgenes are unexpectedly expressed in the germ line, which may lead to a full-body gene knock-out. Another concern is that high levels of Cre expression cause cellular toxicity and can produce observable phenotypes. Each of the discussed reverse genetic techniques has been employed to great benefit over the past 20 years of research on learning and memory. In combination, these genetic techniques helped to identify many of the components of signaling cascades that guide transcription during memory consolidation.

α -CaMKII is Critical for Learning and Memory

In 1992, Susumu Tonegawa's lab published one of the first studies of learning and memory in a knock-out mouse, a knock-out of the α -CaMKII isoform. Four distinct genes encode CaMKII isozymes in the mammalian genome, but the α -CaMKII isoform is neuron specific and heavily expressed in forebrain structures, including the hippocampus. Because of this expression pattern and the disruption of synaptic plasticity by CaMKII inhibitors, Alcino Silva generated a knock-out mouse line lacking α -CaMKII. These knock-out mice have impairments both in hippocampal long-term potentiation (LTP) and in the hippocampus-dependent Morris water maze learning, thus suggesting mechanistic overlap between synaptic plasticity and learning. The traditional gene knock-out approach used in these studies has two major limitations: the mutation is present throughout development and all biochemical activities of the protein of interest are eliminated. These considerations may explain the learning-unrelated behavioral abnormalities, including a decreased pain threshold and increased aggression, observed in a later study of this same α -CaMKII knock-out mouse line.

Identifying the mechanisms that guide memory storage requires not only identifying which proteins are important for memory formation, but also how the proteins carry out that role. The biochemical cascades that guide memory formation are likely to provide deep insight into how memories are maintained after learning. For instance, after CaMKII is activated by transient bursts of intracellular calcium, the enzyme becomes calcium independent through autophosphorylation at a particular amino-acid residue, threonine 268. This observation suggests that CaMKII autophosphorylation may temporally store information about recent neuronal activity during synaptic plasticity and learning. Based on this hypothesis, Giese and colleagues generated knock-in

mice with a single-point mutation that converted the phosphorylated threonine residue into an alanine residue ($\alpha\text{-CaMKII}^{T286A}$), which cannot be phosphorylated. In these mutant mice, calcium-dependent CaMKII activity was preserved, but calcium-independent kinase activity was substantially reduced. $\alpha\text{-CaMKII}^{T286A}$ mutant mice have severe deficits both in forms of synaptic plasticity and spatial learning. In addition to these defects, the firing patterns of hippocampal CA1 place cells in response to spatial location were altered. When rodents explore an environment, individual neurons in the CA1 subregion of the hippocampus, called place cells, become tuned to particular positions within that environment. When a wild-type mouse is placed back into a previously explored context, these place cells typically fire in the same location and even come to have a more marked preference for specific parts of the environment. In $\alpha\text{-CaMKII}^{T286A}$ mutant mice, place cells are unstable and shift location with repeated context exposure. Furthermore, the spatial information in place cells, as measured by refinement of place field, does not increase with further exposure. This work showed that a single amino-acid residue on CaMKII is important for learning, highlighting the possibility that biochemical processes in individual neurons may store information during memory formation. Furthermore, these studies provided the first evidence linking synaptic plasticity, spatial learning, and hippocampal place cells by showing that each of these processes is modulated by CaMKII signaling.

Gene knock-out and knock-in are extremely useful tools for studying the mechanisms underlying learning and memory, but these tools have distinct disadvantages. For one, many of the same cellular signaling pathways are used for different processes in different parts of the body. Therefore, components of the molecular machinery of memory may cause decreased overall fitness or even death. In addition, gross changes in behavior caused by mutations can lead to learning and memory deficits that are secondary to other unrelated causes. In some cases, careful behavioral analysis can dissociate specific memory deficit in the face of unrelated phenotypic defects, but other genetic strategies such as transgenesis provide region-specific ways to interfere with gene function. By targeting regions of the brain that are involved with memory, transgenic approaches reduce the likelihood that other processes are disturbed.

The forebrain-specific expression pattern of $\alpha\text{-CaMKII}$ makes this promoter a versatile tool for regulating transgene expression specifically in forebrain neurons. Appropriately, the first use of this promoter was to control transgenic expression of a mutant form of $\alpha\text{-CaMKII}$. Calcium/calmodulin-independent activation of $\alpha\text{-CaMKII}$ by autophosphorylation at threonine 286 can be mimicked by replacing the threonine residue with an aspartate residue ($\alpha\text{-CaMKII}^{T286D}$), resulting in

elevated calcium-independent CaMKII activity. Using the $\alpha\text{-CaMKII}$ promoter, Mark Mayford in Eric Kandel's lab generated a transgenic mouse line expressing $\alpha\text{-CaMKII}^{T286D}$ in the forebrain. These mice have impairments in spatial learning and certain forms of hippocampal LTP, which suggests that dynamics of CaMKII activity are important for effective spatial learning. Furthermore, these results strengthen the argument that CaMKII is involved in the mechanisms of memory itself by showing that its signaling is important in a brain region required for spatial memory, the hippocampus. A major benefit of this work was the identification of a promoter that can regulate, or drive, transgene expression specifically in forebrain neurons of adult mice.

The utility of the $\alpha\text{-CaMKII}$ promoter becomes clear when considering molecules that are vital to mouse survival. For instance, Nr1 is an obligate subunit of a functioning NMDA receptor and traditional knock-outs of the gene encoding Nr1 die shortly after birth. Therefore, Tsien and colleagues used the Cre–LoxP system to remove the Nr1-encoding gene selectively from the forebrain neurons. Cre recombinase was expressed under control of the $\alpha\text{-CaMKII}$. Fortuitous transgene expression patterns, presumably due to the site of transgene insertion, led to an even more restricted expression pattern than that seen with the $\alpha\text{-CaMKII}$ gene itself. When this transgene was combined with two copies of a floxed Nr1-encoding allele, at 3 weeks of age, the Nr1 subunit was deleted predominantly within the CA1 sub-region. Spatial memory and LTP were both severely disrupted in these mice, suggesting that NMDA receptor activity in hippocampal CA1 neurons is critical for memory formation.

cAMP Signaling Regulates Memory Formation

Seminal studies using forward genetics approaches in the fruit fly *Drosophila* and electrophysiological approaches in the sea slug *Aplysia* independently identified a role of the cAMP pathway in learning and memory in the mid-1970s. Nonetheless, evidence supporting a role for the cAMP-signaling pathway in mammalian memory formation awaited the application of genetic approaches in 1990s. The first genetic evidence that cAMP signaling plays a role in mammalian memory came from conventional knock-out mice lacking type I adenylyl cyclase, a calcium/calmodulin-regulated source of cAMP. Daniel Storm's lab observed that these adenylyl cyclase mutant mice have reduced calcium-stimulated cAMP and impaired performance in the spatial version of the Morris water maze. One of the major effectors of cAMP signaling is PKA, but studies with conventional knock-out of individual PKA subunits were confounded by

redundancy and compensation in null mutant mice. The α -CaMKII promoter provided the opportunity to test the role of PKA in memory using a transgenic approach. Forebrain-specific expression of a mutated form of the PKA regulatory subunit that reduces PKA activity (R(AB)) under control of the α -CaMKII promoter impaired spatial memory in the Morris water maze, but both learning and the visual platform version of this task were unaffected. Furthermore, long-term contextual fear memory was selectively impaired with normal short-term contextual and long-term cued fear memory. In wild-type mice, hippocampal CA1 neurons have place fields that are similar during initial exploration to those found with context reexposures 1 h or 24 h later. In addition to defects in long-term synaptic plasticity and long-term memory, place fields in R(AB) mice change upon reexposure to a context 24 h after the first exposure, but are stable between reexposure spaced by only an hour. This finding provides further support for a role of PKA selectively in formation of long-term representations of spatial information. An interesting aspect of this work on cAMP signaling is that, unlike mutations in NMDA and CaMKII, the PKA mutant mice have specific impairments in long-term memory with normal short-term memory. Thus, NMDA receptor activation and CaMKII activity are required for hippocampus-dependent learning, but cAMP signaling appears to mediate subsequent consolidation of learned information into a long-term memory (**Figure 3**).

Memory storage has distinct phases, such as acquisition, consolidation, and retrieval. In addition, memories are subject to changes after initial storage. The study of these processes independently from one another has required the development of conditional transgenic systems with some degree of temporal control. For instance, after contextual fear conditioning, repeated reexposure to the context without reinforcing shock reduces the fear response through the formation of new memories that suppress the original fear response. This process is referred to as extinction learning and experiments in R(AB) mutant mouse lines suggested that the molecular processes guiding the formation of extinction memory are partly distinct from initial fear learning. In *CaMKII-R(AB)* mutant mice, contextual fear memories undergo extinction more rapidly than in wild-type mice. To determine whether this effect was due to a role of cAMP signaling in the extinction process or a consequence of changes in the initial contextual fear memory, an inducible dual transgene system was used that consisted of the α -CaMKII promoter regulating the tetracycline transactivator (*CaMKII-tTA*) and the tetracycline operator regulating R(AB) (*tetO-R(AB)*) (**Figure 5(a)**). The inducible aspect of this expression system is based on the bacterial tetracycline-inducible operon. In *Escherichia coli*, the tetracycline repressor (TetR) binds to tetO sequences at

tetracycline-inducible promoters to repress gene transcription under basal conditions, but when tetracycline binds to the TetR protein, the repressor releases the promoter to allow transcription. This system has been modified by fusing a strong viral activator domain (VP16) to the DNA-binding domain of TetR yielding a hybrid tetracycline-regulated transactivator (tTA) for control of transgenes with tetO sequences in their promoter. The CaMKII-tTA system was developed for the study of CaMKII in memory formation but was applied by Isiegas and co-workers to show that PKA contributes to extinction as well as fear memory formation. In this study, mice were trained in contextual fear conditioning while being fed doxycycline to repress R(AB) expression and were taken off doxycycline after learning (**Figure 5(b)**). Four weeks later, when R(AB) expression was robust throughout the forebrain, the mice were subjected to repeated exposure to the conditioning context in the absence of shock. The rate of extinction learning was facilitated by R(AB) expression, showing that PKA has distinct and opposing roles in initial memory formation and extinction memory (**Figure 5(c)**). An additional advantage to this study was that the role of PKA in memory *per se* rather than developmental process was supported by observation that R(AB) expression in the adult mouse impairs contextual fear memory consolidation. The development of more rapidly inducible transgenic systems will be critical for the separation of effects on acquisition, consolidation, and retrieval.

One strategy to more rapidly manipulate neuronal signaling cascades relies on transgenic expression of receptors that bind ligands not normally present in the brain. This pharmacogenetic strategy combines the cell and region specificity of genetic approaches with the temporal control afforded by pharmacological approaches. A recent study using this strategy provided further support for the role of cAMP in memory formation. In this work, a G_s-coupled octopamine receptor from the sea slug *Aplysia* was expressed in forebrain neurons using the CaMKII-tTA/tetO system. Octopamine is a major neurotransmitter in invertebrates but is present only at trace levels in vertebrates with no known physiological functions. Because the *Aplysia* octopamine receptor is G_s coupled, binding of octopamine by this receptor activates adenylyl cyclase and transiently increases cAMP. In mice expressing the octopamine receptor, octopamine injection increases hippocampal cAMP levels and enhances both short-term and long-term memory. The lack of a short-term memory deficit in PKA mutant mice suggests that the enhancement of short-term memory by this transient burst of cAMP may be a consequence of rapid recruitment of consolidation mechanisms. Alternatively, this enhancement may be mediated by recruitment of other cAMP-regulated proteins, such as exchange-factor activated by cAMP (EPAC), which

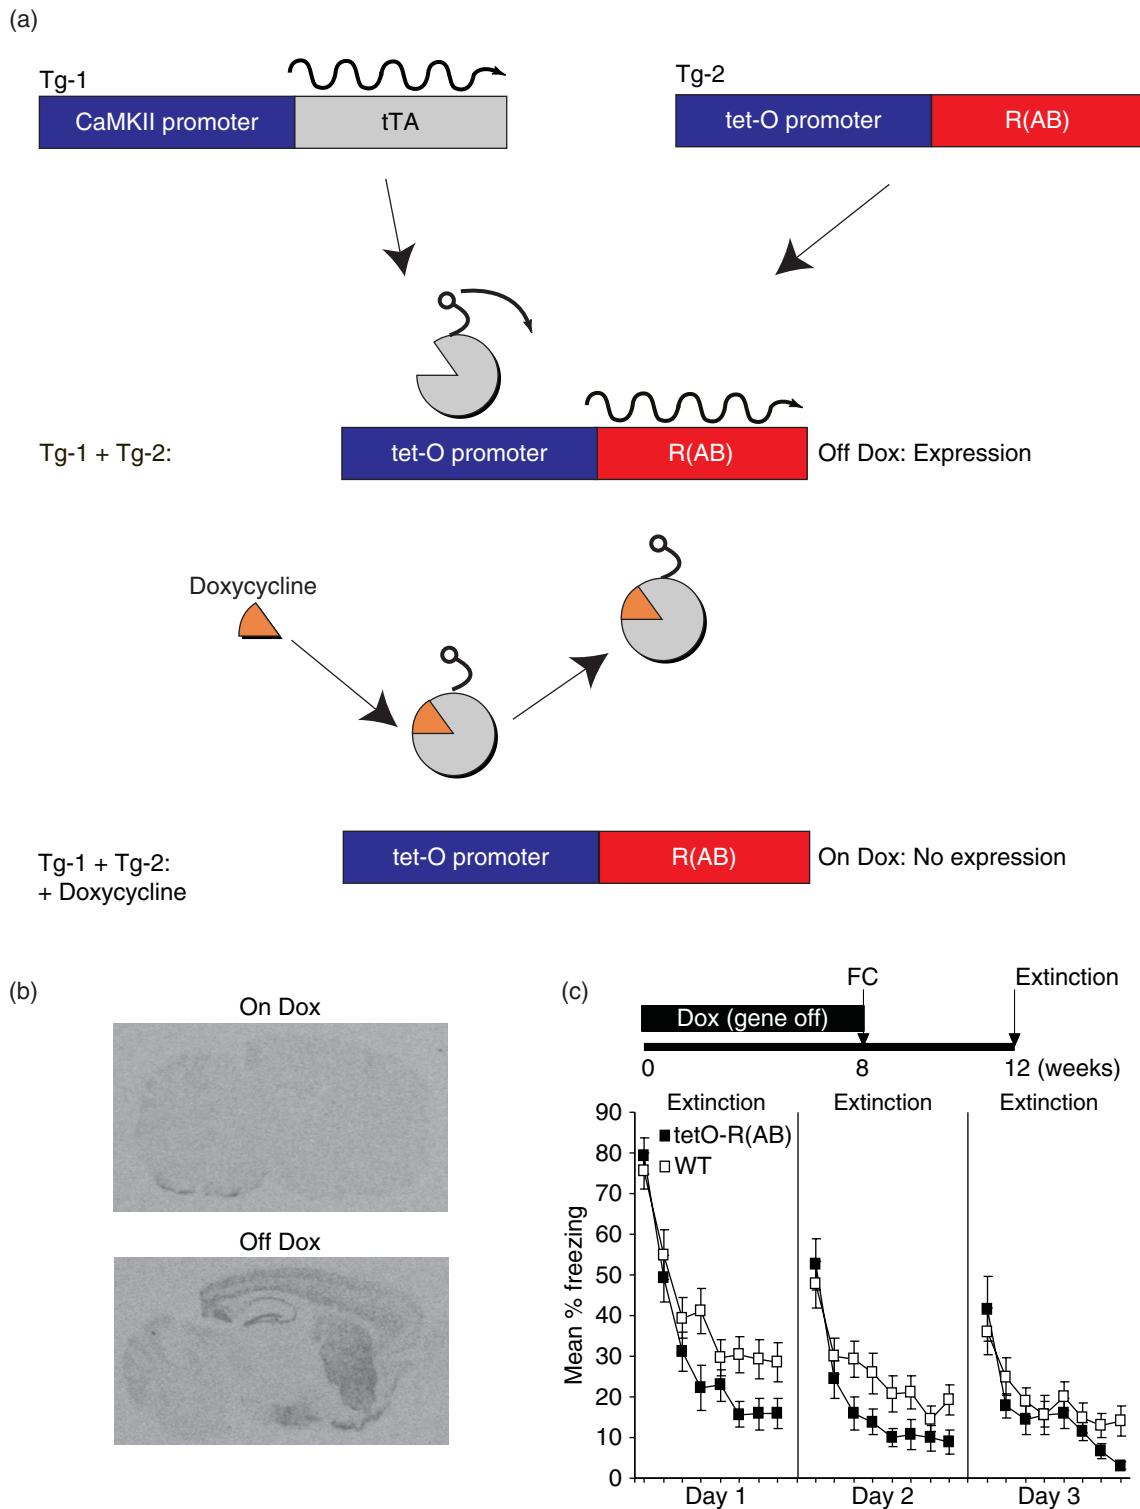

Figure 5 Conditional reduction of PKA activity enhances extinction memory. (a) Temporal and spatial regulation of the PKA inhibitor R(AB) was achieved using a dual transgenic tTA/tetO system. The specificity of this system stems from the tetracycline transactivator (tTA) under control of the α -CaMKII promoter, which drives forebrain-restricted transgene expression. The tTA protein binds tetO sequences in the promoter of the R(AB) transgene to induce expression of R(AB) in forebrain neurons. In the presence of the tetracycline analog doxycycline, tTA cannot bind the tetO sequence, allowing temporal regulation of R(AB) expression by feeding the mice doxycycline. (b) *In situ* hybridization shows that administration of a doxycycline diet efficiently suppresses R(AB) expression (On Dox). In addition, the transgene is specifically expressed in forebrain structures when the mice are removed from the doxycycline diet for 28 days (Off Dox). (c) Inhibition of PKA activity facilitates extinction of contextual fear memory. Wild-type and R(AB) transgenic mice were raised on doxycycline, trained in contextual fear conditioning, and taken off a doxycycline diet 24 h after training. Contextual fear extinction was performed after 28 days on a doxycycline-free diet. Repeated reexposure to the context formerly associated with a footshock reduced freezing more rapidly in R(AB) transgenic mice than in wild-type littermates. Error bars indicate SEM. Source: Isiegas et al., 2007.

activates mitogen-activated kinases (MAPKs). Because of the precise temporal regulation of cAMP increases, Isiegas and colleagues were also able to show that increasing cAMP signals during memory retrieval enhances performance, suggesting that cAMP signaling modulates retrieval as well as consolidation. In complementary studies, several other approaches that increase cAMP signals after training also enhance memory consolidation. For instance, pharmacological blockade of cAMP degradation produces long-lasting L-LTP after a stimulation paradigm that normally evokes short-lasting E-LTP and improves contextual fear memory. Similarly, overexpression of calcium-responsive adenylyl cyclase produces LTP and memory enhancement. It is important to note that these approaches increase cAMP dynamics after learning, leading to an increase in the cAMP signals. By contrast, manipulations that chronically increase basal cAMP or effector levels often lead to impairments in long-term memory.

The CREB Family of Transcription Factors Regulates Memory Formation

The similarity between the memory and synaptic plasticity deficits caused by PKA inhibitors and transcriptional inhibitors suggests that PKA may regulate memory formation by inducing transcription. In many physiological contexts, cAMP signals are converted into long-lasting changes in cellular physiology by activating the transcription factor CREB. PKA and MAPKs phosphorylate CREB on serine residue (S133), causing CREB to bind its coactivator CBP. CREB is constitutively expressed but is activated through phosphorylation to drive expression of genes containing cAMP-response elements (CREs) in their promoters. This inducibility after neuronal activity is a key feature that made CREB an attractive candidate for initiating transcriptional cascades after learning. Both spatial and contextual learning are accompanied by increases in CREB phosphorylation within the hippocampus, and the windows of CREB phosphorylation after learning coincide strikingly well with the windows of sensitivity to inhibitors of PKA, protein synthesis, and mRNA synthesis. Once again, research in both *Aplysia* and *Drosophila* foreshadowed subsequent research in mammalian memory by demonstrating a role of CREB in long-term memory. The first of these invertebrate studies by Pramod Dash in Eric Kandel's lab found that injection of excess DNA containing the CRE sites blocks a form of long-term synaptic plasticity at *Aplysia* synapses known as long-term facilitation (LTF). The first mammalian CREB mutant was a conventional knock-out of the α and δ isoforms, the major CREB isoforms in the brain, and the history of these CREB $\alpha\delta$ knock-out mice illustrates many of the risks and benefits associated with

conventional knock-out mice. To reduce the effect of genetic variability on experimental results, mice are studied on inbred genetic backgrounds, but these different strains of mice can have very different behavioral phenotypes. The initial examination of memory in CREB $\alpha\delta$ mice on a mixed B6- and 129-genetic background showed impaired cued and contextual memory formation, as well as impaired spatial memory formation in the Morris water maze. Shortly after these mice were generated, it was discovered that the β isoform of CREB and the CREB family member cAMP-responsive element modulator (CREM) were upregulated in CREB $\alpha\delta$ mice. Although the consequences of these compensatory mechanisms are still subject to debate, it appears that the overall genetic background may determine whether a CREB $\alpha\delta$ mutant mouse has memory deficits. After initial studies in a B6-129 mixed genetic background, CREB $\alpha\delta$ mutation was backcrossed into two inbred mouse strains, C57BL/6 (B6) and FVB/N. These B6 and FVB/N heterozygous CREB $\alpha\delta$ mutants were mated to produce CREB $\alpha\delta$ knock-outs in a defined F1 hybrid. Surprisingly, these F1 hybrid CREB $\alpha\delta$ mice lacked the memory deficits previously observed on the B6-129 mixed background. Yet, when mice from this same F1 hybrid background contained one CREB $\alpha\delta$ mutant allele and one complete CREB knock-out allele, the memory deficits were observed even on this hybrid background, suggesting that strain-specific differences in compensation by the β -CREB isoforms could account for the effect of genetic background. Later studies confirmed that B6-129 F1 hybrid CREB $\alpha\delta$ mice have fear memory deficits. These findings highlight both the risk of compensatory changes in gene regulation after gene knock-out and the possibility that the genetic background of an individual inbred mouse strain may make a single gene appear more or less pivotal for memory formation.

Because the gene in question is not removed from all cells throughout development, transgenic approaches suffer to a lesser extent from compensatory changes in gene expression. The role of CREB in long-term memory has been further studied using transgenic approaches. For instance, Chris Pittenger in Eric Kandel's lab generated a transgenic mouse line expressing a strong dominant negative allele of CREB (KCREB) that heterodimerizes with CREB family members and blocks DNA binding. Using the α -CaMKII promoter, this dominant-negative transgene was expressed in the striatum, limited cortex, and the CA1 subregion of the dorsal hippocampus. In support of a role for CREB in long-term memory formation, these mice had deficits in the spatial version of the Morris water maze, but surprisingly no deficit was observed in contextual fear conditioning. Either the absence of KCREB expression in the ventral hippocampus, which is more directly connected to the amygdala than the dorsal hippocampus, or the level of impairment

of CREB function by this transgene may account for the absence of fear memory deficits in these mice. In the same year, Alcino Silva's lab produced a transgenic mouse line expressing a form of CREB that lacks the activating residue at serine 133, once again under control of the α -CaMKII promoter. This mutant form of CREB was fused to a variant of the estrogen ligand-binding domain that preferentially binds to the estrogen analog tamoxifen (ERT). The ligand-free ERT domain inactivates the protein by sequestering it into an HSP90 complex, which dissociates upon tamoxifen binding. In this inducible CREB repressor (CREB^{IR}) line, a few hours of tamoxifen treatment causes severe impairment in long-term contextual and cued fear memory tasks, but leaves initial learning and short-term memory intact. The CREB^{IR} transgenic line confirmed the role of CREB family members in long-term memory and, importantly, showed that serine 133, the site of PKA phosphorylation, is central to this role. Because the levels and regions of CaMKII-regulated transgene expression vary considerably due to the effect of transgene insertion site, it is difficult to directly compare behavioral outcomes from distinct transgenes, an effect that is further confounded by redundancy and compensation among CREB family members, but the overall message from the past 20 years of research suggests that CREB or CREB family members play an important role in long-term memory formation.

NF κ B Family Members are Latent Transcription Factors that Regulate Memory Formation

The ability of CREB family transcription factors to lie latent in neurons prior to activation by extracellular signals is a key feature that places this family at the interface between environmental signals that encode information about the world and the most fundamental information storage system in biology, the genome. Another transcription factor family with similar activity-dependent regulation is the Rel/nuclear factor κ B (NF κ B) family, which consists of five members (p50, p52, p65, c-Rel, and RelB) that can act as homo- and hetero-dimers. In the basal state, I κ B inhibitory proteins sequester NF κ B in the cytoplasm by masking a nuclear localization sequence (NLS), but activation of I κ B kinase (IKK) causes ubiquitination and degradation of I κ B, thus freeing NF κ B for nuclear import and activation of target genes. Two kinases thought to play a role in memory formation, CaMKII and protein kinase C (PKC), can activate NF κ B by phosphorylation of IKK. The earliest studies of NF κ B found increased protein levels for p50 and p65 after high-frequency stimulation, whereas I κ B levels decrease. It was subsequently shown by Meffert and colleagues that neuronal activity causes a calcium-

dependent increase in DNA binding by p65-containing NF κ B dimers accompanied by increased nuclear translocation of GFP-labeled p65 and that mice lacking the p65 subunit have deficits in the spatial version of the radial arm maze, a task that requires the hippocampus. Further support for a role of NF κ B family members in memory formation comes from mice expressing a dominant-negative form of IKK (IKK-AA) under control of the inducible, neuron-specific CaMKII-tTA/TetO system. These mice have deficits in the spatial version of the Morris water maze and L-LTP produced by theta burst stimulation. The most direct consequence of IKK-A expression is reduced NF κ B signaling, but expression of IKK-AA also substantially reduces the expression of the catalytic subunit of PKA and impairs forskolin-induced CREB phosphorylation in the hippocampus, suggesting that NF κ B signaling may amplify CREB-mediated transcription after learning.

Microarray experiments are capable of examining the expression of thousands of genes simultaneously and computational analysis using bioinformatics techniques allows the identification of transcription factors that may regulate identified changes in gene expression. Levenson and colleagues used bioinformatics analysis of microarray results after fear conditioning to identify another NF κ B subunit, c-Rel, as a candidate for regulating gene expression during memory consolidation. This finding led the researchers to examine the role of c-Rel in long-term memory using conventional *c-Rel* knock-out mice, where they saw a significant deficit in long-term contextual fear memory, but normal short-term contextual and long-term cued fear memory. Results that are more recent have confirmed this initial finding in *c-Rel* knock-out mice and demonstrated that c-Rel protein is translocated to the nucleus in CA1 neurons at 30 min after contextual fear conditioning. The identification of c-Rel by bioinformatics analysis of microarray data highlights the ability of unbiased screening approaches to reveal important information about molecular mechanisms regulating memory processes.

The analysis of gene expression after learning raises the question of what component of associative memory drives hippocampal gene expression: the unconditioned stimulus (US shock), the conditioned stimulus (CS context), or the CS-US association. In the study by Levenson and co-workers, the vast majority of the learning-induced genes did not have increased expression in the hippocampus when mice were shocked immediately after placement into the novel training context, a protocol that fails to produce associative memory. In a similar microarray experiment, Keeley and colleagues found that hippocampal gene expression 30 min after fear conditioning is very similar to the pattern observed after context exposure alone, suggesting that contextual learning (CS) may drive a substantial amount of gene

expression after contextual fear learning. These findings suggest that the control task can affect the expression profile, and perhaps that the immediate shock control impairs gene expression involved in CS encoding. Yet, certain immediate early genes, such as *Nr4a1/NGFI-B*, have increased expression after context–shock (CS–US) pairing, but not context (CS) exposure alone. Thus, the questions of what role the hippocampus is playing in associative memory processing and how behavioral paradigms affect this processing are still vital open questions that may be clarified by continued studies of gene expression after learning paradigms.

Immediate Early Genes Are Activated by Latent Transcription Factors after Learning

Immediate early gene (IEG) expression is directly induced by latent transcription factors, so protein synthesis is not required for expression of these genes after a stimulus. Interestingly, several IEGs activated after learning and synaptic plasticity are themselves transcription factors, suggesting that cascades of transcription may be critical for long-term changes in plasticity and memory. Notable among these learning-induced IEGs are *Fos*, *C/EBP*, and *Zif268*. As IEGs, the expression of these transcription factors after stimulation does not require translation, suggesting that their expression is a result of activation of latent transcription factors, such as NF κ B and CREB. In fact, there is evidence that each of these three IEGs is regulated in part by CREB. Yet, it is important to mention that the expression of genes after learning is probably not simply regulated by any single transcription factor, but is a result of simultaneous binding of multiple transcription factors to the promoter regions of genes acting as an enhanceosome to cooperatively recruit transcriptional coactivators (Figure 3). For instance, the transcriptional coactivator CBP interacts with CREB, NF κ B, C/EBP, Fos, and Zif268, and cooperative recruitment of CBP by multiple transcription factors is a hallmark of this coactivator. This cooperative CBP recruitment allows computation through the integration of multiple signals of biochemical activation, such as the transcription factors activated after learning, as well as cell-type-specific signals.

C/EBP: A Second Wave of Transcription after Learning

The role of C/EBP in the transcriptional cascade supporting memory was first identified in studies of *Aplysia* LTF, a long-lasting and protein synthesis-dependent form of synaptic plasticity. The *Aplysia* C/EBP gene is

expressed rapidly after repeated treatment with serotonin or pharmacological activation of the cAMP pathway, stimuli known to induce LTF and increased PKA activity. This expression is protein-synthesis independent, further suggesting that a constitutively expressed and PKA-activated transcription factors such CREB drives the expression of this transcription factor. Alberini and co-workers used several approaches to demonstrate that LTF requires C/EBP, and perhaps more interestingly this requirement for C/EBP extends for more than 9 h after LTF induction, suggesting that long-lasting changes in gene expression are required for long-lasting changes in synaptic strength. Subsequent studies in rats showed that after a hippocampus-dependent contextual memory task, long-lasting increases in C/EBP expression are observed for 28 h after learning. Using antisense oligonucleotides to block expression of the C/EBP β -isoform, Alberini's lab went on to show that this transcription factor is required at 24 h after learning for memory retrieved at 48 h after learning. These studies of C/EBP have highlighted two very important aspects of memory formation: transcriptional cascades are likely to mediate waves of transcription during memory formation and the changes in transcription responsible for memory formation are much longer lasting than previously thought.

Fos Expression can be used to Stably Tag of Neurons Activated by Learning

Expression patterns of IEGs have been very useful for addressing systems- and network-level questions about learning and memory. In 1989, Paul Worley's lab examined the expression of seizure-induced genes in the hippocampus after LTP, finding that several IEGs such as *Zif268*, *JunB*, *c-Jun*, and *Fos* are rapidly induced in the hippocampus after LTP-inducing stimuli. *Fos*, an archetypal immediate early gene that is regulated by a wide variety of cellular stimuli, hetero-dimerizes with *Jun* family members to form the transcription factor AP-1. *Fos* gene expression is robustly induced in memory-related structures after acquisition and recall of memory. Because of this expression pattern, Mark Mayford's lab developed a genetic system to stably label neurons that have *Fos* induction during a defined time window, dubbed the TetTag mouse. This bigenic TetTag system uses the *Fos* promoter to regulate the expression of tTA (*Fos-tTA*), leading to activity-dependent production of the doxycycline-repressed tTA transactivator. In addition, a tetO-regulated bidirectional promoter-controlled expression of the reporter enzyme LacZ and a doxycycline-insensitive mutant form of tTA (*tTA**). These mice were raised on doxycycline, so that *Fos-tTA* activation is transient and leaves activated cell unmarked. When these bigenic TetTag mice are taken off doxycycline, any stimulation

that induces the *Fos* promoter regulating tTA activates transcription of the doxycycline-insensitive tTA*, marking these cells with continuous expression of tTA* and the reporter LacZ (**Figure 6(a)**). Therefore, the TetTag mice were trained in the absence of doxycycline. After training, the mice were once again treated with doxycycline to block further marking of neurons. The initial report of the TetTag system focused on the tagging of neurons in the amygdala after fear conditioning. In addition to examining the neurons marked during learning,

expression of the IEG *Zif268* was used as a marker of transcriptional activation after retrieval in the presence of doxycycline (**Figure 6(b)**). More than twice as many neurons were labeled after training relative to home-cage or context-only controls kept off doxycycline for the same interval (**Figure 6(e)**). By examining both TetTag LacZ labeling and Zif268 expression, the researchers asked whether the same neurons activated after learning (LacZ positive) were also re-activated during retrieval (Zif268 positive). The overlap between LacZ

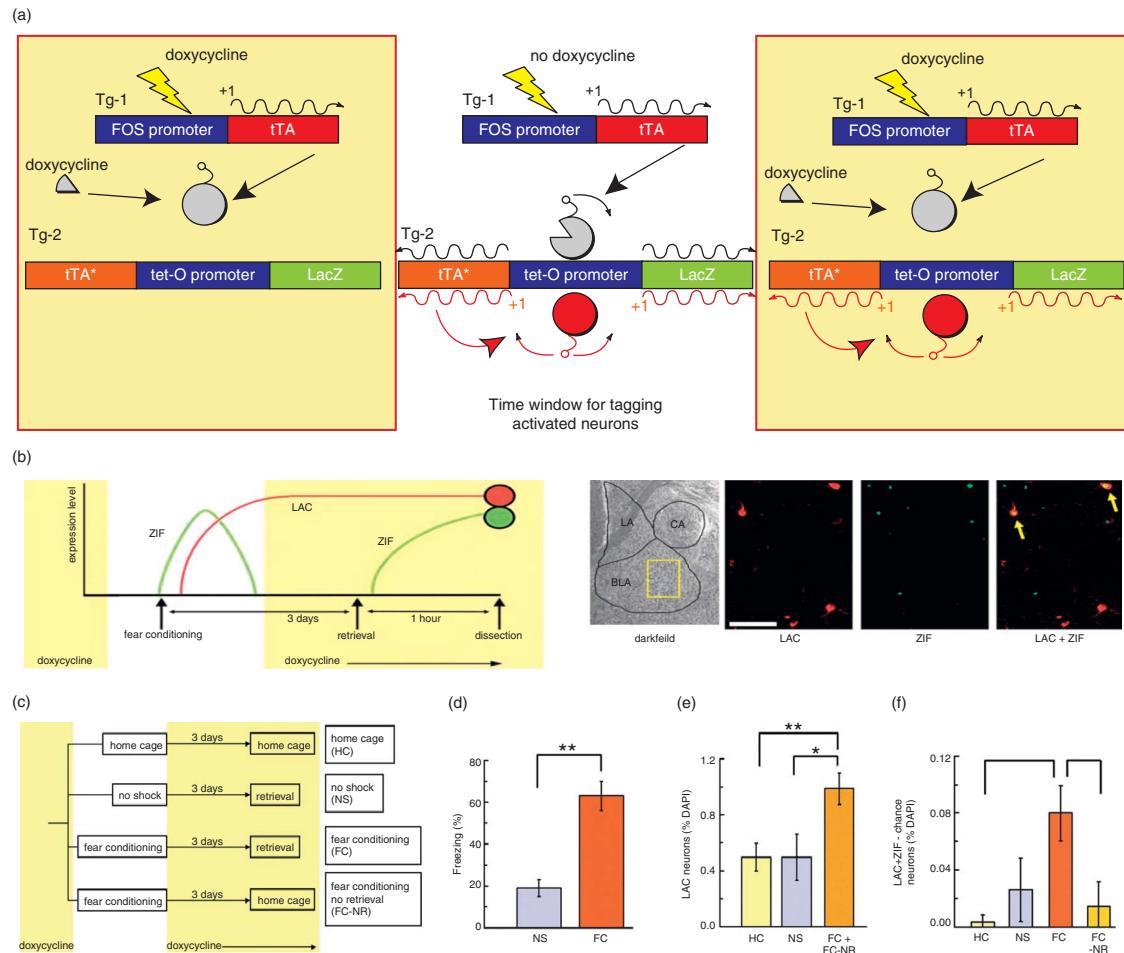

Figure 6 Identifying a memory trace: TetTag system. (a) The TetTag systems combine two transgenes to stably label neurons activated during a defined time window. The first of these transgenes is a *Fos* promoter-regulated tetracycline transactivator (Fos-tTA). The second transgene consists of a LacZ marker and a tetracycline-insensitive version of tTA (tTA*) under control of a bidirectional tetracycline operator (TetO-LacZ-tTA*). In the presence of doxycycline (dox), which can be mixed into the mouse's food, the Fos-tTA transgene is expressed with neuronal activity, but the dox inactivates tTA. In the absence of dox, tTA expressed after neuronal activity binds to the TetO-LacZ-tTA* to induce the expression of the doxycycline-insensitive tTA*, resulting in continued expression of tTA* and the LacZ marker even when the animals are returned to a dox-containing diet. Thus, the window of tagging is limited to when the animals are not being fed dox, but the tag persists after dox is returned to the diet. (b) This system was used in conjunction with immediate early gene labeling of *Zif268* to determine whether the same neurons that were activated by learning were re-activated during retrieval. (c) For these experiments, mice were reared on dox to prevent labeling, taken off dox to allow neuronal tagging for a short window during which the experimental mice received fear conditioning, and placed back on dox for 3 days to prevent tagging during the retrieval. (d) Mice learned the context-shock association as measured by the percent time spent freezing during a retrieval test. (e) Fear conditioning led to significantly more labeling of neurons than exploration of the context alone (NS) or being left in the home cage (HC). (f) Neurons activated during training (LacZ+ neurons) were more likely to be activated during retrieval (ZIF+ neurons) than chance levels, whereas neurons activated in the home cage or simply with context exploration were not. Source: Reijmers et al., 2008.

and Zif268 was significantly above chance in mice that were examined after retrieval and were trained in the absence of doxycycline. In control mice that did not experience retrieval and in control mice that were off doxycycline in the home-cage and context-only group, co-labeling for these two markers was approximately at chance levels (**Figure 6(f)**). In addition, a significant correlation was found between the number of co-labeled neurons in the amygdala and retrieval performance. This approach allows researchers to ask network-level questions about the incorporating neurons into potential memory traces and to use the tTA* transactivator to selectively modulate these neurons.

Local Capture of Transcripts Correlates with Associative Aspects of Memory

The utility of this *Fos*-driven TetTag system for analyzing the incorporation of neurons into hippocampal networks activated after contextual learning has yet to be examined, but the *Fos-tTA* component was used to examine the incorporation of a newly synthesized AMPA receptors into hippocampal CA1 neurons after contextual fear conditioning by combining the *Fos-tTA* transgene with a TetO-regulated EGFP-labeled AMPA receptor subunit (*TetO-GluR1-EGFP*). In this study, roughly 25% of hippocampal CA1 neurons were labeled with GluR1-EGFP after fear conditioning, compared with approximately 5% of neurons in home-cage mice. A similar level of GluR1-EGFP was observed in mice exposed to the context alone, which is in agreement with previous observations that *Fos* and many other IEGs are transcribed in the hippocampus in response to configural learning rather than the associative component of contextual fear memory. Within 24 h, these GluR1-EGFP proteins were trafficked to dendritic spines, but only about 50% of spines were labeled within individual EGFP-labeled neurons. Strikingly, the trafficking to a specific spine type, mushroom body spines, was increased in mice that received context-shock pairing relative to mice that experienced only context exposure. Repeated exposure to the context alone in the absence of reinforcing shock reduces freezing in that context through a process known as extinction, and extinction was accompanied by a reduction in the percentage of EGFP-labeled mushroom body spines relative to other spine types. These findings suggest a startling dichotomy of information encoding in the hippocampus in which neuron-wide transcriptional processes encode information about context whereas spine-specific synaptic capture of transcripts encodes certain associative components of fear memory. If this dissociation exists, a sharp line may not be easily drawn between the two processes because *de novo* transcriptional processes most likely account for the

transcripts that are captured and a few genes appear to be transcribed selectively in response to associative aspects of contextual fear memory, such as *Nr4a1*.

Temporal Dynamics of Arc mRNA Expression allow Examination of Place Representation in the Hippocampus

The finding in TetTag mice that 25% of hippocampal neurons are Fos-activated by contextual fear conditioning echoes fascinating studies carried out by John Guzowski, in which a surprisingly high number of neurons were marked by IEG expression after learning. In these studies, Guzowski used fluorescent *in situ* hybridization (FISH) in conjunction with confocal microscopy to provide extremely high-resolution images of hippocampal gene expression after context exploration (**Figure 7**). For the first 5 min after seizure activity, the transcripts of IEGs *Arc* and *Zif268* were identified in discrete foci within the nucleus (**Figure 7(b)**), but by 15 min after seizure these transcripts had been trafficked to the cytoplasm (**Figure 7(c)**). Similar dynamics were found after the exploration of a novel context. Impressively, approximately 45% of CA1 pyramidal neurons were found to have nuclear *Arc* transcript after 5 min of context exploration, the same number had cytoplasmic *Arc* transcript when examined after a 25-min delay, and very few (<5%) had detectable transcripts in both compartments simultaneously (**Figure 7(d)**). This knowledge of the temporal dynamics of *Arc* trafficking allowed Guzowski to ask a variety of interesting questions about the recent activity of neural networks during context exposure. When the rat was returned to the same context after a 20-min delay, roughly 40% of CA1 neurons had *Arc* transcripts in both nuclear and cytoplasmic, showing that the network of neurons activated by a particular context was stable across time and that these networks are surprisingly large. When the rat was exposed to a distinct context after the same 20-min delay, only 20% of CA1 neurons had exclusively nuclear or cytoplasmic labeling and 16% of CA1 neurons displayed both nuclear and cytoplasmic labeling, suggesting that these representations overlap at roughly the same level that would be predicted by chance (**Figure 7(d)**). The observation that a large percentage of CA1 neurons is activated by single context fits well with observations using electrophysiological and biochemical techniques suggesting that between 20% and 40% of CA1 neurons are involved in representation of a single context. With such a large number of neurons involved in each single representation, how is it possible that the hippocampus is not quickly overwhelmed in the daily life of a wild rat? First, the actual number of distinct representations consisting of 120 000 neurons (40%) within 300 000 CA1 neurons is staggering.

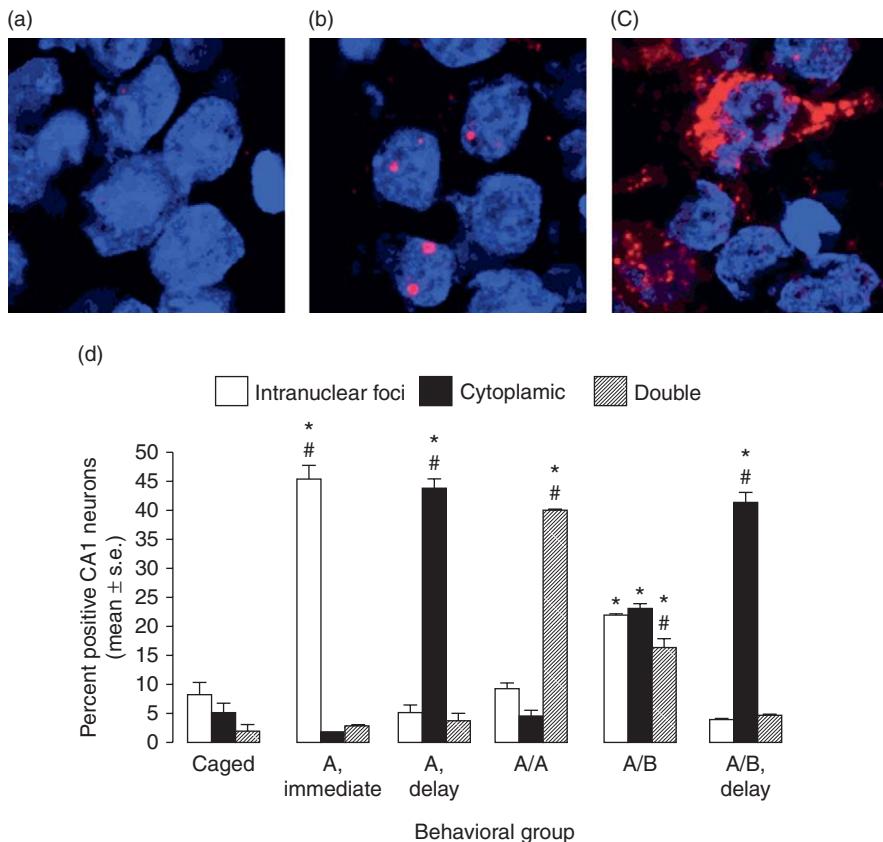

Figure 7 Immediate early gene imaging with catFISH. Fluorescent *in situ* hybridization (FISH) can be used to provide high-resolution images of the localization of mRNAs in neurons. Compartment analysis of temporal activity by fluorescent *in situ* hybridization (catFISH) uses this resolution to identify the neurons activated at two times. (a) Prior to context exploration, *Arc* is largely absent from hippocampal CA1 neurons. (b) At 5 min after exposure to a context, *Arc* mRNA is localized to intranuclear foci that presumably mark the sites of transcription. (c) At 30 min after context exposure, *Arc* mRNA moves to the cytoplasmic and intranuclear foci are no longer found. (d) More than 40% of neurons in area CA1 have intranuclear *Arc* foci immediately after context exposure (A, immediate), and a similar number have cytoplasmic *Arc* labeling 20 min after context exploration (A, delay). Repeated exposure to the same context leads to intranuclear and cytoplasmic labeling in the same neurons, suggesting that the same neurons are activated with repeated exposure to the same context (A/A). When a second context is explored 20 min after the first (A/B), three populations of neurons are identified: 22% with only intranuclear labeling, 23% with only cytoplasmic labeling, and 16% with both intranuclear and cytoplasmic labeling. These results suggest that immediate early gene expression patterns may be context specific and extensive representations of contextual information. Source: Guzowski et al., 1999.

The question really requires knowing how much of a difference between any two representations is needed for faithful discrimination, but by assuming that 10 000 neurons is a sufficient difference to robustly differentiate memories it is possible to estimate the lower limit of this number. If neurons are imagined to function in a bundle of 10 000 neurons, guaranteeing a difference of 10 000 neurons between any two representations, there are still 86 million different representations consisting of 120 000 neurons possible within a CA1 network composed of 300 000 neurons. Second, systems-level consolidation limits the time of hippocampal storage by transferring hippocampal memories to the cortex in representations that may use fewer neurons, a possibility that would be consistent with both systems-level consolidation and the increased generalization that often occurs with remote

memories. Third, it is possible that hippocampal representations become more refined in the days following learning. Such a focusing of memory could account for the basic principle that memory becomes more resistant to interference with consolidation. Fourth, the analysis above ignores the temporal order of neuronal activation, but a given contextual representation is likely to be defined by the sequential activation of neurons representing distinct but adjacent components of the environment. If this sequence of activity matters, then a vastly larger number of firing patterns are possible with the same number of neurons. Lastly, analysis of activation of a few IEGs may not reflect the induction patterns of other IEGs. Perhaps genes other than *Arc* have more selectively expression patterns in the hippocampus, just as some have more selectivity for associative aspects of memory.

Transcriptional Metaplasticity: Recent Experience regulates the Ability to Induce Transcription

Although *Arc* activation occurs in the same neurons with repeated exposure, the ability to induce *Arc* in these neurons is affected by the recent activity history of the neurons. Massed repeated reexposure to a context substantially decreases the number of neurons activated by a final exposure to that context but only mildly affects *Arc* induction in response to a distinct context, suggesting that the recent transcriptional activity modulates the ability to induce further transcription and that this modulation is neuron-wide rather than synapse specific. The firing properties of CA1 neurons measured by electrophysiological methods did not change with repeated context exposure, showing that this change in transcriptional activity is not a consequence of altered electrical activity. Thus, transcription is not only dynamic after learning, but the ability to transcribe genes is altered by experience, a process that could be considered transcriptional metaplasticity. Transcriptional metaplasticity may explain the ability of spaced training to facilitate long-lasting memory more readily than massed training and may allow for better separation of memories by selectively biasing against incorporation of neurons that are involved in recently encoded events. Selectivity of incorporation into neuronal networks based on transcriptional capacity is consistent with recent work by Sheena Josselyn in the amygdala, where she has observed that the level of CREB activity in a neuron can modify the likelihood that it is incorporated into a memory trace. A remarkable aspect of these findings is that if different IEGs show distinct patterns of transcriptional metaplasticity, a wealth of information may be stored by mechanisms that guide the ability to re-induce gene expression based on recent neuronal activity.

Epigenetic Mechanisms in Memory Formation

Together, the existing data on transcriptional regulation after learning suggest that long-lasting changes in gene expression accompany memory formation and that the regulation of transcription during memory may contribute to information storage. Transcriptional activation is a tremendously complex computation that integrates multiple distinct cellular signaling events to determine whether genes are expressed. In developmental biology, the results of these computations are stably stored in the form of epigenetic marks that can alter the future transcription of a gene. Epigenetic marks consist of covalent modifications to the chromatin complex that packages

DNA, as well as DNA itself. The fundamental unit of chromatin is the repeated nucleosome structure, which consists of the four core histones, each in duplicate, tightly encircled by genomic DNA. The amino-terminal tails of histone proteins protrude out of the nucleosome and are sites for post-translational modifications that regulate the ability of the transcriptional machinery to bind to and transcribe the underlying genes. Specific amino-acid residues on histone tails are targets for acetylation, methylation, phosphorylation, sumoylation, and/or ubiquitination. Histone modifications, often associated with another epigenomic mark, DNA methylation, facilitate or repress transcription, and synergistic interactions have been identified among many of these modifications. The exact combination of these epigenomic marks at the promoter and enhancers of a gene is thought to represent a histone code that determines the present rate and future capacity for transcription of that gene. Therefore, epigenomic marks play an acute signaling role that regulates transcriptional activation and an information storage role that dictates the transcriptional programs available for a cell based on prior signaling events. This information storage role of epigenetic modifications may account for the metaplasticity observed in *Arc* studies, and has been shown to stably maintain changes in behavior caused by early life experience.

The Histone Acetyltransferase CBP regulates Memory Formation

The role of CREB in long-term memory formation provides a compelling connection between memory and one particular epigenetic mark, histone acetylation, through the known interaction of CREB with the histone acetyltransferase CBP. Phosphorylation of PKA on serine 133 stabilizes an alpha-helix domain of CREB that recruits the transcriptional coactivators CBP and p300, which are important for transcription of some CREB target genes. CBP and p300 are histone acetyltransferases that modify the local chromatin environment to allow transcription at repressed genes. Acetylation of histone proteins is a type of epigenomic mark that can acutely alter the rate of transcription of underlying genes and potentially function as a type of information storage about past gene activity to regulate future gene transcription. Increased histone acetylation occurs within CA1 of the hippocampus after contextual fear conditioning. Humans with mutations in CBP have a disorder known as Rubinstein-Taybi syndrome (RTS), a genetic disorder characterized by facial abnormalities, broad toes and thumbs, and mental retardation. Although the cognitive deficits in RTS could be explained by developmental abnormalities, the role of cAMP signaling and CREB in memory consolidation suggests an acute role for CBP during memory formation.

This hypothesis has been tested with many of the genetic approaches mentioned earlier in this chapter. Mice with a single knock-out allele of CBP not only have bone morphologies characteristic of RTS, but also have impaired long-term contextual and cued fear memory. Using the α -CaMKII promoter to allow expression of mutant forms of CBP in postnatal forebrain excitatory neurons, two different groups found that expression of mutant forms of CBP lacking the histone acetyltransferase activity selectively impairs long-term memory, suggesting that histone acetylation regulates memory consolidation. In addition, mice homozygous for a knock-in mutation in the domain of CBP that interacts with phosphorylated CREB, the kinase inducible interaction (KIX) domain, have defects in long-term contextual fear memory but normal learning and cued fear memory. This series of papers on the coactivator CBP suggests that not only genetically encoded information but also interactions of the environment with the gene at the epigenetic level are important for memory formation, an exciting possibility that has opened an entirely new avenue of research into the contribution of epigenetic modifications in memory formation. In addition, as discussed previously, CBP may provide a critical role in integrating the activity of multiple transcription factors with the ultimate readout being histone acetylation.

HDACs Act as Memory Suppressors

The role of histone acetyltransferases in memory consolidation predicts that the histone deacetylases (HDACs) opposing histone acetylation may act as memory suppressors and, in fact, inhibitors of these HDAC enzymes enhance long-term memory formation. The first demonstration of a role for HDACs in hippocampus-dependent memory showed that systemic administration of HDAC inhibitors enhances contextual fear memory. In subsequent studies, it was demonstrated that direct injection of the HDAC inhibitor trichostatin A (TSA) into the hippocampus immediately after learning enhances long-term memory without affecting cued fear memory. Thus, HDAC inhibitors act within the hippocampus during memory consolidation to strengthen memory storage. This memory-enhancing effect of HDAC inhibitors requires the CREB–CBP interaction, suggesting that HDAC inhibitors may enhance memory through increased transcription of CREB–CBP target genes. Although many CREB target genes have been identified, TSA was found to effect the expression of only two out of 13 CREB target genes after learning, the orphan nuclear receptors *Nr4a1* and *Nr4a2*. Further studies that identify the subset of CREB target genes that mediates the enhancement in memory by TSA and the individual HDAC(s) that target them promise to provide novel

drug targets for memory enhancement and amelioration of cognitive deficits in neuropsychiatric and neurodevelopmental disorders.

DNA Methylation Dynamics regulate Memory Formation

Histone acetylation is only one of collection of epigenetic marks that includes histone phosphorylation, methylation, sumoylation, ubiquitination, as well as DNA methylation. DNA methylation represses transcription through direct disruption of transcription factor binding sites and recruitment of methyl–DNA binding repressors, such as MeCP2, a transcriptional repressor that recruits histone deacetylases providing a potential link between DNA methylation and histone acetylation. Recent research from David Sweatt's lab suggests that DNA methylation regulates memory formation. For instance, DNA methylation decreases after learning at the CREB target gene *Bdnf*. Surprisingly, intrahippocampal injection of DNA methyltransferase (DNMT) inhibitors blocks the change in DNA methylation and the increase in histone acetylation that accompanies learning in the absence of inhibitor, and impairs long-term memory formation. Although the findings on DNA methylation in memory consolidation are more perplexing than the findings on histone acetylation, they suggest that the dynamics of DNA methylation may be a critical aspect of memory formation. This possibility is supported by the recent findings of Huda Zoghbi's lab that MeCP2 can function as a transcriptional activator as well as a repressor, especially at CREB target genes. Thus, MeCP2 binding through DNA methylation may regulate both basal repression by recruiting HDAC activity and the ability to achieve maximal activity-mediated gene expression during memory consolidation, a possibility that might explain the results observed with DNMT inhibitors and connect DNA methylation directly with histone acetylation.

Conclusion

Research on memory formation has moved through three stages that reflect our growing understanding of information storage in the brain. First, it was discovered that neurons are electrically excitable; allowing for the insight that communication between neurons through these electrical signals can compute information and guide behavior. Second, biochemical changes in neurons were identified that could alter the relative strength of these connections within neuronal networks, suggesting plasticity as a mechanism of learning. Recently, it has been discovered that transcriptional processes guide these

changes in plasticity, allowing for the possibility that one of the most ancient information storage and processing systems in biology, the genome, has been adapted for behavioral information storage through epigenetic modifications.

Sleep Genetics

C Cirelli and G Tononi, Department of Psychiatry, University of Wisconsin-Madison, Madison, WI, USA

© 2010 Elsevier Ltd. All rights reserved.

It has long been known that sleep is under partial genetic control. Studies in the 1930s reported that some sleep phenotypes, such as latency to sleep onset, percentage of REM sleep, and density of spindles in NREM sleep, have higher concordance in monozygotic than in dizygotic twins. Only in the last 15 years, however, at least 10 single genes have either been linked to a human sleep disorder, or have been shown to strongly affect sleep in animals.

Sleep phenotypes (or traits) are complex (quantitative), controlled by many genes, and characterized by strong interactions between genetic and environmental factors. Overall, genes with effects on sleep have been identified in flies, mice, and humans, and can be subdivided in several major functional categories: circadian regulation, neurotransmission and other signaling pathways, and ion channels.

'Circadian mutations' not only affect the timing of sleep but also its homeostatic regulation. For instance, Cry1/Cry2 double KO mice seem to live under a stronger sleep pressure in baseline conditions, when they sleep more and have higher NREM delta activity, but show little further increase in sleep duration and sleep intensity after sleep deprivation. Other mutations of circadian mouse genes (Clock, Bmal1, Npas2, and Prok2) also result in an abnormal response to sleep deprivation, as do mutations of the fly genes Cycle and Clock. Studies in humans, instead, point to an important role for another circadian gene, PERIOD3, which contains variable-number tandem-repeat polymorphisms in its coding region. Relative to PER3^{4/4} carriers, PER3^{5/5} individuals have longer duration of slow wave sleep (SWS), higher NREM delta activity, and after sleep deprivation are more impaired in executive functioning tasks in the early morning. If confirmed in a larger number of subjects, PER3 would be the first gene with a clear role in modulating susceptibility to sleep deprivation.

Many mutations of genes coding for receptors and synthetic enzymes of all major neurotransmitters and neuromodulators have been tested for their effects on sleep. Overall, these experiments have confirmed the arousal-promoting role of the noradrenergic, histaminergic, serotonergic, cholinergic, and hypocretin/orexin systems. One of the novel findings, instead, relates to narcolepsy. In dogs, narcolepsy is an autosomal recessive, fully penetrant, disorder due to a mutation in the gene coding for the hypocretin receptor 2. A narcolepsy-like

phenotype is present in both preprohypocretin/orexin KO mice (where the hypocretins/orexins producing cells are spared but the corresponding peptides are lost) and in hypocretin/orexin-ataxin 3 transgenic rats and mice (where both cells and peptides are missing). Thus, the lack of hypocretins/orexins alone is sufficient to cause a narcolepsy-like syndrome. Genetic studies have also clarified the mechanisms by which some drugs affect sleep. Mice lacking the adenosine receptor A2AR are insensitive to the waking-promoting effects of caffeine. In line with this, in humans a polymorphism in the same gene contributes to individual sensitivity in the effects of caffeine on sleep. Moreover, a functional polymorphism in the human gene coding for the catabolic enzyme adenosine deaminase results in reduced enzymatic activity in blood cells, increase in SWS duration, and increase in NREM slow wave activity. It remains unclear, however, whether this genetic variation also affects the response to sleep deprivation.

Ion channel mutations affect sleep in flies and mammals. In *Drosophila melanogaster*, mutagenesis screenings have identified two genes with striking effects on fly sleep. One is Shaker, which codes for the alpha subunit of a tetrameric potassium channel that passes a voltage-activated fast-inactivating IA current. Homologous channels in vertebrates have similar properties and, in both mammals and flies, IA plays a major role in the control of membrane repolarization and transmitter release. Flies carrying Shaker loss of function mutations sleep only 2–4 h everyday rather than 8–10 h. The second gene is called Sleepless, and Sleepless flies sleep only ~2 h a day (~85% less than controls). Sleepless codes for a glycosyl-phosphatidylinositol-anchored protein with unknown function, and has no obvious vertebrate homolog, but Sleepless flies have reduced levels of SHAKER, suggesting that their short sleeping phenotype is at least in part mediated by the Shaker current. Mice lacking the closest mammalian homolog of Shaker, Kv1.2 (KcnA2), show a decrease in NREM sleep, but their short sleeping phenotype is not as strong as in Shaker flies, perhaps because of redundancy – there is one Shaker gene in *Drosophila*, against at least 16 genes coding for alpha subunits of voltage-dependent potassium channels in mammals. A striking sleep phenotype is also observed in double KO mice lacking the voltage-dependent potassium channels Kv3.1 and Kv3.3, which sleep less (by 40%), have shorter sleep episodes, an overall decrease

in the EEG power spectrum more evident in NREM sleep, and no response to sleep deprivation. These mice are also hyperactive and show motor dysfunction, which may be partly responsible for their sleep fragmentation. The mechanism underlying the effect of these mutations on sleep is most likely different from those involved in Shaker and Sleepless mutants, because Kv3-type channels are mainly expressed in cortical and thalamic GABAergic interneurons, where their presence enables these cells to fire repetitively at high frequency.

There are two sleep disorders with a clear-cut genetic basis: fatal familial insomnia (FFI) and familial advanced sleep-phase syndrome (FASPS). FFI is a rare autosomal-dominant disease due to a point mutation at codon 178 of PRNP, the gene coding for the prion protein. The same mutation is present in patients affected by the familial form of Creutzfeldt–Jakob disease (CJD), another prion disease with extensive cortical, rather than thalamic, damage, and in which dementia, rather than insomnia, is the main clinical feature. In FFI patients, codon 129 on the mutated allele codes for a methionine, while in CJD patients it codes for a valine. Thus, a mutation at codon 178 determines the presence of a prion disease (either FFI or CJD) while codon 129 on the mutated allele determines the phenotype of the disease (CJD or FFI).

FASPS is also transmitted in a highly penetrant autosomal-dominant manner. FASPS subjects have a normal duration of sleep but go to bed ~ 4 h earlier than usual. Some FASPS individuals carry a serine to glycine mutation in PERIOD 2, one of the canonical circadian genes. Other FASPS individuals carry a mutation in the gene coding for casein kinase I delta, and the mutation may affect the ability of the enzyme to phosphorylate PERIOD 2.

While in dogs and mice narcolepsy is genetically determined, nongenetic factors play a major role in human narcolepsy. No association has been found between human narcolepsy and polymorphisms in the genes of the hypocretin/orexin system, and only one case of narcolepsy with very early onset has been associated with a mutation in hypocretin (HCRT). Yet, most patients with narcolepsy–cataplexy have low or undetectable levels of hypocretins, and narcolepsy is strongly associated with the human leukocyte antigen (HLA) allele DQB1*0602. This suggests that the deficit in hypocretinergic neurotransmission in human narcolepsy could be due to an autoimmune attack.

Restless leg syndrome (RLS) is a common sleep disorder often characterized by periodic limb movements

during sleep. RLS can be familial in up to one-third of cases. A recent genome-wide case-control study identified three predisposing loci on chromosomes 6p, 2p, and 15q, which may explain $\sim 50\%$ of the risk for RLS in individuals with European ancestry. Obstructive sleep apnea syndrome (OSAS) is also to some extent under genetic control, but the responsible genes are difficult to identify, because many of the risk factors for OSAS, including obesity and alterations of the craniofacial morphology, are also under genetic control.

A common but inaccurate view is that with age, cognition deteriorates across the board. Instead, certain cognitive domains show strong effects of aging, whereas others are relatively unaffected, and some even show positive age-related changes.

Cognitive Domains that Show the Greatest Age-Related Declines

Attention

Attention is not a single, monolithic construct, but rather has been fractionated into several subtypes, some of which are more strongly affected by aging than others. On tasks of sustained attention or vigilance, older people generally perform well. When it comes to selective attention (i.e., the ability to focus on information that is currently relevant and ignore that which is irrelevant), older people are more likely to have difficulty. For example, when asked to detect a target against a background of distractors on a visual search task, older adults are usually slower than young people. Older adults seem to be especially impaired on tasks that require switching or dividing attention between perceptual or response sets.

Working Memory

Working memory is a limited-capacity system that is necessary for holding information and using it in the course of decision making, planning, and related cognitive operations. According to the influential model advanced by Baddeley and colleagues, information is held over the short term in material-specific buffers, with a central executive selecting and manipulating output from them. Whereas the ability to maintain information in these buffers remains relatively intact in normal aging, there is deterioration in the ability to manipulate it and apply it to other tasks.

Executive Functions

The executive functions are a family of cognitive processes that allow one to control and guide behavior. These processes, including planning, goal setting, strategizing, and switching, are classically impaired in patients with

discrete lesions to prefrontal cortex (PFC). Older adults are typically impaired on neuropsychological tests that measure these abilities. For example, in a meta-analysis, Rhodes showed that on the Wisconsin Card Sorting Test older people achieved fewer categories and made a greater number of perseverative errors than young people, a pattern of impairment also shown by prefrontal lesion patients. However, not all studies show significant impairment on executive tasks in older adults. Furthermore, poor performance on cognitive tests that are very sensitive to deficits in specific domains is not necessarily a predictor of poor function in practical situations: older adults are often very good at planning, strategizing, and problem solving in the real world.

Episodic Memory

A dominant view of long-term memory distinguishes between explicit and implicit or procedural memory systems, with the former handling information that is available to consciousness, and the latter not so. Explicit memory suffers with age to a much greater degree than implicit memory does. This can be seen in experiments that contrast word-stem cued recall with word-stem completion, a classic paradigm that was used to show the dissociation between impaired explicit and intact implicit memory in cases of organic amnesia. Older people are significantly impaired on word-stem cued recall, but show fewer problems when tested using word-stem completion. Explicit memory can be further subdivided into semantic (i.e., factual knowledge) versus episodic (i.e., recollection of personally experienced events) components. It is the episodic component which is especially vulnerable to aging, particularly in cases where contextual details or associations among arbitrarily linked pieces of information (such as novel names and faces) must be remembered. All other things being equal, the degree of episodic memory impairment displayed by older people is greatest when memory is tested using free recall, is lesser for cued recall, and is least for recognition; this has led to speculation that episodic memory problems in aging can be attributed, at least in part, to faulty retrieval (as opposed to encoding). Well-learned skills, routines, and habits are relatively preserved in aging.

Many researchers posit that age-related impairment in one of the aforementioned cognitive domains may be the reason for impairment in other domains. For example, age differences in episodic memory have been variously attributed to age-related impairments in attention, working memory, and/or executive function. These underlying factors may be at play even in domains that are relatively impervious to the negative effects of age, for example, language. Kemper and colleagues have argued that problems with working memory underlie subtle age-related difficulties in speech production and speech perception (e.g., losing track when listening to an especially long and grammatically complex sentence).

Many Cognitive Functions Are Preserved in Aging

There are some domains in which older adults' performance is as good as, or even superior to, that of young people. For example, general knowledge and vocabulary are accumulated throughout the life span (although there may be a slight decline in the very last years of life).

This accumulation of knowledge and experience (wisdom) may provide a mental scaffolding to help attenuate, although perhaps not completely eliminate, age differences in cognition. For example, older adults sometimes perform relatively better compared to young on tests of attention and memory when tested using materials in which they are domain experts. In daily life, older adults may often do better than expected due to reliance on well-worn routines, or because they have learned to develop and use strategies to reduce cognitive load (including using external aids, such as making a grocery list to compensate for episodic memory decline).

Cognitive Models

Several cognitive theories of normal aging have been advanced. Each of these models has roots in the literature on memory and aging, with either the original theorist(s) or others endeavoring to extend its scope from memory to cognition overall.

Processing Speed

Salthouse has posited that general slowing in cognitive and neural systems is the key mechanism of cognitive aging. This assertion is based on the observation of strong correlations between reaction times and memory: older adults who show longer reaction times tend to show poorer memory. Critics, however, have asserted that general slowing does not easily account for the complex patterns of impaired versus spared cognitive functions in

normal aging. In addition, several objections have been raised regarding this method. For one, the choice of task from which one derives reaction time may be important: tasks that are more difficult and complex tend to show stronger reaction-time correlations with memory. Also, support for the processing speed model may be weaker in longitudinal compared to cross-sectional studies.

Cognitive Resources

Craik has suggested that cognitive aging may best be characterized as the result of a shrinking pool of cognitive resources that are available to an individual. These cognitive resources (mental energy) are especially taxed by self-initiated operations as seen, for example, on memory tests involving recall as opposed to recognition. This notion is supported by studies showing that tying up cognitive resources in young people (dividing attention, by having people perform a concurrent secondary task) yields a qualitatively similar pattern in memory to that produced by aging. However, there appear to be subtle but important differences between the effects of normal aging, on the one hand, and dividing attention in young people, on the other. Further, critics have called for a clarification of the exact nature and neurobiological bases of cognitive resources.

Inhibition

Hasher and Zacks proposed that memory loss in old age primarily involves dysfunction of the ability to keep irrelevant information out of mind, and to remove no-longer relevant information from one's mind (akin to wiping clean one's mental chalkboard). A somewhat related use of the concept of inhibition has been made by Jacoby and colleagues to explain many age-related memory errors as reflecting a failure to inhibit habit by using controlled, deliberative processing (e.g., by automatically taking one's usual route home today, and failing to recollect to stop for milk at the store as one had intended). The concept of inhibitory failure does a good job of explaining some memory failures in older adults, but whether it can be extended to all of cognition is currently unclear.

Although each of the aforementioned models has the virtue of parsimony, at present, no single model appears to offer a complete explanation of the data (although, as mentioned above, many of the original theorists did not intend their theories to extend to all of cognition). Currently, most researchers would posit that multiple cognitive mechanisms go awry in aging, and recently, interest has increased in the brain changes that may underlie these cognitive changes.

Brain Changes

Current studies seeking links between cognitive aging and brain changes most often use magnetic resonance imaging (MRI), which permits inferences about neural structure and function at the molar level. Although no brain region or system is invulnerable to the effects of aging, some are more obviously susceptible than others. Three regions have received considerable interest in particular.

Prefrontal Cortex

Aging of the brain appears to follow an anterior–posterior continuum, with anterior regions especially vulnerable to aging, and posterior regions less so. Both cross-sectional and longitudinal studies indicate that PFC deteriorates more rapidly than most other regions of the brain. This pattern is evident in both gray matter (usually measured volumetrically) and white matter (whether indicated by volumetric measures, counts of white matter hyperintensities, or estimates of tract integrity from diffusion tensor imaging). In general, studies attempting to link decreases in frontal gray matter volumes with poorer performance on cognitive tasks have not yielded strong results (perhaps because the vast majority of such studies is still cross-sectional, or perhaps because of differential age effects within different subregions of PFC). In contrast, white matter integrity appears to be a relatively good predictor of cognitive function in older adults. Several recent studies have shown that, as the number of white matter hyperintensities increases and/or tract integrity decreases, attention, working memory, and episodic memory are reduced. Positive correlations between white matter integrity and cognition have been reported for both interhemispheric (e.g., corpus callosum) and intra-hemispheric connections (e.g., tracts linking PFC with parietal cortex and the striatum).

Across cognitive domains, many functional neuroimaging studies report relatively less activation in posterior regions of the brain in older adults, accompanied by greater activation in anterior regions. Within PFC, patterns of activation are often different between young and older people. Grady and colleagues were the first to report that, whereas young people showed relatively greater left PFC activation during encoding and right PFC activation during retrieval on an episodic memory task, older adults showed less activation in left PFC during encoding coupled with bilateral activation during retrieval. Cabeza has argued that this pattern exists in other domains, including working memory, executive function, and perception, although the functional role of this pattern remains unclear. Some researchers suspect that it reflects compensation on the part of older brains,

whereas others postulate that it reflects inefficiency. To answer this question, a useful and increasingly popular strategy has been to compare brain activation patterns between older adults who show relatively high versus low levels of performance, but the extant data are mixed: some studies have reported that high-performing older adults showed bilateral activation, whereas young people and low-performing elders showed unilateral activation, supporting the notion of bilateral activation being compensatory. Yet, others have found that high-performing older adults showed relatively unilateral activation patterns (similar to young people) and low-performing older adults showed bilateral activation, supporting the notion of inefficiency.

Medial Temporal Cortex

Given the fact that older people show a prominent episodic memory impairment, the hippocampus and surrounding structures in medial temporal cortex have received considerable attention. Volumetric MRI studies show robust declines in medial temporal volume with aging; although some researchers have asserted that different structures may decline at different rates (e.g., hippocampus compared to entorhinal cortex), a clear consensus has not yet emerged. Surprisingly, studies seeking links between medial temporal volume and memory have often failed to show strong correlations. Functional neuroimaging studies of episodic memory have generally shown reduced activation in medial temporal regions in older adults, accompanying their poorer behavioral performance.

Striatum

The striatum is strongly interconnected with PFC and medial temporal regions, and also shows significant structural and functional deterioration with age. Interest in the striatum's role in cognitive aging has been bolstered by assertions that the cognitive profile of normal aging is a less extreme version of that of Parkinson's disease. At present, however, it is unclear what the unique and combined roles of PFC, medial temporal cortex, and the striatum may be.

Neurotransmitter Systems

Many neurotransmitter systems are affected by aging. Historically, a loss of cholinergic cells and corresponding decline in the availability of acetylcholine in the hippocampal system have been considered an early indicator of brain and cognitive aging. Consistent with this view, there is evidence that the degree of memory loss in old age correlates with reductions in brain acetylcholine levels. Further support derives from studies showing that young

adults receiving injections of scopolamine, a drug that blocks acetylcholine activity, show cognitive changes similar to those seen in old age, whereas treatment with drugs that increase acetylcholine supply (e.g. physostigmine) can enhance memory and related functions. The cholinergic depletion is also thought to be a factor in Alzheimer's disease (AD), with current pharmacological treatments (e.g., donepezil) targeting this system in an attempt to slow down the progression of the disease. Several other neurotransmitters are necessary for cognitive function and appear to be linked with cognitive aging. For example, in both the striatum and throughout the cerebral cortex, concentrations of dopamine decline with age, and its binding is reduced. The reductions in dopamine tend to be correlated with impairments in executive functions and memory in older adults.

Neurocognitive studies of aging are still in their infancy, and will be aided by advances on several fronts. First, despite the explosion of functional MRI (fMRI) data, we still do not understand what the fMRI signal reflects about neural activity and how this relation may be affected by aging. Second, perhaps more important than the contributions of individual regions, are the interactions among them. As mentioned above, structural neuroimaging has implicated deterioration of tracts connecting different brain regions in age-related declines in several cognitive domains. In functional neuroimaging, system-level interactions are being explored with new statistical analysis methods; these have suggested that age differences in cognition can be attributed to complex changes in the interactions among PFC, medial temporal, parietal, and other regions. Third, today, most investigations focus on one cognitive domain and one neural technique (e.g., fMRI of working memory). There is a need to examine the potential combined effects of multiple influences (e.g., by combining structural with functional neuroimaging, or by examining the combined effects of working memory and frontal lobe volume on episodic memory).

Potential Confounds

Several factors must be taken into account when performing and evaluating research on cognitive aging. These include: prodromal dementia, sensory decline, affect, and variability.

Prodromal Dementia

Aging is the greatest risk factor associated with AD, and cognitive studies that recruit seemingly healthy older adults risk including participants who are in the early stages of, or on a trajectory toward, AD or another dementia. Predicting whether an older adult will show dementia

in the next few years is very difficult at present, for clinicians and researchers alike. The concept of mild cognitive impairment (cognitive function that is below average, but not impaired enough to qualify as dementia) has been proposed as useful in identifying those who are particularly at risk of developing dementia in the relatively near future. However, a certain proportion of the population will show such a cognitive profile yet remain stable. Many samples of older adults (especially in earlier studies) undoubtedly contain a few people who are on the brink of dementia, and thus such studies risk overestimating the effects of normal aging on cognition. However, the opposite danger exists, in studies in which the inclusion criteria regarding cognitive and physical health are so stringent that only a small proportion of older adults (super-agers) meet them, and the sample is no longer representative of the population.

Sensory Decline

The loss of sensory acuity is one of the first aspects of aging that comes to a layperson's mind, but is an underappreciated factor in cognitive aging research. Studies of perception and memory that add noise to visual or auditory signal can mimic the effects of aging in young people. The influence of perceptual loss may also be indirect – straining to hear or see an unclear stimulus ties up additional cognitive resources (mentioned above), leading to fatigue and a decline in performance. Despite this clear confound, not enough current studies of cognitive aging attempt to equate sensory function between older and younger samples.

Affect

A significant number of older people experience depression (and its effects on cognition can be difficult to tell apart from early dementia), although many studies show that mood grows less negative over the life span. In fact, Carstensen and colleagues have argued that with age comes a change in emotional focus, with older adults paying greater attention to positive and ignoring negative emotional information and experiences. This putative change in orientation is thought to affect processing of stimuli in laboratory studies, as well as reminiscences and social interactions in the real world.

Variability

Traditionally, studies of cognitive aging have been concerned with mean differences between older adults and college freshmen. Recently, however, interest has been revived in the question of individual differences. Not all older adults show the same cognitive profiles. For example, Glisky and colleagues have divided older adults into

those who are above average (high) versus below average (low) on executive function. These groups yield qualitatively different patterns of memory performance, supporting the assertion that executive decline underlies memory decline in aging. Such studies are generally cross-sectional, however, and require additional longitudinal and cohort-sequential data for corroboration – it is currently unclear whether low-executive older adults have always been this way, or have only recently declined to this level. Another factor is circadian arousal patterns: with age, there is a tendency for one's optimal time of day to shift from afternoon to morning. Consequently, if all participants are tested in the morning, memory differences between young and old are much smaller than if both groups are tested in the afternoon. Variability within older adults from moment to moment may also be informative: such fluctuations in cognitive function may be a harbinger of significant cognitive decline in the near future, and perhaps even imminent death!

Lifestyle Factors

Cognitive aging is largely the result of structural and functional decline in particular brain regions (e.g., PFC and medial temporal cortex/hippocampus) but several lifestyle factors also contribute. ‘Use it or lose it’ has become a familiar refrain to remind us of the importance of keeping busy and engaged in stimulating activities in order to preserve cognitive function in old age. Research has given truth to this old adage and there is now abundant evidence from animal and human studies that enriched environments, intellectual stimulation, and physical exercise all contribute to superior performance on tests of learning and memory. The interplay between biological and lifestyle factors is underscored by findings that experientially related cognitive benefits are associated with corresponding changes in brain plasticity as measured, for example, by enhanced neurotransmitter (e.g., acetylcholine and dopamine) function, increased cerebral blood flow, activity-related gene expression, and new cell growth (neurogenesis) in hippocampus.

Other lifestyle factors also affect the rate of cognitive decline in old age. Education seems to be a positive factor, possibly because intelligent, highly educated people have more cognitive reserve upon which they can draw in old age. It is sometimes difficult to determine if the effects of education are direct or indirect, in the sense that educated people are often part of a privileged sector in society that is also better informed on, and able to afford, healthy lifestyles. In contrast, excessive stress is a destructive force to which older adults, because of limited physical and psychological resources, are especially vulnerable. The adverse effects of stress in the elderly extend to cognitive performance, particularly to memory. It is not

surprising perhaps that education and stress influence cognitive function in old age; however, perhaps less predictable is the emerging relationship between cognitive ability and psychosocial status. Older people living at home function at a higher cognitive level than matched counterparts living in institutions but, in both groups, measures of psychosocial health (e.g., personal control, optimism, happiness, and meaningfulness) correlate significantly with performance on neuropsychological tests measuring a wide range of cognitive processes. These relationships have been tracked over long periods of time and the consistent finding is that the changes in one domain (e.g., psychosocial) are accompanied by parallel changes in the other. More work is needed to understand how such relationships are related to other factors (e.g., physical and mental health, and significant life events) that affect the lives of older people in major ways.

A growing body of research indicates that dietary factors significantly contribute to cognitive decline in old age, as well as to various types of cognitive impairment associated with age-related diseases. It is well established that high-fat diets harm cardiovascular and other biological systems but it is now known that high-fat (particularly saturated fat) diets, consumed over an extended period of time, can impair cognitive function. The latter effect can be substantial even in young adults but is exacerbated in older populations and in individuals at-risk for conditions that affect brain function (e.g., type 2 diabetes and AD). With respect to the latter, it has been estimated, for example, that long-term consumption of diets high in saturated and trans-fats may increase the chances of developing AD by as much as 150%. The mechanisms of such dietary effects are not fully understood but possibilities include increased insulin resistance, oxidative stress, and neuroinflammation – all of which are associated with brain aging. As a complement to studies highlighting the risk factors in dietary fat, there is also evidence that low-fat diets, especially those rich in antioxidants, or diets high in omega-3 fatty acids that have anti-inflammatory properties can enhance cognitive function.

The search for lifestyle protective factors that help to slow down the process of cognitive decline is in its early stages but the evidence is mounting that cognitive aging is as much about what happens to us as we age, as it is about getting old.

Cognitive Recovery and Rehabilitation

Historically, research into cognitive aging has been concerned largely with the pattern of lost and spared functions associated with the aging process, but interest is growing in the potential for improving cognition in the

elderly, particularly with respect to memory function. Clearly, older adults can benefit from the use of external aids as reminders (e.g., post-it notes, memory books, and electronic managers) and there seems to be relatively little resistance to this practice. However, for more complex learning and remembering, older people must make a conscious effort to summon and apply the types of internal mnemonic strategies (e.g., visual imagery and deep encoding) that young adults use automatically. In addition, considerable research has focused on developing specialized forms of practice and some interesting techniques have emerged. An example is spaced retrieval, which involves repeated rehearsal at progressively longer delays, and has the advantage of directing attention to the studied material during critical stages in the learning process. Another is the method of vanishing cues, in which the individual attempts to remember specific information with diminishing numbers of cues – a method that has been moderately effective with brain-damaged amnesic patients. These and other domain-specific techniques have been tested in normal, older adults and in older individuals with diagnosed cognitive impairment, but with only limited success. Part of the difficulty is that the benefits observed in artificial lab settings do not transfer well to real-world situations where it is necessary to recruit such techniques in the absence of environmental supports.

Domain-specific techniques typically have a relatively narrow focus but age-related cognitive decline can be pervasive, affecting a range of cognitive processes and influenced by numerous factors. Largely in response to this, the emphasis has shifted to more broad-based, multi-dimensional cognitive rehabilitation programs, designed specifically for the elderly. By far, the most ambitious of these is the Advanced Cognitive Training for Independent and Vital Elderly (ACTIVE) program, launched in 1998 as a multicenter, randomized control trial, involving 2802 independent-living older adults. The study compared three cognitive interventions (memory, reasoning ability, and speed of information processing), each consisting of 10 sessions over a 5–6-week period. Outcome measures, which included practical problem solving as well as standard experimental tests, made extensive use of composite measures to assess overall ability in the respective areas. Over a 2-year period, significant improvements followed each training program but, importantly, participants performed better only in the cognitive domain in which they received training, and there was no evidence of generalization to real-world activities.

A team of scientists and clinicians at the Rotman Research Institute in Toronto took a different approach in developing a comprehensive cognitive rehabilitation program. This program is guided by a general model of strategic processing which assumes that cognitive tasks,

whether they involve straightforward aspects of learning and memory or complex problem solving, require strategic thought directed at achieving a particular goal. The protocol divides into three, 4-week modules – memory skills training, practical task training, and psychosocial training where the aim is to enhance psychological well-being and confidence in participants' ability to follow a strategic approach in problem solving. The trial was conducted on 49 community-dwelling, normal older adults, following a multiple baseline, crossover design that allowed for between- and within-group comparisons of training effects. Abilities in all training modalities were evaluated at baseline, immediately, and at 6 months after the completion of training. Significant gains over the long term were achieved in all three modalities. Notably, there were improvements in performing simulated real-life tasks, which reflected generalization of improved cognitive skills to everyday situations.

The results of the ACTIVE and Rotman trials are encouraging and reinforce the value of the multidimensional approach. At the same time, they raise important questions. Among them is whether, in the long run, focusing on specific processes or following a more comprehensive strategy will be more efficacious. Another question relates to the suitability of the respective protocols for clinical populations. The programs were designed for individuals with age-related cognitive decline or relatively mild impairment and it is not known if they can be adapted to individuals with more severe impairment. If that proves to be the case, significant progress will have been achieved in slowing the rate of cognitive decline associated with normal and abnormal aging.

Glossary

Diffusion tensor imaging – This is an MRI method that can detect microstructural alterations in the brain. It is especially useful for detecting structural changes in normal appearing white matter in demyelinating diseases and neurodegenerative disorders.

Entorhinal cortex – A region of the brain that receives multi-modal sensory information from neocortical regions and relays this information to the hippocampus. The entorhinal cortex is also important for memory function.

Gray matter – Gray matter is the other major component of the central nervous system; it contains neural cell bodies, glial cells (astroglia and oligodendrocytes), and capillaries. In contrast, white matter mostly contains myelinated axon tracts. The color difference arises mainly from the whiteness of myelin.

Hippocampus – A region of the brain that is critical for the acquisition of certain types of new information. The normal functioning of the hippocampus is important for memory about events and things (declarative memory).

Magnetic resonance imaging – A technique that allows us to visualize the structure and function of the body and especially of the brain. With this technique, the anatomy of the brain can be seen in great detail so that changes in given regions of interest can be quantified in patients with AD and in those people who are at risk of developing AD.

Mild cognitive impairment (MCI) – Mild cognitive impairment describes individuals who have cognitive impairments beyond that expected for their age and education, but who do not meet criteria for dementia. The cognitive impairments do not interfere with their activities of daily living. Although MCI can present with a variety of symptoms, when memory loss is the predominant symptom it is termed 'amnestic MCI' and is frequently seen as a risk factor for Alzheimer's disease.

Voxel-based morphometry – A neuroimaging analytic technique for quantifying group differences in MRI scans. It allows the detection of focal differences in brain anatomy using a statistical approach.

White matter – One of the main components of the central nervous system and consists mostly of myelinated axons.

Introduction

Alzheimer's disease (AD) is a brain disorder named after the German physician Alois Alzheimer who first described it in 1906. It is one of the most common neurodegenerative disorders among the elderly with more than five million Americans being affected at present. Although age is a major risk factor for AD, the disease is not a normal part of aging. The pathology associated with AD starts in parts of the brain that are critical for recent memory, such as the entorhinal cortex and hippocampus, and then spreads to other parts of the brain. It is for that reason that one of the earliest behavioral symptoms of the disease is a deficit in recent memory. In the early stages of the disease, patients may have trouble remembering, for example, what they had for breakfast, although they can remember events from their past in great detail. Some pharmacological agents can slow down the progression of AD in some people; however, at present there is no cure for this devastating disease which is the sixth leading cause of death in the United States.

Although a pathological diagnosis is the gold standard for a definitive diagnosis of AD, quantitative structural magnetic resonance imaging (MRI) can provide a proxy measure of the underlying pathology in neurodegenerative diseases. With these techniques, one can visualize, with excellent resolution, the anatomy of the brain in three dimensions in living people and quantify changes in given regions of interest. With quantitative structural MRI, it is possible to (1) examine the relation between alterations in given brain regions and the sequential development of behavioral symptoms in degenerative diseases and (2) develop biomarkers of risk of, for example, AD.

Quantitative Structural MRI Studies in People with Mild AD and in those at Risk of Developing AD

Since one of the hallmarks of AD during its initial stages is a disturbance in recent memory, medial temporal lobe regions important for memory function, such as the hippocampus and the entorhinal cortex, have received special attention in both *postmortem* and *in vivo* investigations on the pathophysiology of AD. It is for that reason

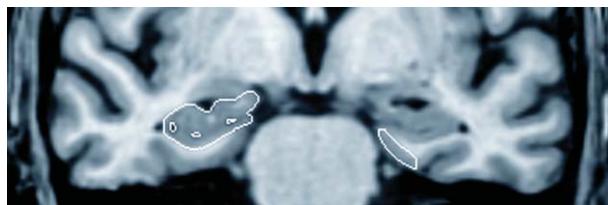

Figure 1 A coronal MRI section of the temporal lobe showing the entorhinal cortex (right hand side outline) and the hippocampus (left hand side outline).

that in this article, which focuses on sensitive MRI markers of risk of AD, we concentrate mostly on investigations of medial temporal lobe structures that show pathology very early in the disease.

Figure 1 shows the hippocampus and the entorhinal cortex on a single coronal MRI section. Atrophy of the hippocampus, a region critical for normal memory function, has been well documented in patients with a clinical diagnosis of AD using quantitative structural MRI techniques. In particular, those studies that evaluated patients with very mild AD have shown that significant hippocampal atrophy can be detected even in the very early stages of the disease.

In addition to patients with mild AD, there is now increased interest in studying elderly individuals who are at high risk of developing AD. One such at-risk group consists of people who are diagnosed with amnestic mild cognitive impairment (aMCI). Such older individuals have a deficit in the memory domain, but do not meet criteria for dementia. A number of centers have now demonstrated that people with aMCI convert to AD at the rate of approximately 12–15% per year. Among structural MRI studies that have examined the volumes of medial temporal lobe structures in older people with aMCI or cognitive complaints, the majority have reported hippocampal atrophy. Thus, aMCI may represent the very beginning stages of the disease.

Postmortem pathological studies have implicated the entorhinal cortex and the trans-entorhinal region as very early sites of involvement in AD. In fact, it has been suggested that early AD-related pathology may start in the trans-entorhinal region and the entorhinal cortex, and then spread to the hippocampus and other parts of the brain. With the development of MRI-based protocols for segmenting the entorhinal cortex, interest in quantifying the extent of atrophy in this structure to track disease progression and to differentiate those at risk for developing AD has increased. A number of structural MRI studies have reported significant entorhinal atrophy in patients with AD. More important, however, is the fact that MRI-derived entorhinal atrophy can be detected even in incipient or preclinical AD, that is, in older people with aMCI and in those with objective or subjective cognitive complaints.

In concluding this section, it should be emphasized that *in vivo* structural MRI studies of brain regions known to be pathologically involved very early in the disease process of AD show results very comparable to *postmortem* tissue findings. Thus, MRI-derived changes in brain regions of interest can be used as surrogate markers of the underlying pathology. Tissue studies, however, are by definition cross sectional and cannot determine who among nondemented older individuals will decline in cognitive status with time and develop AD. Longitudinal MRI investigations provide a unique tool for tracking the progression of the underlying pathology and for detecting those at risk of developing AD.

Age-Related Structural Alterations in Medial Temporal Lobe Gray Matter Regions

The information reviewed above regarding both *in vivo* imaging and *postmortem* tissue studies demonstrates that the so-called pathological aging affects posterior regions of the brain to a greater extent than anterior regions. However, cross-sectional MRI studies have suggested that anterior brain regions (i.e., prefrontal and frontal lobes) are more significantly affected by aging *per se* than temporal lobe regions. A number of investigations on aging have reported age-related shrinkage of hippocampal volume, although not to the same extent as in mild or incipient AD (see **Figure 2** which shows hippocampal

shrinkage as a function of aging and disease progression). The effects of age on entorhinal cortex volume are less clear, with some publications demonstrating lack of an age effect, while others reporting minimal change. Since the entorhinal cortex is one of the earliest brain regions pathologically affected in AD, it may be an important region to track longitudinally in order to develop markers important for differentiating healthy from pathological aging due to degenerative disorders such as AD.

In Vivo Anatomical Markers of Risk of AD

There is now increased interest in developing imaging markers that can discriminate reliably those among elderly individuals who are at high risk of developing AD as determined by longitudinal clinical as well as imaging follow-up. The impetus for this interest stems from the conviction that therapeutic interventions, when available, may be much more effective if initiated when older people are in the prodromal stages of the disease process. An exemplary longitudinal multi-center study is the Alzheimer's Disease Neuroimaging Initiative (ADNI) funded partly by the National Institute on Aging and initiated in 2004. ADNI is following 200 elderly control subjects with no cognitive impairment, 400 individuals diagnosed with aMCI, and 200 patients with mild AD. The aim of ADNI is to develop improved methods for clinical trials and to provide a large database which will improve the design of treatment trials by collecting

information on the trajectory of anatomical, biomarker, and cognitive changes.

Although smaller in scale than ADNI, a number of longitudinal MRI studies that measured the volumes of medial temporal lobe structures such as the entorhinal cortex and hippocampus have shown the annual rate of atrophy of both structures to be greater in patients with AD and in those with aMCI than in healthy elderly controls with no cognitive impairment. Furthermore, longitudinally detected decreases in entorhinal cortex and hippocampal volume were shown to be closely related to the rate of decline in memory function.

Centers that have been following older participants longitudinally have also reported on MRI-derived anatomical markers that predict conversion from MCI to AD. However, the findings are not all concordant, partly due to differences among investigations in regions examined or techniques used in determining atrophy in given structures. A number of laboratories have reported that the volumes of the entorhinal cortex and hippocampus are predictive of who among people with a diagnosis of aMCI will convert to AD in the future. This is the case when the volumes of these structures are derived from the baseline scan at entry into a longitudinal study, as well as when volumes are tracked longitudinally.

Those laboratories that have compared the volumes of the entorhinal cortex and hippocampus in predicting risk of AD have found entorhinal volume to be a somewhat better predictor. This is not surprising since AD-related pathology may start in the entorhinal area before the

hippocampus. In a longitudinal MRI paper from our laboratory, we sought to determine if baseline entorhinal and hippocampal volumes and their rate of atrophy could predict risk of AD. We used proportional odds models to assess the relationship between entorhinal and hippocampal size and risk of AD among 58 nondemented elderly people, 23 of whom had a diagnosis of aMCI. All participants were followed with yearly clinical evaluations and structural MRI scans for up to 5 years (baseline and 5 years of follow-up). Fourteen of 58 nondemented people developed AD during the follow-up period, only three of whom had entered the study as healthy control subjects. Not surprisingly, initial diagnosis of aMCI was found to be a risk factor for incident AD. In addition, both baseline entorhinal volume and its rate of decline were found to be independent predictors of risk of incident AD, but, surprisingly, initial hippocampal size and its rate of decline were not, after controlling for entorhinal volume. These *in vivo* results are in line with *postmortem* tissue investigations suggesting that AD-related pathology affects the entorhinal region before the hippocampus. Structural MRI results indicating that entorhinal volume reductions may precede those of the hippocampus have also been reported by other laboratories.

White Matter Changes in Normal and Pathological Aging: Diffusion Tensor Imaging

Most MRI investigations of medial temporal lobe structures in MCI and AD have concentrated on changes in gray matter regions. However, alterations in white matter can also contribute to age- or disease-induced cognitive changes by partially disconnecting different parts of the brain and disrupting information flow. The white matter of the parahippocampal region is especially important in this respect, since its disruption can partially disconnect the hippocampus from incoming sensory information important for forming memories. The anterior medial parahippocampal white matter region includes the perforant path, known to be pathologically involved very early in AD. The perforant path is a white matter tract that relays multi-modal sensory information from the entorhinal cortex to the hippocampus. Majority of perforant path fibers originate from cells in layer II of the entorhinal cortex. These cells are known to be vulnerable very early in AD and, therefore, their loss may affect the structure of the perforant path.

Using an automated analytic technique called voxel based morphometry, a study from our laboratory demonstrated a significant decrease in the volume of the parahippocampal white matter region that includes the perforant path in people with aMCI compared to healthy control subjects (see **Figure 3**). Furthermore, we found

that both hippocampal volume and parahippocampal white matter volume were significant predictors of memory performance. Thus, in addition to hippocampal atrophy, the disruption of parahippocampal white matter fibers contributes to memory decline in older individuals with aMCI by partially disconnecting the hippocampus from incoming sensory information. Other laboratories have reported similar alterations in parahippocampal white matter in patients with AD.

White matter volume change may reflect not only loss of afferent and efferent fibers in the region of the parahippocampal gyrus, but may also be due to partial demyelination in remaining fibers. These events are accompanied by increased brain water content. Since MRI is based on excitation and relaxation of hydrogen atoms, this increased water content alters the MRI signal. One novel MRI technique that takes advantage of this alteration in signal is diffusion tensor imaging (DTI). This technique allows the examination of alterations in the microstructure of white matter *in vivo*; in addition to volumetric changes, it can determine if the remaining normal appearing white matter is really normal.

DTI is based on sensitizing the MR signal to the movement of hydrogen on the order of several microns (diffusion-weighted MRI) and measuring the direction and magnitude of hydrogen diffusion in at least six noncollinear gradients simultaneously. The three-dimensional geometry of the diffusion in a particular volume element (voxel) can be described by a mathematical construct called a tensor that can be represented by a 3×3 matrix. From the diffusion tensor in each voxel, one can derive three eigenvectors defining the magnitude and direction of the diffusion system, with corresponding eigenvalues λ_1 , λ_2 , and λ_3 . The average of the three eigenvalues represents the mean molecular motion and is referred to as mean diffusivity (MD). MD is affected by barriers to diffusion, but does not provide information on the directionality of diffusion. Based on the three eigenvalues and the mean eigenvalue (λ), the intra-voxel organization of diffusion direction can be measured and is referred to as fractional anisotropy (FA). FA values range from 0 to 1, with 0 indicating completely random diffusion (isotropic diffusion) and 1 representing completely directional diffusion (anisotropic diffusion). Highly organized and myelinated white matter tracts have high FA because hydrogen diffusion is highly constrained by the tract's organization. When the barriers to free diffusion of hydrogen in white matter degenerate, either due to age or degenerative disorders, mean diffusivity increases and fractional anisotropy decreases.

As was the case for gray matter, in general, studies that have used DTI to examine the effects of age on white matter integrity have reported age-related reductions in fractional anisotropy and increases in mean diffusivity

with a tendency toward greater effects in anterior versus posterior regions of the brain. In contrast to the findings of decreased white matter integrity in anterior regions in healthy older people, DTI investigations in people with MCI and AD have reported that posterior white matter regions are more severely affected than anterior ones. Those studies that have especially targeted the parahippocampal white matter region as a region of interest to investigate with DTI have demonstrated that remaining fibers in this region show microstructural alterations in people with AD as well as MCI. Thus, in addition to parahippocampal white matter atrophy, microstructural alterations in remaining fibers would further degrade transmission of sensory information from the entorhinal cortex to the hippocampus in AD and contribute to the memory dysfunction.

MRI-Derived Markers that Differentiate Healthy from Pathological Aging

Recently, there has been increased interest in a handful of centers in determining MRI markers of risk of AD not only among people who are known to be at risk, such as those with aMCI, but also among older people who enter longitudinal projects as healthy controls with no cognitive impairment. Such studies have shown that even at the baseline MRI evaluation, control subjects who decline over time and receive a diagnosis of AD have smaller entorhinal cortex, hippocampus, and parahippocampal white matter volumes compared to controls who remain stable.

Conclusions

In conclusion, the material covered in this article shows that MRI-derived volumes of mesial temporal lobe structures that are pathologically involved early in AD provide sensitive markers of risk of AD. Atrophy in these regions can detect, years ahead of time, not only those who will

convert from a diagnosis of MCI to AD, but also those among healthy older individuals who are at risk of developing AD.

Glossary

Acetylcholinesterase (AChE) – An enzyme that degrades (through its hydrolytic activity) the neurotransmitter acetylcholine, producing choline and an acetate group. It is mainly found at neuromuscular junctions and cholinergic synapses in the central nervous system, where its activity serves to terminate synaptic transmission. AChE has a very high catalytic activity – each molecule of AChE degrades about 5000 molecules of acetylcholine per second. The choline produced by the action of AChE is recycled and transported, through reuptake, back into nerve terminals where it is used to synthesize new acetylcholine molecules.

Alzheimer's disease (AD) – Also called 'senile dementia of the Alzheimer type (SDAT)' or simply Alzheimer's, it is the most common form of dementia in the elderly. This incurable, degenerative, and terminal disease was first described by German psychiatrist Alois Alzheimer in 1906. Generally, it is diagnosed in people over 65 years of age, although the less-prevalent early-onset Alzheimer's can occur much earlier.

Choline acetyltransferase (ChAT) – An enzyme that is synthesized within the body of a neuron. It is then transferred to the nerve terminal via axoplasmic flow. The role of ChAT is to join acetyl-CoA to choline, resulting in the formation of the neurotransmitter acetylcholine.

Metalloproteinases (or metalloproteases) – A family of enzymes from the group of proteinases, classified by the nature of the most prominent functional group in their active site.

Neurotrophins – A family of proteins that induce the survival, development, and function of neurons. These substances belong to a class of growth factors which are (secreted proteins) capable of signaling particular cells to survive, differentiate, or grow. Growth factors such as neurotrophins that promote the survival of neurons are known as neurotrophic factors.

Neurotrophic factors are secreted by target tissue and act by preventing the associated neuron from initiating programmed cell death – thus allowing the neurons to survive. Neurotrophins also induce differentiation of progenitor cells to form neurons.

Tau – A microtubule-associated protein, which is abnormally hyperphosphorylated in Alzheimer's disease and accumulates in neurons undergoing neurofibrillary degeneration.

Introduction

Age is the main risk factor for the development of a spectrum of neurological disorders including Alzheimer's disease (AD). AD is a progressive and fatal age-related neurodegenerative disorder manifested by cognitive/memory decline, loss of executive functioning, progressive impairment of activities of daily living, as well as a variety of neuropsychiatric symptoms and behavioral sequelae. Prevalence studies indicate that approximately 18 million people worldwide have AD. In the USA, there are more than 5 million people with AD. The percentage of people with AD increases by a factor of 2 with approximately every 5 years of increased age, meaning that approximately 1% of 60-year-olds and approximately 30% of 85-year-olds suffer from the disease. In many neurological disorders, specific neuronal populations are selectively vulnerable. This is especially true for AD. A consistent pathological feature of AD is the degeneration of cholinergic basal forebrain (CBF) neurons ([Figures 1\(a\)](#) and [1\(b\)](#)). CBF neurons located within the septal/diagonal band complex and the nucleus basalis provide the major cholinergic innervation to the cortex and hippocampus ([Figure 1\(c\)](#)). Pronounced neurodegeneration of CBF neurons is also found in patients with Down syndrome (DS) as these subjects display AD-like pathology by the third decade of life. Over the last three decades, the relationship between CBF function and cognition, especially age-related cognitive decline, has engendered great scientific interest and is a major focus for pharmacotherapeutic intervention in AD. Several reports have demonstrated a significant reduction in CBF neurons, cortical choline acetyltransferase (ChAT) activity, and cholinergic cortical fibers in human aging. In particular, clinical-pathologic studies show that deficits in the basocortical cholinergic system correlate highly with

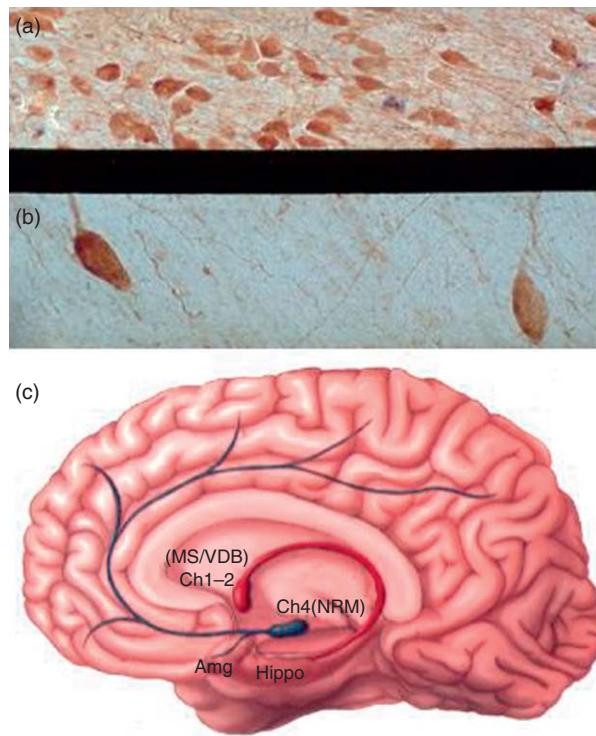

Figure 1 (a) Photomicrograph of human cholinergic neurons with the nucleus basalis in an aged normal subject. Cholinergic neurons were immunohistochemically visualized using an antibody that recognizes choline acetyltransferase. disease severity and duration in AD patients. Supporting this concept are studies of the CBF system in nonhuman primates and rodents, demonstrating clear involvement in conscious awareness, attention, working memory, and other mnemonic processes. Taken together with the human findings, this line of research has supported the so-called 'cholinergic hypothesis.' This hypothesis essentially states that a reduction in cholinergic function in the brain contributes to the pernicious cognitive decline seen in senescence and AD. Although degeneration of CBF neurons in AD is well described, there appears to be a capability for neuroplasticity, at least for certain populations of cells. For example, CBF degeneration is accompanied by an increase in the number of nicotinamide adenine dinucleotide phosphate diaphorase (NADPH-d) neurons and an overexpression of the neuropeptide galanin (GAL) which may either exacerbate or slow CBF dysfunction, and this potential for neuroplasticity is a source of extreme interest in the field of AD. While it is clear that many brain regions degenerate in aging and AD,

cholinergic hypofunction is still thought to be central to cognitive decline.

Aging and CBF System

Since age is a major risk factor for the onset of AD, it is crucial to understand the consequences of aging on the CBF system. Mice aged 30 months display a 75% reduction in the biosynthesis of acetylcholine (ACh). In the aged brain, cholinergic neurons are more impaired in ACh release following potassium stimulation than in their ability to synthesize the transmitter. It has been suggested that brain cholinergic neurons function at a normal level until they are stressed or damaged. Furthermore, sustained stress or damage to the CBF neurons is posited to interfere with the ability of CBF neurons to generate sufficient ACh release required for normal cell function during aging. In young rats trained on an attentional task, submaximal chemical lesions of CBF neurons were created and a difference between young lesioned and control rats did not occur until 30 months of age, when the damaged group displayed significant deficits in the task performance. These results are relevant since the age-related changes were related to the dynamic aspects of a second hit of brain CBF neurons. Although animal models of aging provide direct evidence of CBF impairment during aging, data derived from human autopsy material often show dramatic structural age-associated changes. For example, cholinergic axons exhibit axonal and neuronal abnormalities in nondemented middle-aged people, which increased in nondemented older subjects and were reduced in intensity in severe AD. By contrast, these types of axonal abnormalities did not occur in young people, although CBF neurons containing neurofibrillary tangles (NFTs) were found as early as the third decade of life. Perhaps CBF system abnormalities are present very early in aging and progress during the onset of AD and DS.

Cortical ChAT Activity in Early AD

The loss of cholinergic markers within selectively vulnerable neurons and their respective projection sites has been a major tenet in AD. A progressive phenotypic down-regulation of markers within CBF neurons as well as frank CBF cell loss has been observed consistently along with an associated reduction of ChAT and acetylcholinesterase (AChE; a cholinergic degrading enzyme) activity within the cortex in AD. It is presumed that progressive disruption of cholinergic function underlies much of the short-term memory loss seen in AD. In fact, delaying or preventing cholinergic neurodegeneration or minimizing its consequences is the mechanism of

action for most currently available Federal Drug Administration (FDA)-approved drugs for the treatment of AD. Since physostigmine and oral anticholinesterases have beneficial effects on patients with AD, it is suggested that the CBF system is somewhat preserved or has the propensity for neuroplasticity during the progression of dementia, despite a well-documented loss of cholinergic biosynthetic machinery (including ChAT and AChE enzyme deficits) in patients with this disease. Interestingly, ChAT activity is preserved in the hippocampus and neocortex of people with prodromal AD termed 'mild cognitive impairment (MCI).' This suggests that cholinergic enzyme deficits are likely not the primary deficit of memory loss observed in MCI, although this does not eliminate other types of cholinergic dysfunction early in the course of the disease. These findings indicate that the hippocampal and frontal cortical cholinergic projection systems are capable of compensatory and/or neuroplasticity responses during the early stages of AD and can possibly be exploited by well-designed therapeutic regimens with novel drug treatments. This upregulation of hippocampal and frontal cortex cholinergic tone may be important for promoting transmission and/or delaying neurodegenerative defects impacting the transition to frank AD. In this regard, increased ChAT activity in the MCI hippocampus was associated with high Braak scores, a marker for tau pathology that, to some extent, correlates with cognitive decline (Braak III/IV stage), suggesting a compensatory upregulation of ACh production in response to the disconnection of glutamatergic entorhinal cortex input to the hippocampus early in the disease process. In this scenario, increased hippocampal ChAT activity may reflect reactive synaptogenesis, the filling in of denervated glutaminergic synapses by cholinergic axons arising from the septum. The factors underlying the elevation of frontal cortex ChAT activity in MCI are less clear, but may be related to the finding that the anterior cholinergic subfield of the nucleus basalis, which innervates the frontal cortex, is less affected in AD and therefore most likely capable of cholinergic neuroplasticity. AChE, the enzyme that hydrolyzes ACh at the synapse, fails to show a reduction in cortical areas until at least moderately severe levels of dementia. Positron emission tomographic (PET) investigations utilizing a ligand, which labels AChE *in vivo*, suggest only a mild loss of AChE in MCI and mild AD. Moreover, a functional magnetic resonance imaging (fMRI) study of the brain demonstrated that people with MCI treated with the FDA-approved anticholinesterase donepezil showed increased frontal cortex activation relative to untreated controls, which was positively correlated with task performance. In addition to AChE, butyrylcholinesterase (BChE), a serine hydrolase that also catalyzes the hydrolysis of ACh, is found in neurons and glia and is associated with NFTs and senile

plaques (SPs) in AD brain. An AD population-based genetic analysis identified a point mutation that changes alanine 539 to threonine in the K variant of BChE, which reduces serum BChE levels, and could be associated with cognitive decline. BChE activity is increased, whereas AChE activity remains unchanged or declines in AD brain. These data and the observations of cholinergic neuroplasticity in people with MCI support the continued use of cholinesterase inhibitor drugs as a treatment during the onset of AD. Since some patients respond better to a particular cholinesterase inhibitor compared to others, MRI or related noninvasive imaging technologies may be a tool to match patients to an optimal AChE treatment regime or drug design strategy.

CBF System in Early AD

Another tenet of AD is the reduction in the number of CBF neurons in end-stage patients. However, numerous studies using different phenotypic cholinergic cell markers have revealed that CBF neuron alterations during AD progression are more complex than originally proposed. For instance, the vesicular ACh transporter (VACHT), which co-localizes with ChAT in human CBF neurons and participates in loading ACh into synaptic vesicles in cholinergic terminals, is not severely altered in AD. Pharmacological investigations of VACHT in postmortem AD tissue or *in vivo* imaging studies using vesamicol and its analogs suggest that VACHT levels are preserved or minimally reduced coincident with a severe decline in cortical ChAT activity. The discordance between CBF neuronal ChAT and VACHT in projections to the cortex is intriguing in light of the discovery that they are part of a single cholinergic gene locus with shared regulatory elements. Moreover, rodent cholinergic lesion studies and postmortem human brain studies suggest that cholinergic neurons shrink, are depleted of phenotypic markers, and/or persist in an atrophic state after injury or during the pathological process rather than degenerate outright, despite containing NFTs in early AD. Taken together, these observations suggest that CBF neurons may be viable, albeit dysregulated, early in AD, and amenable to pharmacological treatments that may delay cognitive impairment associated with cholinergic deficits.

CBF Neuron Survival – Live and Let Die

The neurotrophic factor, nerve growth factor (NGF), and its cognate high-affinity tyrosine kinase A (TrkA) and low-affinity ($p75^{NTR}$) receptors maintain the survival of CBF neurons (Figure 2). NGF is synthesized from its precursor molecule, proNGF, and is proteolytically

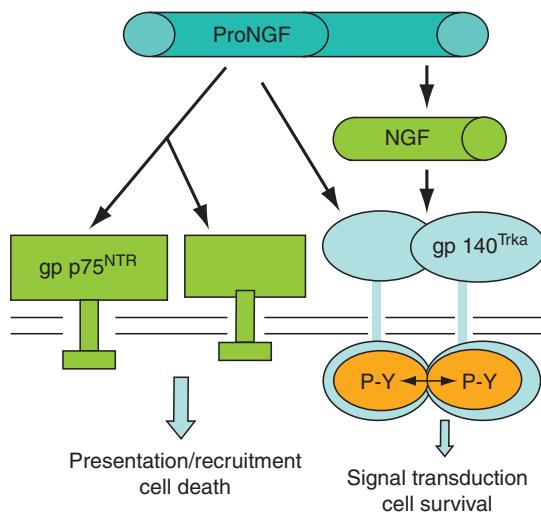

Figure 2 Schematic drawing showing the proNGF-, NGF-, TrkA-, and p75^{NTR} pathways.

cleaved to a mature biologically active neurotrophin peptide (Figure 2). Mature NGF (mNGF) binds to TrkA, which activates signal transduction pathways mediating the survival effects of NGF, and to the p75^{NTR} receptor, a positive modulator of NGF/TrkA binding. Activation of the p75^{NTR} receptor has multiple actions, including apoptosis, which are dependent on interactions with other chaperone molecules. The physiological consequence of TrkA and p75^{NTR} signaling depends upon their interactions with proNGF. The dysregulation of the NGF receptor system plays a key role in CBF neuron dysfunction in AD. In this regard, proNGF activity is increased in the cortex of people clinically diagnosed

antemortem with MCI or mild AD compared to age-matched normal subjects (Figure 3). Several studies suggest that recombinant proNGF binds TrkA and promotes neuronal survival and neurite outgrowth similar to mNGF, but is approximately fivefold less active than the mNGF peptide. Although TrkA-mediated proNGF retrograde transport has not been demonstrated, proNGF accumulation in CBF cortical target sites may be due to reduced cortical TrkA levels and/or impaired retrograde transport of TrkA to CBF perikarya. Furthermore, reduced cortical TrkA levels were positively associated with lower cognitive performance, whereas increased cortical proNGF levels were negatively correlated with a test of cognition.

Studies indicate that increases in cortical proNGF may result in proapoptotic signaling via binding to the p75^{NTR} receptor. Other recombinant proNGF forms bind the p75^{NTR} with high affinity and promote neuronal apoptosis. Perhaps increased proNGF, in combination with reduced TrkA, results in increased binding between proNGF and p75^{NTR}, potentially shifting away from cell survival signaling to apoptotic proNGF signaling (Figure 3). In this regard, *in vivo* studies indicated that the precursor region of the NGF proneurotrophin molecule alone binds to TrkA. This binding differs from another site located on the mNGF molecule that induces downstream TrkA and extracellular signal-regulated kinase 1/2 (ERK1/ERK2) phosphorylation. Since proNGF binds with TrkA to a lesser degree than NGF, it has been proposed that during the progression of AD, the increased proNGF:NGF and p75^{NTR}:TrkA ratios shift in favor of cell death over neuroprotective actions. Moreover, proNGF can initiate apoptosis even in the presence of trophic activation by the

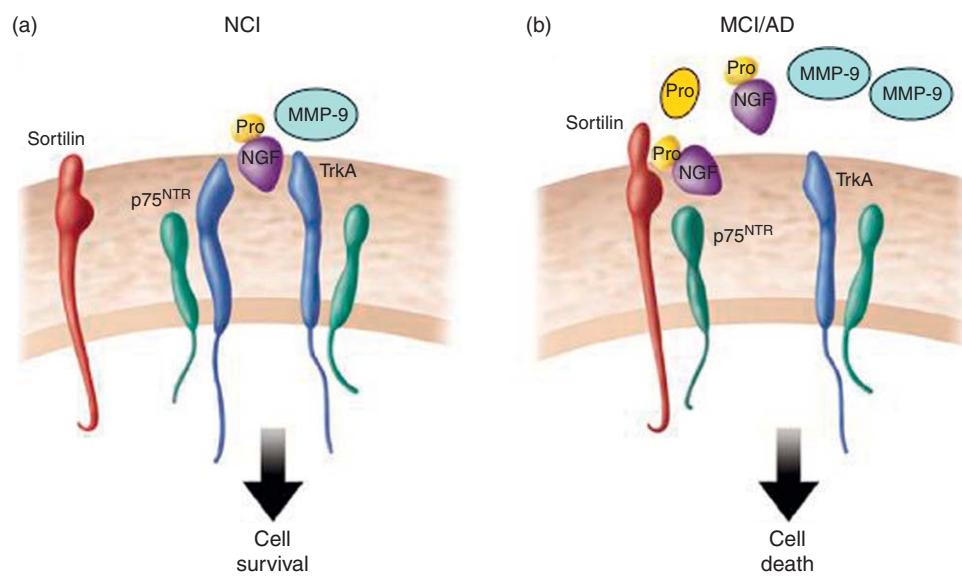

Figure 3 Drawing showing the shift in the balance of proNGF; NGF : TrkA; p75^{NTR}/sortilin : MMP-9 cell survival to death pathways during the progression of Alzheimer's disease (see text for details).

mNGF binding to TrkA, demonstrating that the death signal can override survival, and further exacerbate ongoing neurodegenerative processes. Since aging is also accompanied by increases in proNGF protein levels within afferent targets of cholinergic neurons, a role for proNGF in connectivity-based, age-dependent cell death may exist. In the face of reduced TrkA, p75^{NTR} may activate beta-site amyloid cleaving enzyme 1 (BACE1) cleavage of the amyloid precursor protein (APP), which requires NGF binding and activation of the second-messenger ceramide. Since aging activates β -amyloid (Abeta) generation in the brain by switching from TrkA to p75^{NTR} binding, it is possible that NGF receptor balance is a molecular link for amyloid processing between normal aging and AD. Therefore, drugs that maintain a homeostatic balance between TrkA and p75^{NTR} may slow Abeta accumulation and SP deposition in the aged population and slow the onset of MCI and, ultimately, AD.

Sortilin Regulation of Cholinergic Forebrain Cell Survival

The proapoptotic effect(s) of p75^{NTR}-mediated proNGF signaling is dependent on interactions with the neurotensin receptor sortilin, a Vps10p-domain-trafficking protein, which acts as a cell surface co-receptor with p75^{NTR} to mediate proNGF-induced cell death. Sortilin is required for p75^{NTR}-mediated apoptosis following proNGF treatment and blocking this binding event precludes high-affinity binding of proNGF to p75^{NTR} and subsequent cell death. Sortilin levels are significantly upregulated in aged CBF neurons, but not in the cortex of patients with severe AD (Figure 3). Pro-survival or proapoptotic signaling in the CBF system in aging and during the progression of AD may depend upon alterations in the stoichiometry of TrkA, p75^{NTR}, and proNGF binding, the availability of various co-receptors (e.g., sortilin), and the physiological role of proNGF within these different milieus (e.g., decreased neurotrophism or increased apoptotic signaling). A shift in the ratio of any of these factors during the onset of AD may alter the functional outcome that proNGF binding imparts upon CBF neurons. Ultimately, defining these relationships *in vitro* and *in vivo* in relevant cell culture and animal models along with parallel human postmortem brain-tissue investigations will be a major research effort in the development of neurotrophic mimetics for the treatment of age-related dementia. If proNGF binds with the p75^{NTR} and induces apoptotic cell death, then it is crucial to design drugs that exert neuroprotection by blocking proNGF binding to p75^{NTR}. On the other hand, if proNGF binds with less affinity to TrkA, resulting in cell survival, then the development of drugs that enhance this binding event could provide neuroprotection in aging and AD.

Metabolic Dysfunction in NGF Degradation in AD

The upregulation of cortical proNGF in subjects with MCI and AD suggests that changes occur in the metabolic pathways modulating the maturation and degradation of NGF, which in turn are crucial for the survival of CBF neurons. *In vitro* studies indicate that a protease cascade, which converts proNGF to mNGF and degrades NGF in the extracellular space by the coordinated activity of plasminogen, tissue plasminogen activator (tPA), neuroserpin, matrix metalloproteinase 9 (MMP-9), and tissue inhibitor of matrix metalloproteinase 1 (TIMP-1), may be defective in AD. MMP-9 is a member of the family of Zn²⁺-containing and Ca²⁺-requiring endoproteases capable of degrading NGF in the extracellular matrix. Upregulation of MMP-9 protein levels and activity can occur in both AD and MCI cortex and correlate inversely with cognitive status, suggesting that the dysfunction of the NGF protease degradation cascade plays a prominent role in the dysregulation of the NGF system during the prodromal stage of AD (Figure 3). The protease MMP-9 pathway most likely impacts degradation of proNGF to mNGF and an increase is likely to enhance the breakdown of NGF more readily in AD, leading to CBF neuron death.

Neurotrophin Gene Expression Defects in CBF Neurons in MCI and AD

Single-cell gene expression profiling was coupled with custom-designed microarrays and validation with both real-time quantitative polymerase chain reaction (qPCR) and *in situ* hybridization to evaluate the genetic signature of CBF neurons during the progression of AD. During disease onset, there is a significant downregulation of TrkA, TrkB, and TrkC gene expression in CBF neurons during the development of AD (Figure 4(a)). An intermediate reduction occurs in MCI, with the greatest decrement in mild AD compared to aged controls. Moreover, two separate expressed sequence-tagged cDNAs (ESTs) for each Trk gene, for example, ESTs targeted to the extracellular domain (ECD) and tyrosine kinase (TK) domains, were downregulated. In contrast, there was a lack of regulation of p75^{NTR} expression in CBF neurons. A step-down dysregulation of Trk expression may, in part, underlie CBF neuron demise associated with the clinical presentation of AD. Supporting this concept is the finding that Trk receptor downregulation in CBF neurons is associated with multiple measures of cognitive decline, including a global cognitive score (GCS) and the mini-mental state exam (MMSE).

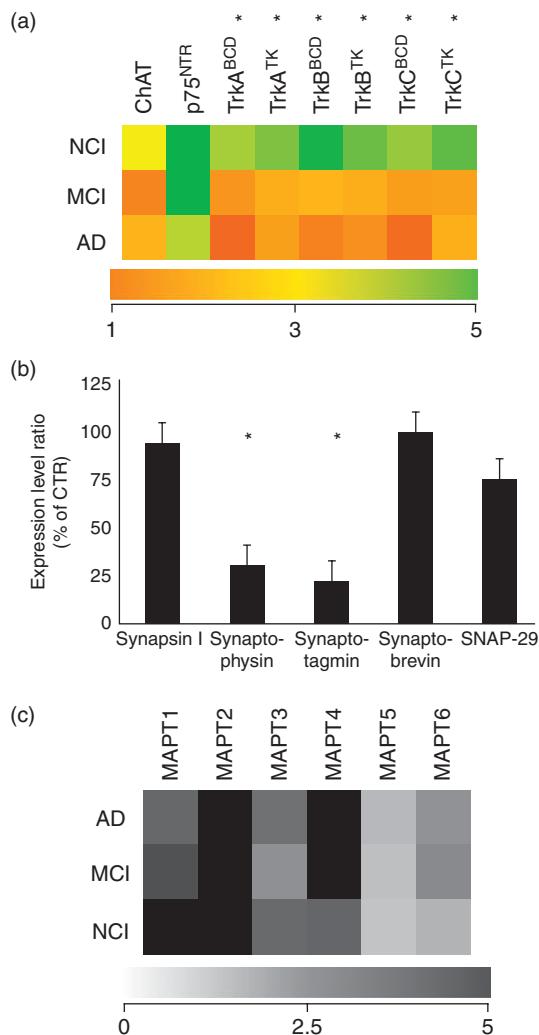

Figure 4 Expression profiling of cholinergic basal forebrain (CBF) neurons during the progression of dementia. (a) Expression profile analysis of p75^{NTR}, TrkA, TrkB, TrkC, and ChAT derived from individual nucleus basalis neurons from NCI, MCI, and AD subjects. Heatmap with a color-coded scale (green = low levels and red = high levels) illustrates relative expression levels. No significant differences are found for ChAT and p75^{NTR} gene expression. In contrast, statistically significant downregulation (* denotes $p < 0.01$) of TrkA, TrkB, and TrkC is observed in MCI and AD as compared to NCI. ESTs identifying the extracellular (ECD) and tyrosine kinase (TK) domains display downregulation. The decrement of Trk gene expression in MCI is intermediate relative to AD, indicating a step-down effect in expression levels from NCI to MCI to AD. (b) Histogram showing selective downregulation of the synaptic-related markers synaptophysin and synaptotagmin observed in AD as compared to age-matched nondemented controls (* denotes $p < 0.01$). In contrast, no significant differences are observed for synapsin I, synaptobrevin, or SNAP-29, indicating a relative specificity of gene expression regulation. (c) Heatmap indicating no overall differences in tau isoform expression in single CBF neurons during the progression of AD. However, a significant shift in the 3Rtau/4Rtau ratio was observed in AD and MCI (CBF neurons) relative to NCI.

Cholinergic Receptor Expression in MCI and AD

Two classes of receptors involved in cholinergic transmission are drug targets for AD: nicotinic ion channels, which mediate fast postsynaptic transmission, and muscarinic G-protein-coupled ACh receptors. The ionotropic nicotinic ACh receptor (nAChR) is a pentameric membrane protein composed of four polypeptide subunits designated nAChRs α , β , δ , and γ . The muscarinic ACh receptor (mAChR) family includes five members, M1–M5. A single-cell expression study via microarray analysis uncovered differential expression levels for nAChR and mAChR receptors as well as ChAT within single CBF neurons obtained from people with no cognitive impairment (NCI), MCI, and AD. Although ChAT messenger ribonucleic acid (mRNA) expression levels did not differ across clinical conditions (Figure 4(a)), there was a significant upregulation of $\alpha 7$ nAChR subunit expression in AD compared to NCI and MCI. No differences were found for other nAChR subunits across clinical groups. This increase in $\alpha 7$ nAChR expression levels within CBF neurons was inversely associated with performance on the GCS and MMSE. CBF upregulation of $\alpha 7$ nAChR is also consistent with reports of increased $\alpha 7$ nAChR mRNA and protein expression levels in hippocampal neurons, astrocytes, and peripheral blood leukocytes in AD. Despite a putative beneficial role for increased CBF neuron $\alpha 7$ nAChR expression in AD (that may be relevant to smoking behavior as well), evidence suggests that increased $\alpha 7$ nAChR expression contributes to cellular degeneration. Notably, $\alpha 7$ nAChR binds and/or interacts with APP and Abeta peptides. Increased CBF neuronal $\alpha 7$ nAChR expression may arise as a compensatory response that is offset by aberrant Abeta- $\alpha 7$ nAChR interactions, leading to cholinergic dysfunction. M1 subunit expression in CBF neurons remains stable during the progression of AD. The M1 receptor is a potentially interesting drug target as it links several of the major hallmarks of this disorder including cholinergic deficiency, cognitive dysfunction, and Abeta and tau pathologies. Therefore, it has been argued that restoring cholinergic tone via activation of M1 mAChR may alter the onset and/or the progression of AD. Despite this intriguing concept, the clinical use of muscarinic agonists in AD has been limited due to adverse side effects that occur at high doses. A novel group of M1 partial agonists, AF102B, AF150(S), and AF267B-i, has been developed and tested in a series of experiments using a transgenic mouse model of AD that recapitulates the major pathologies of AD. Chronic AF267B treatment rescued cognitive impairment and decreased Abeta42 and tau pathologies in the cortex and hippocampus of these mice. These changes were associated with M1 mAChR-mediated activation of the tumor necrosis factor- α converting enzyme

ADAM17/TACE, decreased BACE1 steady-state activity, and inhibition of glycogen synthase kinase 3 beta (GSK3 β). Recently, a report was published, describing a highly selective allosteric activator of the M1 muscarinic receptor, which affects the processing of the APP toward the non-amyloidogenic pathways and decreases Abeta production, *in vitro*. If clinical trials prove efficacious for newly developed M1 mAChR receptor drugs, they may become a viable treatment candidate and the first monotherapy to treat multiple pathologic and biochemical deficits during the progression of AD.

Synaptic, Trafficking, and Neuropeptide Gene Expression in AD

Synapse loss is the strongest correlate of cognitive decline in AD, and requires further effort for pharmacotherapeutic intervention. Single-cell gene array studies report that synaptic transcripts are selectively downregulated in CBF neurons in AD, with significant reductions in synaptophysin and synaptotagmin, but not synaptobrevin or SNAP29 mRNA (Figure 4(b)). Intriguingly, synaptotagmin function is related to vesicle–presynaptic membrane fusion and neurotransmitter release, suggesting that perturbations in presynaptic vesicle trafficking comprise an event in vulnerable neurons in AD. In contrast to synaptic transcripts, mRNAs encoding APP and Notch were unchanged between control and AD subjects, whereas the acid hydrolase cathepsin D mRNA was upregulated in AD. In addition, subunits of protein phosphatase 1 (PP1) (Unigene-NCBI annotation PPP1CA and PPP1CC) mRNAs were downregulated in CBF neurons in AD. This observation is interesting since PP1 can phosphorylate tau on several serine/threonine residues and downregulation of PP1 activity leads to increased tau hyperphosphorylation, which may affect NFT formation in CBF neurons. However, single-cell gene expression of CBF neurons hyperinnervated by fibers containing the neuropeptide GAL, which displays neurotrophic actions and functions via the interaction of three G-protein-coupled receptors (GALR1, GALR2, and GALR3), stabilized levels of mRNAs encoding PP1 subunits and even increased ChAT expression in late AD cases. These observations suggest that GAL overexpression may delay NFT formation and increase cholinergic function in CBF neurons in AD.

Tau Isoform Expression in Cholinergic Forebrain Neurons in Aging and AD

CBF and cortical neurons display NFT formation in the MCI brain, suggesting a concomitant alteration in tau gene expression during the early stage of AD. The human brain contains six isoforms of tau, ranging from 48 to 67 kDa, which are expressed through alternative splicing of a single

tau gene on chromosome 17. Three of these tau isoforms contain three tandem repeats in the carboxy-terminus end of the molecule (3Rtau), while three display four tandem repeats (4Rtau) in this region. Expression levels of the six-tau isoforms within CBF neurons do not differ during the onset of AD. However, there was a significant shift in the 3Rtau/4Rtau ratio with a decrement in 3Rtau in relation to 4Rtau levels for each tau transcript analyzed within CBF perikarya from MCI and AD cases (Figure 4(c)). A similar shift did not occur during normal aging. Shifts in the ratio of tau transcripts may be a basic mechanism contributing to the selective vulnerability of neurons to NFT formation.

Cholinergic Drug Targets

The ultimate goal of translational AD research is to develop therapies to prevent progressive cognitive impairment that occurs during aging and AD, as well as restore memory and cognitive function. The vast majority of clinical trials aimed at treating the cholinergic deficit in AD have concentrated on testing the efficacy of AChE inhibitor drugs (e.g., donepezil, galantamine, rivastigmine, or huperzine A), which are derivatives of tacrine, the prototypical cholinesterase inhibitor. However, evidence suggests that NGF can prevent cholinergic neuron atrophy and correct the behavioral deficits caused by experimental injury or associated with normal aging in animals. This information led to the implementation of an *ex vivo* phase I trial aimed at both protecting CBF neurons from degeneration as well as augmenting the function of remaining cholinergic neurons by delivery of cells genetically engineered to produce human NGF into the area of the CBF in AD. Following a period of 22 months, no long-term postsurgical adverse effects were found and the rate of cognitive decline appeared to be reduced. It should be kept in mind that this was not a double-blind study and further clinical investigations of this gene therapeutic approach is warranted.

In summary, combining basic molecular and cellular research of neurotrophin and cholinergic biology should enhance the ultimate and pressing goal of amelioration of age-related neurologic disease processes. The keys to success include further characterization of the molecular fingerprint of CBF neurons in the nucleus basalis and septal/diagonal band during the progression of AD as well as in relevant animal models of tauopathy, Abeta deposition, and DS.

Glossary

CA1 region of hippocampus – CA stands for *Cornu Ammonis* (Ammonis horn or the horn of a ram). This name was given to fields of pyramidal neurons in the hippocampus that are curved and resemble a ram's horn. CA1 is one of four *Cornu Ammonis* areas: first CA4 (which underlies the dentate gyrus), then CA3, followed by a very small zone called CA2, and then CA1.

Delay procedure – A sequence of stimulus presentations, in classical conditioning, such that the conditioned stimulus (a neutral stimulus such as a tone or light) precedes and then overlaps with the reflex-eliciting unconditioned stimulus.

Eyeblink classical conditioning – An associative learning paradigm in which a neutral stimulus called the 'conditioned stimulus' precedes at a specified interval an eyeblink-eliciting stimulus called the 'unconditioned stimulus.' The pairing of the conditioned and unconditioned stimuli results in the subject blinking to the conditioned stimulus before the onset of the unconditioned stimulus. This new association is called the 'conditioned response.'

Interpositus nucleus – One of the deep cerebellar nuclei in the center of the cerebellum, also called the 'interposed' nucleus, which is embedded in the white matter. Rodents and langomorphs have three deep nuclei, with the interpositus being the center deep nucleus. In humans, the emboliform and globose nuclei are the 'interposed' nuclei of the cerebellum.

Long-term depression (LTD) – The weakening of a neuronal synapse that lasts from hours to days. It results from either strong synaptic stimulation (as in the cerebellar Purkinje cells) or persistent, weak synaptic stimulation (as in the hippocampus).

Long-term potentiation (LTP) – The long-lasting improvement in communication between two neurons that results from stimulating them simultaneously.

Stereology – Originally defined as 'the spatial interpretation of sections,' it is an interdisciplinary field that is largely concerned with the three-dimensional interpretation of planar sections of materials or tissues. It provides practical techniques for extracting quantitative information about a three-dimensional material from measurements made on two-dimensional planar sections of the material.

Trace procedure – A sequence of stimulus presentations, in classical conditioning, such that the

conditioned stimulus (a neutral stimulus such as a tone or light) precedes and then turns off so that there is a blank period before the reflex-eliciting unconditioned stimulus is emitted.

Brain memory systems and associated brain structures differ in the magnitude of age-related neuron loss. The studies carried out during most of the twentieth century reported significant loss of neurons with aging in many regions of the brain. These scientific findings were translated into the commonly held notion that tens of thousands of neurons were lost on a daily basis in older adults, resulting in impaired cognition and memory in old age. The contemporary perspective of this phenomenon has changed rather dramatically. There has been a growing recognition that neuronal numbers in many brain structures remain relatively constant. Whereas neuron number remains constant in most brain structures, age-related changes in functional activity of neurons have been documented and associated with impairment in some forms of learning and memory.

The variability in performance on learning and memory tasks increases with age. Research on the neural basis of memory and aging has identified correlates of age-related memory impairment at various anatomical and physiological levels, with some individuals showing greater effects of normal aging than others. The inclusion of older adults in the early stages of neurodegenerative diseases in studies of normal aging has also contributed to a perspective of functional decline in the whole population. Both the magnitude of neuronal loss and the degree of functional memory impairment were likely overestimated in previous research.

Changing Perspectives on the Neural Basis of Memory and Aging

Implementation of methods that have become known as 'stereology' came slowly; however, by the late twentieth century these methods had reshaped perspectives of aging and the brain. Stereological counting principles as an unbiased means for estimating the total number of objects were introduced in the mid-1980s. This method involves a three-dimensional counting chamber with inclusion and

exclusion planes that ensure that all objects have equal probability of being sampled and counted only once. Until unbiased stereological methods were introduced, researchers often used counting profiles, which introduced bias because taller objects can be counted in more than one profile, and smaller objects may never get counted at all. In the case of studies of age differences in cell number, differential shrinkage of brain tissue, as it was being fixed for analysis, added additional bias.

Many brain regions assessed with unbiased stereology, including structures, such as the hippocampus, which are critically involved in learning and memory, showed little or no cell loss in rodents and modest cell loss limited to hippocampal regions less essential for learning and memory in humans. Unbiased stereological techniques indicate that neuron number is maintained in neocortex and most regions in the hippocampus. One of the few types of neurons to show significant loss in normal aging is the largest and earliest discovered neurons in the brain, the Purkinje neurons first visualized by Jan Evangelista Purkinje in 1837.

The neural basis of learning and memory in normal aging shows various patterns, depending on the neural structures that are essential for the form of learning and memory. Some forms of learning and memory are preserved well into late life as they are supported by neural systems that are impacted in a minor fashion by normal aging. In addition, neuron loss is not the only means that age-related neural impairment can occur. The subcellular and molecular parameters of neural aging are the focus of many contemporary neuroscientists aiming to elucidate the neural basis of memory and aging.

Model System Perspective of Neurobiology of Memory Aging

To exemplify the neural basis of memory and aging, we draw on examples from the model system of eyeblink classical conditioning. This model system has become one of the best delineated for the study of learning and memory available in the twenty-first century. The neural circuitry is almost completely mapped, and the behavioral and neurobiological parallels in this form of associative learning extend to all mammals that have been studied, including humans. The processes of normal aging affect eyeblink classical conditioning similarly in all species in which older organisms have been tested – mice, rats, rabbits, cats, and humans.

Among the significant advantages of this model system for gerontology are: (1) age differences in the classically conditioned eyeblink responses are large; (2) striking parallels exist between the age differences in eyeblink conditioning in nonhuman mammals and humans; and (3) the neural circuitry is delineated. Behavioral and

neurobiological parallels have been documented that generalize in aging to all mammals studied, including humans.

Brain Circuits and Associative Learning

Cerebellum

A variety of techniques, including electrophysiological recording of multiple and single units, electrolytic and chemical lesions, physical and chemical reversible lesions, neural stimulation, genetic mutations, and pharmacological manipulation, have been used to demonstrate that the dorsolateral interpositus nucleus ipsilateral to the conditioned eye is the essential site for acquisition and retention of conditioned eyeblink responses. Selective lesions (electrolytic or chemical) of the cerebellum prevent the acquisition and retention of conditioned eyeblink responses. Electrophysiological recording of single and multiple-unit activity in the cerebellum indicated that cells in specific cerebellar regions undergo learning-induced changes during eyeblink conditioning. The involvement of the cerebellum in eyeblink conditioning is also supported by studies that show that electrical stimulation of the two major afferents to the cerebellum – the mossy fibers from the pontine nuclei and the climbing fibers from the inferior olive – can substitute for the externally presented conditioned and unconditioned stimuli and can lead to learning. Reversible inactivation of the anterior interpositus nucleus and overlying cerebellar cortex during training completely prevents learning, but when the nucleus is returned to its normal functional status, learning occurs. Inactivation of the efferent output of the interpositus nucleus (i.e., in the superior cerebellar peduncle and red nucleus) does not prevent learning.

A model of the neural circuitry essential for eyeblink conditioning indicates that both the cerebellar cortex and the interpositus nucleus receive information about the conditioned stimulus (CS; that can be a tone or light), conveyed by the mossy fiber system emanating from the pontine nucleus, and information about the unconditioned stimulus (US; i.e., a puff of air to the cornea or a shock to the eye muscles), relayed by the climbing fiber system originating from the inferior olive. Converging signals from the conditioned and unconditioned stimuli are relayed to Purkinje cells in cerebellar cortex and principal cells in interpositus nucleus. The efferent (eyelid closure) conditioned response pathway projects from the interpositus nucleus in cerebellum to the red nucleus and via the descending rubral pathway to act ultimately on motor neurons.

A cellular model system proposed as a mechanism for information storage in the cerebellum is long-term depression (LTD). In this model, coactivation of climbing fiber and parallel fiber inputs to a Purkinje cell induces a persistent, input-specific depression of the parallel

fiber–Purkinje cell synapse. Studies using mutant and transgenic mice with alterations in cerebellar cortex that affected LTD demonstrated a consistent correlation between impaired cerebellar cortical LTD and impaired eyeblink conditioning.

Hippocampus

The hippocampus and the septohippocampal acetylcholine system are normally engaged in basic associative learning of the sort represented by delay eyeblink classical conditioning, and the hippocampus is essential in trace eyeblink conditioning. In a series of studies using delay eyeblink classical conditioning in rabbits, it was observed that activity recorded in the CA1 pyramidal cell region of the hippocampus forms a predictive ‘model’ of the amplitude–time course of the learned behavioral response, but only under conditions where behavioral learning occurs. This response is generated largely by pyramidal neurons. The role of the hippocampus in delay eyeblink classical conditioning is called ‘modulatory’ because manipulations of the hippocampus can impair or enhance the rate of acquisition. The memory trace itself is not in the hippocampus, but the hippocampus can markedly influence the storage process.

Although the hippocampus is not necessary for normal acquisition in the delay procedure, it is necessary for trace conditioning. There is a long-lasting neuronal plasticity formed in the hippocampus following eyeblink conditioning. This change is essential for learning to occur in the trace eyeblink conditioning procedure, at least until the learning is consolidated. Hippocampal slices prepared from animals trained previously in trace eyeblink conditioning had pyramidal neurons showing a marked reduction in the slow afterhyperpolarization compared to neurons in slices from control animals that received presentations of tones and air puffs that were not related.

Delay and Trace Eyeblink Classical Conditioning Procedures

Eyeblink classical conditioning paradigms that have received the greatest research attention are the delay and trace procedures (**Figure 1**). In the delay procedure, a neutral stimulus such as a tone CS is presented before the onset of a corneal air puff US. The organism learns to blink to the tone CS before the onset of the air puff US, and the learned response is called the ‘conditioned response’ (CR). The interval between the onset of the CS and the onset of the US is called the ‘interstimulus interval’ (ISI). The length of this interval affects the rate of conditioning, that is, ISIs greater than 500 ms increase the difficulty level for rabbits and mice. In the trace procedure, the CS is presented and then turned off, and a blank period (trace) ensues before the onset of the US. The trace procedure is called ‘hippocampus dependent’

because organisms with bilateral hippocampal lesions do not acquire CRs. In rabbits, the hippocampus is essential when the trace interval exceeds 300 ms. In humans, the trace interval must be 1000 ms for eyeblink conditioning to be abolished by bilateral hippocampal lesions. In mice, bilateral ibotenic acid lesions of hippocampus abolish eyeblink conditioning in a 500-ms trace procedure with a trace interval of 250 ms. The cerebellar interpositus nucleus is essential in all eyeblink conditioning procedures.

Normal Aging and Eyeblink Classical Conditioning

Since the first studies were carried out in humans in the 1950s comparing young and older adults on delay eyeblink classical conditioning, striking age differences were apparent. When adults over the age range of 20–90 are tested, age-related effects appear in the decade of the 40s. Direct comparisons of a hippocampus-dependent memory measure (California Verbal Learning Test) and a cerebellum-dependent measure (400 ms delay eyeblink classical conditioning) in the same young and older adults revealed a larger age effect on the cerebellum-dependent than the hippocampus-dependent task. These results are consistent with the studies of neural aging that demonstrate significant loss of Purkinje neurons relatively early in the adult life span and age-related stability in hippocampal neuron numbers, with altered hippocampal electrophysiology demonstrated in late life in nonhuman mammals.

Similar to all investigations of normal aging, when participants have subclinical pathology as in the early stages of Alzheimer’s disease (AD), performance is impaired significantly more than it is affected by processes of aging. Indeed, several laboratories have demonstrated that patients diagnosed with probable AD are severely impaired on this task. Disruption of the septohippocampal acetylcholine neurotransmitter system impairs acquisition of eyeblink conditioning in experimental animals. In AD, the cholinergic system is dramatically impaired, such that this dysregulation is the likely cause of severe impairment of delay eyeblink classical conditioning in AD.

Normal Aging in the Hippocampus and Cerebellum

Although there is stability of neuron number in the older hippocampus, electrophysiological investigations of aging in the mammalian hippocampus have revealed that some aspects are compromised. Place cells in the hippocampal CA1 region are less stable in older rats and are associated with poorer spatial learning. In learning-impaired older rabbits, single-unit records of clusters of pyramidal

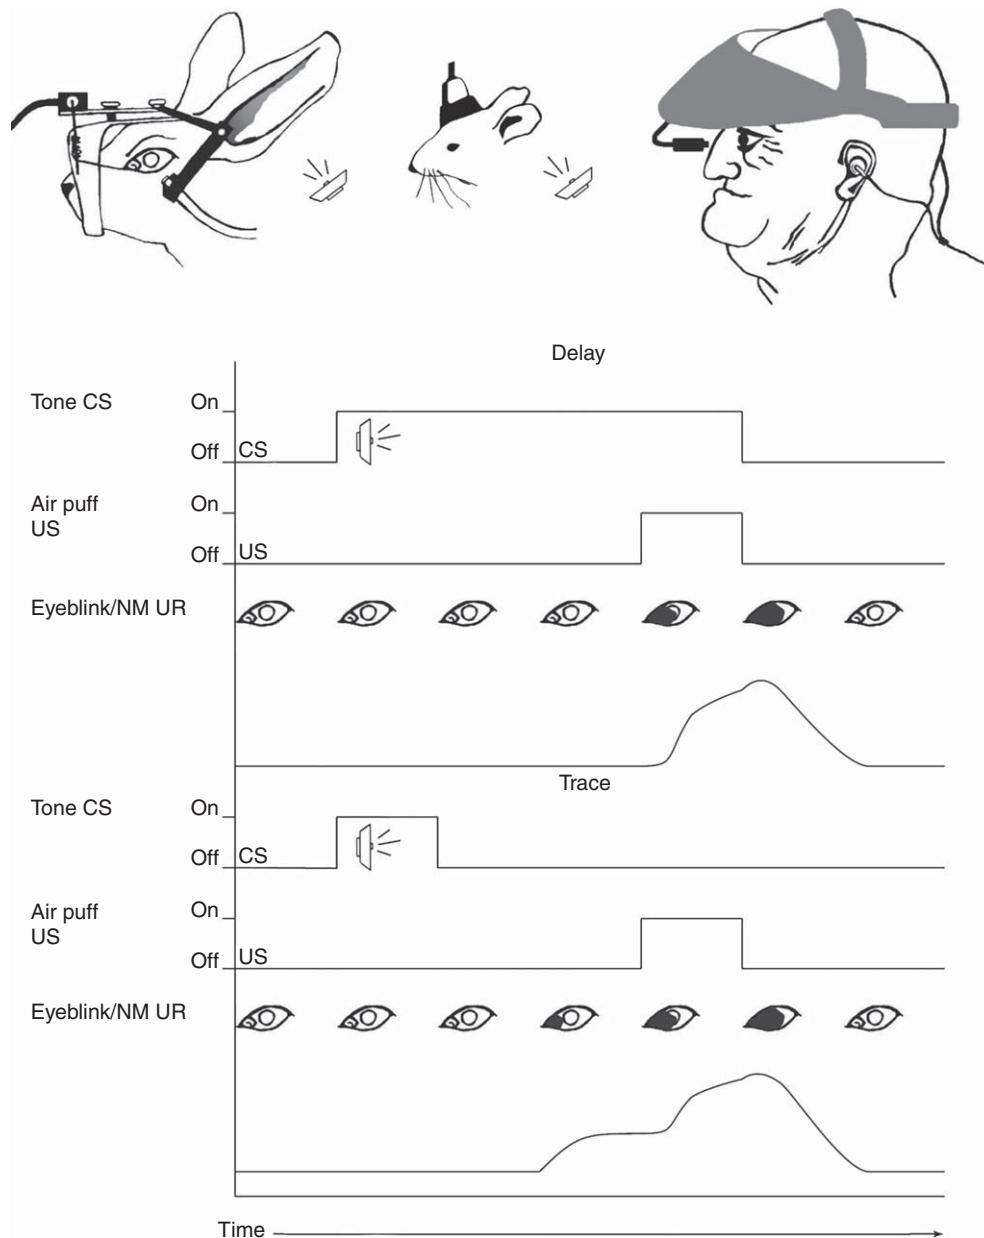

Figure 1 Delay and trace eyeblink classical conditioning paradigms in rabbits, rodents, and humans. (Top) Some examples of apparatus to assess the nictitating membrane (NM)/eyeblink response in rabbits (left), orbicularis oculi muscle activity in rodents (middle), or eyeblink using infrared assessment in humans (right). (Middle row) The delay paradigm involves the presentation of a neutral stimulus such as a tone as the CS, followed by a corneal air puff or orbicularis oculi stimulating US that overlaps and co-terminates with the CS. Below the delay paradigm is a response measure showing a blink after the US, which is called the 'unconditioned response' (UR). (Bottom) The trace paradigm involves the presentation of the CS that is then turned off. A blank (trace) period ensues, and then the US onsets. Below the trace paradigm is a response measure showing a blink after the CS and before the US onset, which is called the 'conditioned response' (CR). When an organism consistently produces CRs, it has learned the association between the CS and US.

neurons in CA1 showed diminished responding. Hippocampal glutamate receptors showed age-related decline. Calcium-dependent afterhyperpolarizations in hippocampal neurons of aged rats were abnormally prolonged. Considerable evidence supports a calcium dysregulation hypothesis of brain aging, and in hippocampus this may be related to elevated postsynaptic calcium

that is closely associated with altered neuronal plasticity. There is a dramatic increase in the amount of LTD induced in the CA1 hippocampal slice in the aged rat. The critical event in the induction of both long-term potentiation (LTP) and LTD is increased intracellular calcium. Dramatic increases in calcium influx (L-type voltage-gated calcium channels) have been demonstrated

in the pyramidal neurons in hippocampal slices from aged rats. Age-related impairments in trace eyeblink conditioning involve an increased afterhyperpolarization in hippocampal pyramidal neurons due, in turn, to an increased calcium-activated potassium current.

In a stereological study of the entire rat cerebellar cortex, 11% fewer Purkinje cells in 23-month-old animals were found. Using unbiased stereological techniques to assess Purkinje cells in the entire cerebellar cortex of mice ranging in age between 4 and 24 months, there is a statistically significant effect of age. There were significantly fewer Purkinje cells in 18- and 24-month-old mice than in 4-, 8-, and 12-month-old mice. Present-day imaging techniques do not have the degree of resolution that enables assessment of human Purkinje cell number *in vivo*. Using human cerebellar tissue at autopsy, it was found that stereological counts of Purkinje cell number were closely related to cerebellar volume. The magnetic resonance imaging (MRI) estimates of cerebellar volume may be an indirect measure of Purkinje cell number. Cerebellar volume is relatively stable in young adulthood, but measurable reductions and increasing variability become apparent around the age of 50 years.

In addition to the loss of Purkinje cells, cellular components show age-related effects. Many Purkinje cells in 26-month-old rats appeared defoliated. Purkinje cell dendrites also showed morphological changes in old mice. In 22-month-old mice, Purkinje cell dendrites had clearly shrunk. One structural reflection of this diminished dendrite was that the thickness of the molecular layer at 22 months of age was reduced in comparison to molecular-layer thickness in younger mice. In addition to anatomical differences in young and older Purkinje cells, other measures of Purkinje cell efficiency have given evidence of age differences. The assessment of Purkinje cell electrophysiology in rats identified a number of cell-firing parameters that were affected. In particular, increasing numbers of aberrant, very slow-firing cells were encountered in older animals. Age-related dysfunction of the cerebellar β -adrenergic receptor was observed to affect spontaneous firing besides modulating the effects of other neurotransmitters such as γ -aminobutyric acid (GABA). This age-related decline in cerebellar β -adrenergic receptor function has been postulated to underlie, in part, age-related deficits in motor learning.

Effects of Aging on Eyeblink Classical Conditioning and Relation to Neural Changes

A strength of the eyeblink conditioning model for research on aging is that humans and nonhuman animals show similar age-related deficits. Humans begin to show age-associated deficits in eyeblink conditioning between 40 and 50 years, while rabbits begin to show age-associated deficits at around 2 years. Based on declines

in reproductive capacity, a 2-year-old rabbit is equivalent to a 35–40-year-old human, which suggests similar onset of age-associated declines in eyeblink conditioning in both species. Results with aging in humans and rabbits generalize to other nonhuman species, such as rats, cats, and mice. Aged mice are impaired in middle age (9–12 months) in 250-ms delay and at an older age (18–24 months) in 500-ms delay eyeblink conditioning just as humans are impaired in middle age (45–55 years) in 400-ms delay and at an older age (70–80 years) in 500-ms delay eyeblink conditioning.

Loss of Purkinje neurons in cerebellar cortex is associated with age-related deficits in eyeblink conditioning in several species: rabbits and mice with direct Purkinje cell counts and humans with an indirect measure, MRI-assessed cerebellar volume.

Present-day imaging techniques do not have the degree of resolution that enables assessment of human Purkinje cell number *in vivo*. Using human cerebellar tissue at autopsy, it was found that stereological counts of Purkinje cell number were closely related to cerebellar volume. The MRI estimates of cerebellar volume may be an indirect measure of Purkinje cell number. Cerebellar volume is relatively stable in young adulthood, but measurable reductions and increasing variability become apparent around the age of 50 years. Two laboratories have reported a positive correlation between delay eyeblink classical conditioning performance and cerebellar volume.

With regard to the hippocampus, afterhyperpolarization recorded in slice preparations from trained rabbits was observed in relation to normal aging. Excitability of CA1 neurons was studied 24 h after the last training session in aged rabbits that reached a 60% behavioral criterion (learning-intact), rabbits trained for 30 days that never demonstrated more than 30% CRs per session (failed to learn), and naive aging rabbits. Aged CA1 neurons from learning-intact animals had significantly reduced postburst afterhyperpolarizations and reduced spike-frequency adaptation compared with neurons from control groups of naive and aging rabbits that failed to learn. No differences were seen in resting potential characteristics after learning. The data suggest that postsynaptic excitability of CA1 neurons is correlated with learning the hippocampus-dependent trace eyeblink conditioning in both young and older rabbits. In young and in learning-intact older rabbits, the data also suggest that a similar level of postsynaptic excitability is achieved at the time that learning has occurred regardless of (1) rabbit age and (2) the actual speed of acquisition of the CR. To identify the current(s) underlying the age-associated learning deficits and decreases in neuronal excitability reflected by an enhanced postburst afterhyperpolarization in CA1 hippocampal pyramidal neurons, whole-cell voltage-clamp recording experiments were carried out using

hippocampal slices in young and older rabbits. Aging neurons had an enhanced, slow outward calcium-activated potassium current. The amplitude of this current was correlated at a significant level with the amplitude of the postburst after hyperpolarization.

Neural Substrates of Individual Variability in Learning and Memory

Neuron numbers vary widely among individuals, in part as a consequence of chance developmental variations. Individual variations are greatest in large populations of neurons arrayed in parallel, which in the neocortex exceed $\pm 50\%$. Individual variations in neuron cell numbers are likely related to behavioral outcomes in normal aging. Learning and memory show many alternative outcomes and great individual variation during normal aging. In comparison to young adulthood, individual variability increases in middle and older adulthood, with some older organisms showing preserved learning and memory and others showing impairment. The cellular basis for most cognitive aging changes is not clear but, in some learning paradigms, could be independent of neuron loss and related to neuron loss in other paradigms. Neuron number in the hippocampus is relatively stable over the adult years.

In the case of hippocampus-dependent learning and memory paradigms, preserved learning and memory in normal older organisms have been associated with electrophysiological functioning comparable to young adult levels. For example, excitability of CA1 neurons studied 24 h after training in hippocampus-dependent trace eyeblink conditioning differentiated good and poor learning in aged rabbits. In general, aged rabbits required significantly more training trials to reach learning criterion than did young rabbits. However, hippocampal CA1 neurons from aged learning-intact animals had significantly reduced postburst afterhyperpolarizations and reduced spike-frequency adaptation comparable to young rabbits. Hippocampal CA1 neurons from control groups of naive and aging rabbits that failed to learn had significantly elevated postburst afterhyperpolarizations and increased spike-frequency adaptation.

Among the mechanisms that support hippocampal electrophysiological function in adult organisms are neurotransmitter and receptor systems. Extensive evidence indicates that nicotinic acetylcholine receptors (nAChRs) act as neuromodulators in communicative processes in the brain and that nAChRs are involved in cognitive and memory functions. nAChRs in the central nervous system are composed of five subunits arranged around a ligand-gated excitatory ion channel. The most abundant nAChR subtypes are those that participate in high-affinity agonist binding associated with $\alpha 4$ and $\beta 2$ subunits, and those sensitive to blockade by α -bungarotoxin and containing $\alpha 7$ subunits. In normal aging, it is the high-

affinity agonist-binding nAChR subunits that show the greatest deficits in human, rabbit, and rodent brain.

Comparisons of 4- and 27-month-old rabbits that learned rapidly or slowly indicated that there was significant variation in the expression of $\alpha\beta$ heteromeric nAChRs in the hippocampus and temporal-parietal cortex in good and poor learners. This result occurred for both young and older rabbits on a task that was hippocampus dependent (trace eyeblink classical conditioning). In rabbits, there was wide variation in $\alpha\beta$ heteromeric nAChRs in brain structures essential for learning and memory, and this variation was associated with differences in learning.

Individual variations in nAChR expression may also be related to outcomes of aging. The magnitude of nAChR loss required for functional impact may be greater in individuals endowed with higher nAChR expression in early life. The 4-month-old poor learners that had fewer $\alpha\beta$ heteromeric nAChRs would likely have been poor learners when tested at 27 months. However, the 4-month-old good learners may have still remained good learners at 27 months. Age-related deficits in nAChR expression in these good learner rabbits may have been postponed to a later point in the adult life span.

Glossary

Akinesia – An abnormal absence or poverty of movements.

Bradykinesia – Slowing of the executed movements.

Catecholamines – Monoamine neuromodulators and neurotransmitters, including dopamine, norepinephrine, and serotonin.

Dementia – A progressive loss of brain-related abilities.

Hypomimia – An abnormal absence or poverty of facial expressions.

Oxidative stress – Cell damage due to over-production of hydroxyl and other radicals.

PARKIN 1-n – Genes and gene loci associated with Parkinson's disease.

Sialorrhea – Inability to manage oral secretions, drooling.

Epidemiology/Etiology

It is estimated that over 1.5 million people in the United States have PD. It is a disease of the older adults afflicting 1% of the population over the age of 50. Because of the changing demographics of increasing numbers of older adults in the United States and other developed countries its incidence is projected to increase. It is a leading cause of disability, accounting for over 6% of the US nursing home population with the ensuing significant economic burden. While it is fairly certain that genetic susceptibility plays an important role in pathogenesis of Parkinson, many environmental factors have also been identified as causes for Parkinson. Since its formal clinical description in 1817 by James Parkinson, a number of documented endemic outbreaks of parkinsonism related to environmental factors have been reported. For example, it has been known since 1837 that exposure to manganese causes parkinsonism along with other neurological deficits. Outbreaks of parkinsonism among manganese miners and steel workers who were exposed to the inhalant form of Mn⁺ were described in the early twentieth century. The modern debate regarding Mn⁺ relates to its use as a gasoline additive and its release into the environment. There is evidence that manganese interferes with release of dopamine from the vesicles in axon terminals of intact dopaminergic neurons. Another increase in the number of patients with parkinsonism occurred after the flu epidemic of the early twentieth century providing the basis for the popular book by Oliver Sacks, *The Awakenings*. The pathophysiological mechanisms causing parkinsonism in these conditions may not be similar to the typical idiopathic or sporadic PD, but investigation of these cases of environmentally induced disease has contributed to research on the possible mechanisms of genesis of idiopathic PD. In particular, the discovery that 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a byproduct of an illicit drug (MPP) that was synthesized in early 1980s, can produce signs and symptoms of common PD opened an important avenue of research that has furthered our understanding of the pathogenesis of PD. Patients with MPTP-induced PD not only exhibit clinical signs and symptoms of PD, but MPTP also mimics the pathogenesis of sporadic PD by selectively destroying the neurons in the substantia nigra. A number of animal models of PD have been generated using this neurotoxin and others. These models have aided researchers in understanding the pathogenesis of PD and development treatments for this disease.

Introduction

Parkinson's disease (PD) is a degenerative disease of the central nervous system characterized by paucity and slowing of normal human movements. It falls in the category of hypokinetic movement disorders, a group of diseases also known as parkinsonism. The primary clinical manifestations of parkinsonism are bradykinesia and akinesia. Conversely, hypokinetic movement disorders are referred to as parkinsonism. Also common to hypokinetic movement disorders is anatomical localization to basal ganglia and its connections. Furthermore, injury to neurons in the basal ganglia and its connections from causes that include, but are not limited to, ischemic, toxic/metabolic, traumatic, and infectious/inflammatory processes, can also manifest as parkinsonism. Similarly, other neurodegenerative diseases of the brain can present with signs and symptoms of parkinsonism. These are considered Parkinson plus syndromes and include multisystem atrophy, cortico-basal ganglionic degeneration, and progressive supranuclear palsy. Majority of patients with PD suffer from sporadic PD. The salient pathological manifestation in sporadic PD is degenerative death of dopaminergic cells in the substantia nigra. This article discusses the epidemiology, clinical presentations, pathophysiology, and pharmacotherapy of PD.

Clinical Presentation of PD

Although PD is a global neurodegenerative disease, its motor manifestations initially overshadow other symptoms. The major motor signs of PD include: tremor, rigidity, akinesia/bradykinesia, and postural instability (acronym TRAP). The acronym 'TRAP' is appropriate since it also defines the experiences of patients with PD as they are unable to move as fast and or as often as they want.

Tremor. Parkinsonian tremor is oscillating movements of the fingers, hands, neck and jaw, and less frequently legs and trunk. Tremors are usually observed when the affected limb is at rest and are typically of a frequency of 3–5 Hz. Although PD is a hypokinetic movement disorder, tremor by nature is hyperkinetic. This clinical paradox indicates that PD has a complex pathophysiology explained by the bursting pattern of firing in the thalamic motor nuclei.

Rigidity. It is an increased resistance to passive movements of the head, trunk, and limbs across joints with or without cogwheel features. Cogwheel rigidity is more prevalent in patients with tremor-dominant parkinsonism; however, many patients exhibit rigidity without cogwheel. The ticking of the cogwheel is often superimposed on the tremor frequency and is usually manifested in the wrist and elbow joints. Rigidity of legs is often manifested in the form of freezing of gait and gait initiation delay. Rigidity of the trunk is the cause for retropulsive falls and produces a reactive stooped posture that can lead to festinating gait.

Bradykinesia/akinesia. It is an essential feature of PD. Bradykinesia refers to slowing of natural body and face movements and is an essential sign for diagnosis of PD. Parkinson patients often assume the bearing of a statue with paucity of natural fidgetiness and slowing of body and limb motions.

Instability of posture. It is the inability to rapidly adapt to changes in stance and posture.

Other motor signs of PD include shuffling gait, festinating gait, and at times freezing of the gait. Gait and posture abnormalities are most refractory to treatment and often the most debilitating signs. Hypomimia, hypophonia, and sialorrhea are secondary motor deficits. These signs develop as a result of bradykinesia and rigidity of the facial and oral muscles and are perhaps more pronounced signs of PD. In patients with PD, eye movements are abnormal and are parallel to the abnormalities observed in limbs. It is well-known that disorders of movements that involve the cerebral cortex, the basal ganglia, and the cerebellum also affect the movements of the eyes. Thus, in patients with advanced PD the eye movements have the same characteristics as the limb movements, that is, the trajectory of the eye movements are broken similar to cog-wheeling movements of the limbs.

While the initial clinical manifestation of PD is in the motor system, it will ultimately affect other areas of the nervous system. Nonmotor symptoms of PD contribute significantly to disability and impaired quality of life. It is increasingly recognized that nigro-striatal degeneration is not the sole pathology in PD; other monoamine neurotransmitter systems are also involved causing the nonmotor signs and symptoms (see below). Recognition of the nonmotor symptoms in Parkinson is essential for its effective treatment. Autonomic complaints are perhaps the most prevalent and neglected symptoms of PD. At one time or another, patients with PD experience cardiovascular, gastrointestinal, urinary, and sexual dysfunction. Depression and anxiety are common nonmotor symptoms of PD and by some counts 45% of patients develop depression during the course of this disease. Depression may be reactive to the disease or a consequence of loss of dopamine, noradrenalin, and serotonin in the brain. It has been reported that PD patients with depression as comorbidity have a higher burden of pathological features, including neuronal loss, gliosis, and accumulation of Lewy bodies compared to the PD patients without depression. Psychosis and deficit in impulse control are other symptoms that are relatively common in PD patients. Up to two-thirds of PD patients can exhibit confusion, hallucination, impulse control disorder, and paranoia. Sleep disturbances including vivid dreaming, excessive daytime sleepiness, and REM sleep behavior disorder are also common. It is likely that most of these symptoms are not constitutional to PD but are manifested as a consequence of long-term treatment with dopaminergic drugs. The risk of developing dementia is nearly sixfolds higher in PD patients than matched population; approximately 40% of PD patients may exhibit dementia. The pathophysiological basis of dementia in idiopathic PD is not clear. Corticobasal degeneration, diffuse Lewy body disease, and progressive supranuclear palsy all present with Parkinson-like symptoms and signs but have distinct pathological features and are mostly refractory to treatments.

Pathophysiology of PD

As mentioned above, various pathological processes in the basal ganglia can result in motor manifestations of PD. Conversely, a single pathological entity, that is, loss of substantia nigra cells and their connections can result in different constellations of clinical symptoms and signs. This assertion correlates with the broad motor and non-motor clinical manifestations of PD. Since the middle of the last century it has been known that loss of dopamine in nigrostriatal system is the sentinel event in the pathogenesis of PD. Cell loss in substantia nigra is precipitated by slow apoptotic cell death, a hallmark of neurodegenerative

diseases. A common thread in the pathogenesis of neurodegenerative diseases is the misfolding/malformation of cellular proteins leading to the production of abnormal intracellular inclusions. These malformed proteins along with environmental factors precipitate cell death in selected areas of brain. Thus, PD similar to other neurodegenerative diseases is a disease of protein misfolding/malfunction. While all of the cellular and molecular factors and the environmental precipitants that contribute to the genesis of PD and its age of onset are not known at this time, it is clear that genetic risks are associated with loss of cells. Linkage analysis studies on cases of familial PD have identified mutations in a number of genes with confirmed roles in genesis of PD, in particular PARK1, PARK7, and PARK8 have been intensively studied. The genes that have been associated with PD are listed in **Table 1**.

Some of the genetic defects were initially discovered in patients with familial PD; however, in sporadic disease these mutations may act as susceptibility factors and increase the risk or the age of onset of PD. For example, mutations in different loci of two of these genes (PARK2 and PARK8) have been noted in various cohorts of patients with sporadic PD. These mutations are thought to represent genetic risk factors in pathogenesis of PD. The exact molecular mechanisms of how an abnormal LRRK2 causes PD are not yet known. Some data suggest that a mutated LRRK2 causes dopaminergic cell death by interfering with translation of the stress response proteins. Another of the identified offending proteins is α -synuclein coded by the gene (SNCA) located in the PARK1 locus. α -Synuclein is present in the presynaptic complexes in the striatum and other areas of brain. Highest concentration of this protein has been reported in the substantia nigra of patients with PD, presumably because of the impaired proteolytic clearance of this protein. α -Synuclein is synthesized either in the form of a helix or a beta sheath and is a significant component of Lewy bodies and Lewy neuritis. It is also found in the plaques that are associated with Alzheimer's disease. Mutations in α -synuclein, parkin, and ubiquitin hydroxylase 1 all

result in reduced degradation of α -synuclein. Reduced degradation of α -synuclein results in the formation of abnormal intracellular inclusions known as Lewy bodies. While deposition of α -synuclein initially causes only minor cell loss in most areas of brain, it is associated with early destruction and significant cell loss in the substantia nigra. The reason for this early cell death is thought to be increased susceptibility of monoaminergic neurons and their axons to other pathological processes.

A vast body of literature chronicling investigations of degenerative cell death via intracellular signaling pathways and apoptosis has accumulated. During development, apoptotic cell death aids in sculpturing the nervous system. In adult organisms the rate of apoptotic neuronal death is relatively low; however, in patients with neurodegenerative diseases apoptotic cell death is accelerated in selected areas of the nervous system. With regards to PD, a number of intracellular pathways leading to apoptosis in Substantia Nigra cells have been explored including oxidative stress, elevation of cytosolic free calcium in neurons and inflammation. Catecholaminergic cells are highly susceptible to oxidative stress because of the enzymatic degradation of dopamine and norepinephrine by the enzymes monoamine oxidases (MAOs) A and B. One of the by-products of this reaction is hydrogen peroxide. Hydrogen peroxide is a source of hydroxy radicals or reactive oxygen species that are associated with oxidative stress and are capable of damaging cellular proteins, lipids, and nucleic acids. MAO enzymes are tightly associated with mitochondrial outer membranes; this proximity may be responsible for damage to mitochondria in adrenergic cells and leakage of cytochrome C from mitochondria, thus initiation of apoptotic cell death. Another culprit in pathogenesis of PD is the calcium overload of dopaminergic cells. The intracellular concentration of calcium is tightly regulated under normal conditions. Under some pathological conditions, calcium leaks into the cytoplasm from both extracellular and sequestered intracellular compartments. Over abundance of free cytosolic calcium activates proteolytic enzymes and is thought to precipitate organelle damage and is thus another mechanism for apoptotic death of adrenergic neurons.

How does presence of a genetic mutation and the resulting aberrant proteins translate into a constellation of clinical signs and symptoms? A significant body of electrophysiological and anatomical data from *in vivo* experimental models has complemented the cellular and molecular information and has illustrated, albeit incompletely, the motor pathways that are responsible for genesis of clinical symptoms. These pathways form the basis for both pharmacological and surgical treatments of PD. Briefly, widely distributed and multimodal sensory and motor signals from the cerebral cortex flow to the

Table 1 Genes associated with PD

Gene	Chromosome/locus	Protein
PARK 1	4 q21–23	α -Synuclein
PARK 2	6 q25–27	Parkin, (ubiquitin E3 ligase)
PARK 3	2 p13	
PARK 4	4 q21–23	
PARK 5	4 p14	
PARK 6	1 p35–36	PTEN-induced kinase-1
PARK 7	1 p36	Oncogene DJ 1
PARK 8	12 p11–q13	Leucin-rich repeat kinase 2 (LRRK2)
PARK 9	1P36	

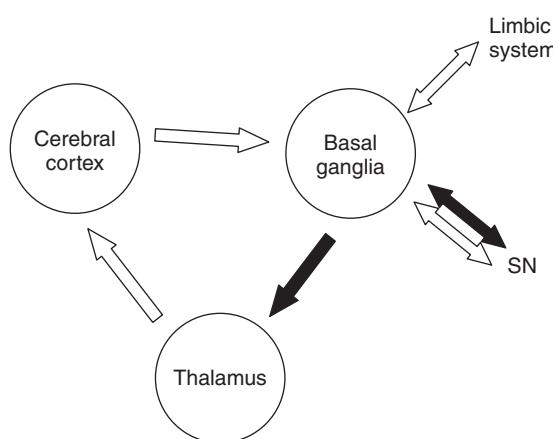

Figure 1 The diagram shows basic flow of information between the cerebral cortex, basal ganglia and thalamus. Each arrow represents a complex set of neural signals representing a variety of modality based information. Open arrows indicate excitatory outputs, closed arrows are inhibitory. Substantia Nigra (SN) and the limbic system have modulatory effects on this circuit, i.e., they are tuning the flow of information.

caudate and putamen nuclei. Caudate and putamen neurons project to globus pallidus, which then projects to motor thalamus and back to the motor areas of the cerebral cortex, completing a circuit. Within this circuit, dopaminergic inputs from the substantia nigra modulate the activity of the medium spiny neurons in the striatum via two classes of dopamine receptors, D1 and D2. At a cellular level, these receptors have opposing effects on the neuronal activity in the striatum, affecting the direct and indirect pathways differentially (Figure 1). Loss of dopamine secondary to cell death in the substantia nigra causes a dysregulation in the activity of striatal neurons that project to the globus pallidus. In turn, this results in a net increased activity of gamma aminobutyric acid (GABA)ergic Globus pallidus *interna* neurons that project to the thalamus. Indeed, electrophysiological single cell recordings from the GPi neurons of patients with PD show that the activity of these neurons increases from a baseline of about 40–60 Hz up to 120 Hz. The resulting increase in the GABAergic output by the GPi neurons affects downstream structures, thalamus and cerebral cortex. Clinical experience in the last decade has validated this circuit and has shown that deep brain stimulation and pallidotomy are effective as surgical therapies for amelioration of some of the symptoms and signs of PD. Pallidotomy refers to a partial destruction of GPi.

Treatment of PD

There is no cure for PD. For the past several decades, treatment of PD has involved replacement of the lost dopamine from the substantia nigra. This has been accomplished by systemic administration (oral) of dopaminergic drugs, for example, Levodopa. It is intriguing

that while loss of dopamine in PD has been thought to involve a small portion of the nervous system, specifically the substantia nigra and nigro-striatal system, diffuse systemic administration of dopaminergic drugs ameliorates the symptoms of PD. This implies that with regards to monoaminergic neurotransmitters and perhaps other neurotransmitters the brain needs only a diffuse supply of these drugs in the neuronal milieu to function seemingly normally. Furthermore, this mode of action of neurotropic drugs provides insights into the global role of monoamines in brain functioning in health and disease. It is conceivable that monoamines function as switches in the sensorimotor continuum of arousal, attention and purposeful motor function, and, that unregulated increase or decrease in their level in the brain result in global diseases such as Parkinson and psychiatric disorders.

Currently, dopaminergic drugs remain the mainstay of pharmacotherapy for PD. Dopamine does not cross the blood-brain barrier and has significant peripheral side effects. However, its precursor Levo-dihydroxyphenylalanine (L-DOPA) can cross the blood-brain barrier and is easily converted to dopamine in the brain by the ubiquitous enzyme, aromatic amino acid decarboxylase (AADC). L-DOPA is administered in conjunction with Carbi-DOPA, which neutralizes the enzyme AADC to block the metabolism of L-DOPA to dopamine in the periphery and thus prevents some of the systemic side effects of dopamine. Administration of C-DOPA also allows a larger quantity of L-DOPA to cross the blood-brain barrier and exert its pharmacodynamic effect onto dopaminergic system. Another group of drugs for the treatment of PD is dopaminergic receptor agonists. These drugs exert their effects directly on D1 and D2 classes of receptors. The older agonists were relatively nonspecific with multiple side effects and consequently are not tolerated well by the patients. This lack of tolerance is attributed to the action of the agonist meds on multiple dopamine receptors, D2, D3, and D4. Although the new meds are thought to be relatively specific, they remain relatively ineffective with different and novel side effects. For example, some of these drugs are reported to bolster addictive behavior, presumably by activating receptors in the nucleus accumbens-septal dopaminergic system. A large number of studies have been performed on pharmacological agents that can stop or reverse degeneration of cells in the substantia nigra; however, as yet no agent has been convincingly proven to change the course of progression of PD. These agents include anti-oxidants, calcium channel blockers, and vitamins. Biological treatments for PD have been extensively explored; however, they are generally in experimental stages. Cell therapies using embryonic, fetal, and adult dopaminergic cells and application of growth factors have shown promise as proof of principle for the treatment of PD. However, before these therapies can be applied for widespread use, much more needs to be done.

Glossary

Blood oxygen level dependent (BOLD) – BOLD effect uses the endogenous contrast agent deoxyhemoglobin as a source of contrast associated with neuronal activity. BOLD contrast in signal intensity using functional magnetic resonance imaging (fMRI).

Diffusion tensor imaging – Diffusion imaging is an MRI method that measures water diffusion in biological tissues. Diffusion tensor imaging also provides information on the orientation of water diffusion.

Functional MRI (fMRI) – fMRI measures the hemodynamic changes that are associated with neuronal activity in the brain and spinal cord of the human and animals.

Positron emission tomography (PET) – PET is a nuclear medicine imaging technique which uses ionizing radiations. In the brain, PET provides information on brain metabolism, receptors, perfusion, or diagnosis (amyloid binding in Alzheimer's disease).

Tractography (also DTI fiber tracking) – Tractography is an imaging method that is used to reconstruct fiber tracts in the brain of the human and animals.

Tractography is performed using diffusion images.

Introduction

During the past decades, the basal ganglia (BG) were largely considered to be a motor system in which different inputs converged to produce an output specific to the control of motor execution. Series of new findings support the view that the BG are essential for behavioral adaptation, the selection of action commands, and reward-based learning.

Human Basal Ganglia Anatomy

The BG represent an important neuronal system, which consists of four main gray nuclei: the striatum, the globus

pallidus, the subthalamic nucleus (STN), and the substantia nigra. These nuclei are located in the depth of the cerebral hemispheres and are interconnected to each other, the cerebral cortex, and some midbrain structures such as pedonculopontine nucleus through a complex series of circuits.

The Striatum

The striatum includes the caudate nucleus and the putamen that originate from the same telencephalic structure and have the same neuronal organization (**Figures 1** and **2**). Incoming cortical information is processed in the striatum principally by the γ -aminobutyric acid (GABA)ergic projection of spiny neurons. Spiny neurons form synaptic contacts with cholinergic interneurons (the tonically active neurons – TANs) and receive inhibitory feedback from small GABAergic interneurons. GABAergic interneurons receive cortical information. Dopaminergic (DA) terminals arising from the compact part of the substantia nigra form synaptic contacts with striatal spiny neurons.

Thus, cortical excitatory input is received on the spines of the spiny neurons, which are in turn submitted to the inhibitory control of local circuit interneurons, the disinhibiting control of cholinergic TANs and the modulating, excitatory (via D1 receptors) or inhibitory control (via D2 receptors) of DA afferents. Dopamine influences striatal activity by two distinct modes of release – a tonic and a phasic mode. The tonic mode of dopamine release appears to be implicated in the passage of information through the BG, influencing the selectivity in relation to ongoing processes. The phasic dopamine release is crucial for modifying functional synaptic connections and consequently for building stimulus-response or context-habit associations by procedural or instrumental learning.

The Globus Pallidus

The globus pallidus is derived from the diencephalon and is divided into an internal and an external segments

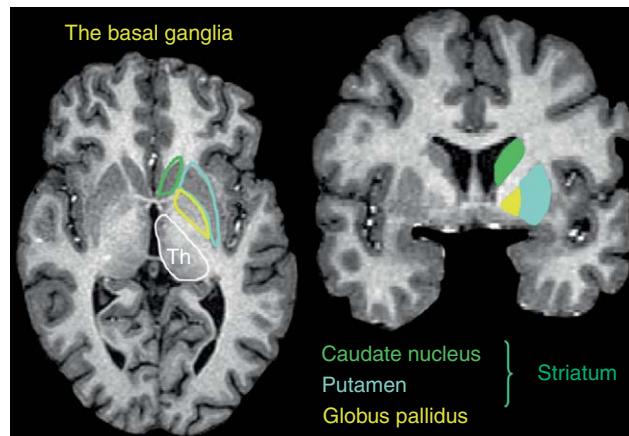

Figure 1 Magnetic resonance imaging of basal ganglia anatomy. T₁-weighted axial slice passing at the level of the anterior commissure–posterior commissure (on the left) and coronal slices passing at the level of the anterior commissure (on the right). The striatum, includes the caudate nucleus (green) and the putamen (light blue); the globus pallidus (yellow). Th, thalamus.

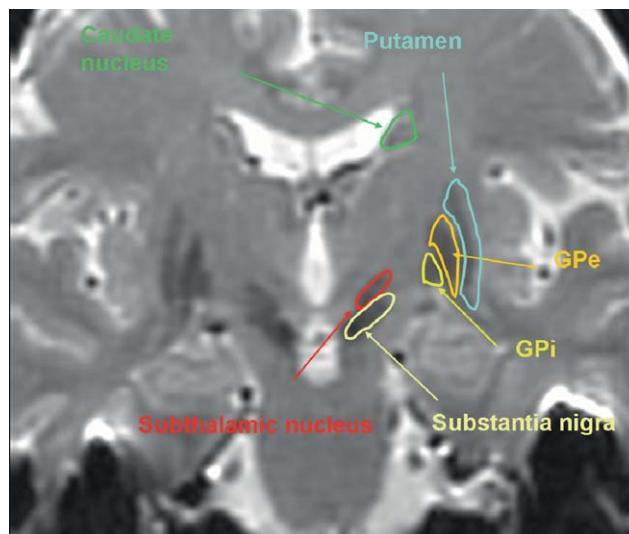

Figure 2 Coronal T₂-weighted image of the basal ganglia. GPe = external segment of the globus pallidus; GPI = internal segment of the globus pallidus.

(**Figures 1 and 2**). Both segments of the globus pallidus contain a single type of neurons. These neurons are characteristically devoid of spines and have very long dendrites (up to 1 mm).

In the globus pallidus, striatal information is greatly reduced through a triple process of volumetric, numeric, and geometric convergence. The number of pallidal neurons is 100 times smaller than that of striatal spiny neurons. A single pallidal neuron receives synaptic input from about 100 striatal spiny neurons. Experimental data in animal models showed that many pallidal neurons could be inhibited by stimulation of more than one cortical area (prefrontal, premotor, supplementary motor, and primary motor areas), and that a significant fraction of pallidal neurons respond to multiple motor, cognitive, or limbic events. This anatomical disposition – which tends to widen

the receptive field of pallidal neurons and thus reduces the specificity of incoming information – is counterbalanced by DA nigrostriatal inputs, which tend to reduce the size of the receptive fields of pallidal neurons.

The Subthalamic Nucleus

The STN is a small ($12 \times 5 \times 3 \text{ mm}^3$), biconvex, lens-shaped structure situated below the thalamus (**Figure 2**). The STN is also derived from the diencephalon. Subthalamic neurons are intermediate in size between the striatal spiny neurons and the pallidal neurons. They use glutamate as their neurotransmitter and have an excitatory action on their target neurons in the internal and external globus pallidus and the substantia nigra pars reticulata.

The STN works as a structure that regulates the level of activity of the output nuclei of the BG (internal globus pallidus and substantia nigra pars reticulata). If hyperactive, as in Parkinson's disease, the execution of motor activity is hampered (akinesia). STN hypoactivity, following vascular lesion or high-frequency stimulation, resulting in motor activity becomes excessive as in hemiballism or hypomania.

The STN can also dynamically control the response threshold as it modulates when a response is executed. This dynamic control results in reduction of impulsive or premature response and provides the support of the STN role in response selection during high-conflict decision-trials.

The STN is also subdivided into functional territories that process motor, cognitive, and emotional information. The STN functional territories enable specific processing in different parts of the nucleus, that is, motor dorsolaterally and associativo-limbic ventromedially. Deep brain-stimulation observations in parkinsonian patients suggest that a complex integration probably occurs at the neuronal level in the STN. Two contacts of a stimulating electrode located in the same associative territory and separated by only 2 mm can produce completely different behavioral effects in the same patient.

The Substantia Nigra

The substantia nigra lies in the midbrain (Figure 2). The substantia nigra contains two zones: a ventral zone, named 'pars reticulata' and a dorsal zone named 'pars compacta'. The majority of cells in the pars compacta are DA

neurons. DA neurons are considered to play a key role in focusing attention on salient and rewarding stimuli. DA terminals modulate the efficacy of corticostriatal synapses – a mechanism that could be implicated in learning. In addition, recent experimental data point to the role of the phasic dopamine signals in contextual regulation of behavior and in response both to novel-neutral, nonrewarded, but behaviourally significant, stimuli and to aversive stimuli.

The afferent control of DA neurons arises from various structures including the striatum, which is believed to be a major source. The precise function of this striatal GABAergic projection to the DA neurons is not known, but some interesting ideas were proposed based on computational approaches. As proposed by Joel et al., the striatonigral projection to the DA neurons may regulate DA neuronal activity and responses to the reward signal.

The pars reticulata of the substantia nigra has striking similarities in cytology and connectivity with the internal segment of the globus pallidus. These two nuclei constitute the major output nuclei of the BG.

Basal Ganglia Circuits

Current Models

The model of BG organization proposed by Delong and Alexander suggested that cortical information is processed through the BG in parallel circuits (Figure 3). This model postulated that the cortical projections from the frontal

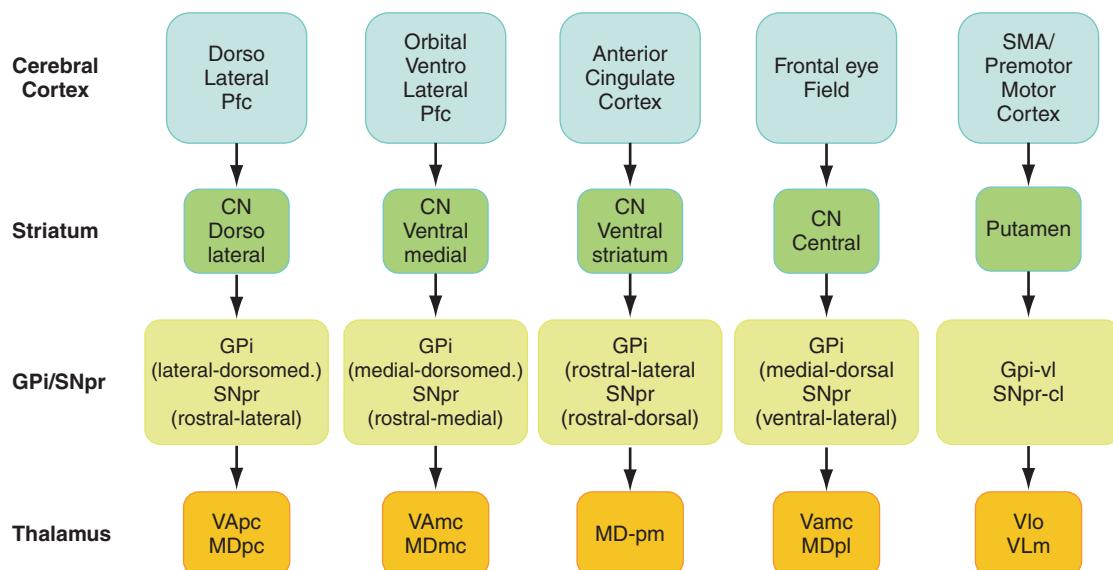

Figure 3 Segregated parallel cortico-BG circuits. Abbreviations. CN = caudate nucleus; GPe = external segment of the globus pallidus; GPI = internal segment of the globus pallidus; mc = magnacellularis; MD = mediodorsal nucleus; pc = parvocellularis; PFC = prefrontal cortex; SMA = supplementary motor area; SNpr = pars reticulata of the substantia nigra; VA = ventral anterior nucleus; VLo = ventrolateral oral nucleus; VLm = ventrolateral medial nucleus. cortex comprise five different circuits – oculomotor, motor, dorsolateral prefrontal, lateral orbitofrontal, and anterior cingulate. This model does not consider integration between motor and nonmotor information in the BG. The assumption that the circuits remain segregated in the BG is contradicted by the anatomical organization of the BG, which exhibits converging properties at several anatomical levels.

Another model, principally developed by Parent and Hazrati, suggests that the functionally organized cortical projections within the BG provide anatomical support in favor of a functional subdivision into sensorimotor, associative, and limbic functional territories, processing somesthetic and motor, cognitive, motivational, and emotional information, respectively. These three functional territories are situated in different portions of the striatum and globus pallidus: the sensorimotor territory in the posterior dorsolateral portions; the limbic territory in the ventromedial portions; and the associative territory in the anterodorsal portions, between the other two territories. The validity of this tripartite model has been demonstrated both in nonhuman primate experiments and in human clinical research.

The model of Mink puts forward the spatial organization of three distinct pathways: direct pathway – striato-pallido-nigro-thalamo-cortical; indirect pathway – striato-pallido-subthalamicopallido-nigro-thalamo-cortical; and hyperdirect pathway – cortico-subthalamic (Figure 4). He also described a center-surround

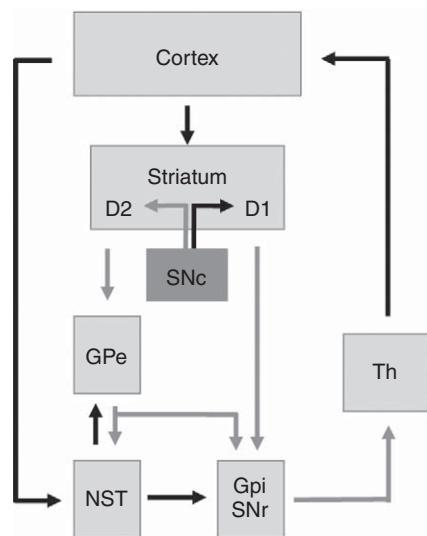

Figure 4 The basal ganglia direct and indirect cortico-striatal-pallido-thalamo-cortical circuits. Excitatory fibers are represented in black and inhibitory fibers in light grey.
Abbreviations: D1 = D1 dopaminergic receptors; D2 = D2 dopaminergic receptors; GPe = external segment of the globus pallidus; GPi = internal segment of the globus pallidus; SNC = substantia nigra pars compacta; SNr = substantia nigra pars reticulata; STN = subthalamic nucleus; Th = thalamus.

organization of information emitted from the cerebral cortex. In this model, the direct pathway provides a centered focalized inhibition of the output nuclei (internal globus pallidus and substantia nigra pars reticulata), allowing a focalized excitation of the thalamus and cortex, thus serving the execution of the desired motor action (Figure 5). In the meantime, the indirect STN pathway provides a large, divergent excitation of the output nuclei, which results in a large inhibition of the thalamocortical projection, leading to an inhibition of competing programs.

A dynamic model of BG function proposed by Nambu expands the center-surround model in the temporal domain. The model privileges the timing aspect of the three pathways. The hyperdirect pathway – which is the most rapid cortico-subthalamo-pallidal projection – first inhibits all motor programs in a reset-like fashion. Then the direct corticostriatopallidal pathway activates the motor sequence to be executed. Finally, the slowest indirect cortico-striato-pallido-subthalamo-pallidal pathway inhibits the motor sequence to terminate the execution. Through this sequential information processing, only the selected motor program is initiated, executed, and terminated at the selected timing, whereas other competing programs are cancelled.

The direct and indirect pathways have been revisited recently in a biologically based computational model. They are interpreted as Go/No-Go devices, which help to choose, among different solutions, the so-called decision-making. The Go pathway is activated by dopamine and helps facilitative responding, while the No-Go pathway is inhibited by dopamine and suppresses responding. Animal models have shown that phasic bursts of DA neurons – which act as teaching signals to learn rewarded behavior – are observed during positive reinforcement, whereas aversive events are associated with DA dips. In the computational model by Frank, dopamine bursts increase synaptic plasticity in the direct pathway while decreasing it in the indirect pathway, supporting Go learning to reinforce the good choice. Dips in dopamine have the opposite effect – supporting No-Go learning to avoid the bad choice.

Thus, from an anatomical point of view, the BG system appears as a device that receives a sample of the three specific functional aspects of cortical information – sensorimotor, cognitive, and emotional – and that processes this information in a convergent manner. However, convergence is not the only aspect of BG processing. A complex integration takes place in each of the BG nuclei that results in the elaboration of a completely new and specific output message that will be sent to the frontal cortex to enable the elaboration of an adapted behavior comprising a motor action executed in a specific cognitive context with an appropriate emotional content.

Thin line means decreased activity, thick line means increased activity. Abbreviations: GPe = external segment of the globus pallidus; GPi = internal segment of the globus pallidus; STN = subthalamic nucleus; Th = thalamus.

Basal Ganglia Circuits in the Human Using Diffusion Tensor Imaging

Tractography-based studies using diffusion tensor imaging (DTI) have reported a strong correlation between human corticostriatal connections and anatomical data from tracing studies in nonhuman primates (Figure 6), in line with the parallel circuit model. Tractography studies showed that each striatal compartment has specific connections with the cortex, and particularly the frontal lobes. The sensorimotor territory of the putamen (posterior part of the putamen) was connected to the primary sensory and motor areas, and to the posterior part of the supplementary motor area – SMA. The anterior striatum was connected to the prefrontal cortex, the frontal pole, and the pre-SMA. The ventral striatum was connected with the limbic system, including the orbitomedial frontal cortex, the amygdala, and the hippocampus.

Although tractography studies showed results that support the anatomical concept of segregated loops in prefrontal, premotor, and sensorimotor networks, evidence of overlapping corticostriatal connections were also observed. Therefore, DTI fiber-tracking studies provided the neuroanatomical correlate of both parallel and integrative networks.

Basal Ganglia Function in the Human, Imaging Studies

Imaging studies in the human have shown that the BG are involved in many aspects of motor control. Location of striatal activation depends upon the nature of the task in a

manner broadly consistent with the predictions of the different functional territories.

Functional Territories in Human Basal Ganglia

The sensorimotor striatum was consistently activated for all types of movements performed using functional imaging, including complex or simple finger movements (Figure 7). Movement activation was somatotopically organized. Basic movement parameters, such as frequency, amplitude, and force, did not or weakly correlated with activational changes (regional cerebral blood flow using PET or percentage-signal increase using functional MRI). Therefore, the striatum is probably not a key structure in coding basic movement parameters.

Many studies have reported striatal activation during the preparation phase preceding movement (Figure 7(b)). Activation in the putamen during preparation was located anteriorly than during movement execution, similar to preparatory activity in cortical structures (SMA, motor cortex, etc.). This suggests that movement preparation and execution are represented within different corticostriatal circuits, in line with animal studies (Figure 7(b)). Simple, horizontal, saccadic eye movements elicit striatal activation in the caudate nucleus.

The associative striatum was activated during more complex types of motor acts. Complex movements require additional motor or cognitive demands. Numerous studies found that striatal activation depended upon the nature of the task and have shown activation in

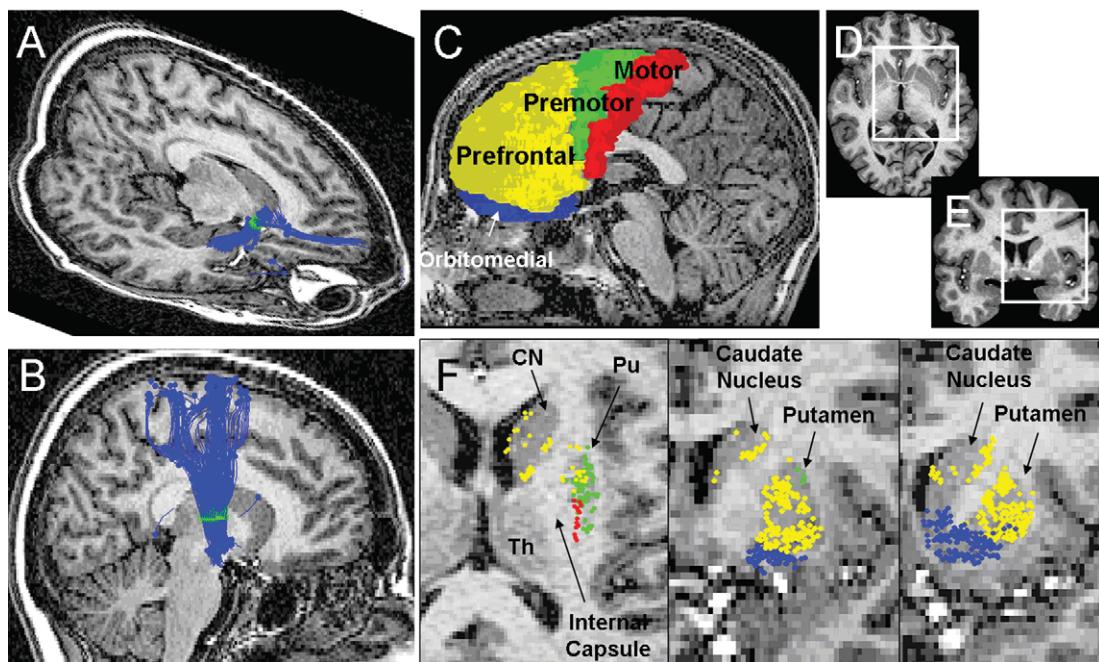

Figure 6 Diffusion tensor-imaging corticostriatal fiber tracts. (a) Fiber tracts from the ventral striatum (the ROI is represented in green). The blue fibers represent the tract in three-dimensional (3D) view as if viewed from the right and projected on a parasagittal slice (up) or from the anterior-right of the brain and projected on a 3D view (down). Fiber tracts connect to the ventral striatum and the medial orbitofrontal cortex, hippocampus, and temporal pole. (b) Fiber tracts from the posterior putamen. The blue fibers represent the tract in 3D as if viewed from the right and projected on a parasagittal slice (up) or from the top of the brain and projected on an axial slice (down). Fiber tracts ended in the primary sensorimotor cortex and adjacent premotor cortex, and the SMA. Fiber tracts are represented on T1-weighted sections. (c) Tractography in F was initiated from four ROIs located in the frontal lobes: the motor (red), premotor (green), prefrontal (yellow), and orbitomedial frontal cortex (blue). (d) Axial and coronal (e) planes presented in (f). (f) Fibers originating from the motor (red), premotor (green), prefrontal (yellow), and orbitomedial frontal cortex. Th = thalamus. Adapted from Lehericy S, Ducros M, Van De Moortele P-F, et al. (2004) Diffusion tensor fiber tracking shows distinct corticostriatal circuits in humans. *Annals of Neurology* 55: 522–529.

the associative compartment during complex movement, including movement selection/decision, mental representation including mental simulation of grasping and hand-movement simulation, complex finger-movement sequences (Figure 7(c)), working memory, and planning tasks. These tasks required the subject to attain a goal through a series of intermediate steps which do not necessarily lead toward that goal.

Activation in the anterior striatum was more specifically involved when subjects had to prepare a sequential action based on information stored in working memory than during simple maintenance of information in line with the hypothesis that striatal neurons convey information that are useful for behavioral acts. These results suggest that the dorsolateral prefrontal cortex (DLPFC)–caudate nucleus loop is activated during higher-order aspects of motor control, such as movement selection and planning.

The limbic circuit is implicated in the motivational aspects of behavior. Several functional magnetic resonance imaging (fMRI) studies have reported activation in the ventral striatum and orbitomedial frontal regions

during monetary reward or punishment, and expectation of monetary reward. Activation in the ventral striatum was more closely associated with anticipation of reward and reward-prediction errors than to reward *per se*, whereas reward outcome was more closely related to activation in the orbitomedial frontal cortex. Signal novelty or unpredictability were also determinants of ventral striatal activation.

In primates, the behavior of the DA neurons has been modeled using the temporal difference algorithm. In the human, the temporal difference algorithm successfully predicted responses in the ventral striatum during tasks that require learning from positive or negative feedback and more recently the ventral tegmental area. Moreover, drugs enhancing or reducing DA function modulated the magnitude of blood oxygen level dependent (BOLD) signal associated with reward-prediction error expressed in the human striatum. Dopamine release in the ventral striatum has also been demonstrated during a goal-directed behavior (a video game) using PET and D2 agonist raclopride binding.

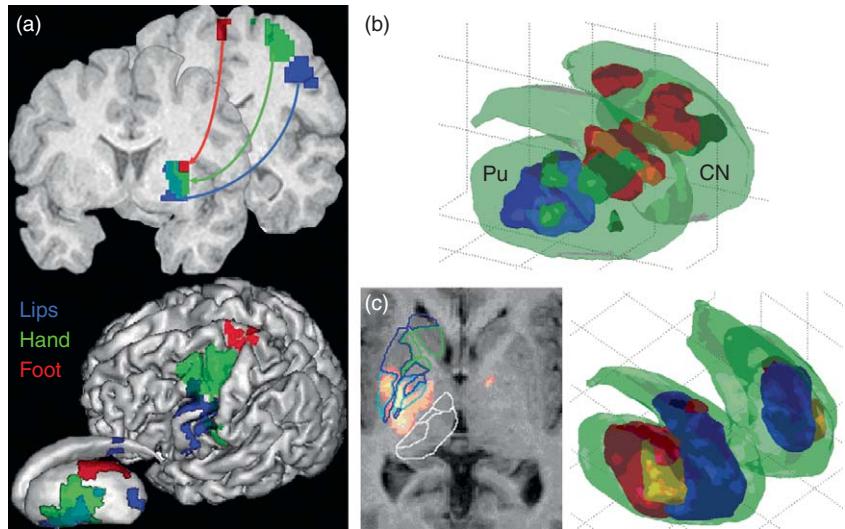

Figure 7 (a) Activation in the putamen and the primary sensorimotor cortex during foot (red), hand (green) and lip (blue) movements superimposed on a coronal T₁-weighted images (up) and a 3D surface render of the brain and striatum (down). (b) Activation observed in the striatum during the selection (red), preparation (green) and execution (blue) of a button press with the left or the right hand. Activation during movement selection was observed in the anterior striatum including the caudate nucleus. Activation during movement preparation was observed in the anterior putamen. Activation during movement execution was observed in the posterior putamen. Abbreviations: CN = caudate nucleus; Pu = putamen. (c) Left: axial view of activation maps obtained during a simple index tapping task was observed in the posterior putamen. The sensorimotor (light blue), associative (dark blue) and limbic (green) territories are territory in the striatum and globus pallidus. Thalamic nuclei are represented in white. DA neurons are believed to have a preferential role in encoding positive rather than negative outcomes. High levels of dopamine improved learning rate to gains in pathological gamblers and Parkinsonian patients on medication, whereas parkinsonian patients off medication were better at learning to avoid choices that led to negative outcomes than they were at learning from positive outcomes. In congruence with these findings, subjects with high baseline dopamine synthesis, measured using PET in the striatum, showed relatively better reversal learning from unexpected rewards than from unexpected punishments, whereas subjects with low baseline dopamine synthesis in the striatum showed the reverse pattern.

The ventral striatum may thus function as a structure capable of using prediction-error signal to update successive predictions of future reward-associated events, whereas the dorsal striatum encodes stimulus-response-reward associations so that actions associated with greater reward are chosen more frequently (Figure 8). This model has been referred to as the actor-critic model of reinforcement learning, in which the ventral striatum acts as the critic and the posterior putamen as the actor (Figure 8).

Motor Learning

Imaging studies have demonstrated that the BG plays a critical role in the learning and execution of new motor programs. Motor learning has been studied using tasks measuring the acquisition of sequences of movements. These tasks require subjects to produce a sequence of movements that they either know explicitly before training (explicit learning), or learn implicitly through repeated practice (without explicit knowledge). Activation in rostral striatal areas is typically observed during the early planning phase of explicit motor learning, when higher-order selection, working memory, and planning aspects of motor control are needed. In contrast, posterior sensorimotor areas were activated during the execution of learned motor sequences as well as during implicit learning (e.g., in the absence of any explicit knowledge). In some studies although not in others (Figure 9), putamen activity increased with learning, suggesting that it may be implicated in the long-term storage of motor programs.

Thus, despite some conflicting observations, these results suggest that anterior associative striatal regions are implicated during the acquisition of new motor skills,

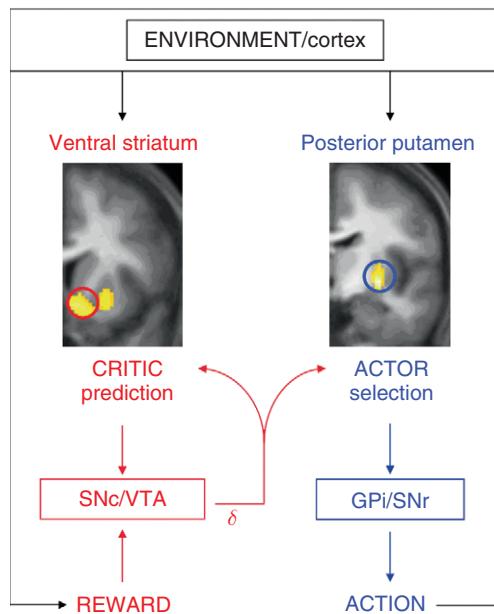

Figure 8 Model of reinforcement learning. The ventral striatum acts as a critic and uses a temporal difference prediction error signal (δ) to update successive predictions of future reward (determined by the arrangement of stimuli). The posterior putamen acts as an actor and uses a similar signal to modify stimulus-response associations, so that actions associated with greater long-term reward are chosen more frequently. Reward-prediction-error signal was observed in the ventral striatum whereas action-related signal was observed in the posterior putamen. Adapted from Pessiglione M, Seymour B, Flandin G, Dolan RJ, and Frith CD (2006) Dopamine-dependent prediction errors underpin reward-seeking behaviour in humans. *Nature* 442: 1042–1045. In this model, the human uses dopamine-dependent prediction errors to guide their decisions, and dopamine modulates the apparent value of rewards as represented in the striatum (courtesy M. Pessiglione, Paris, France).

while posterior sensorimotor regions may be critical for the long-term storage of those skilled behaviors, in congruence with previous models. According to this model, early and advanced learning of motor skills depend upon two independent BG circuits, respectively, one involving the anterior associative/premotor loop, and the other implicating the posterior sensorimotor–BG loop.

The striatum has also been implicated in the consolidation of procedural memory – a process that characterizes the spontaneous performance gains that occur in the immediate posttraining period or during sleep. During a sequence-learning task, responses observed in hippocampus and striatum were linearly related to the gain in performance observed overnight (and related to consolidation), but not over the day, suggesting that both structures interact during motor-sequence memory-consolidation to optimize behavior. Learning performances have also been linked to dopamine release in the human BG and pre-SMA.

Movement Inhibition/Selection

One role commonly allocated to the BG in motor control is to coordinate decision-making processes by facilitating adaptive frontal motor commands while suppressing others. In the BG circuitry, the STN is critically located to reduce premature responding and, therefore, may have substantial effects on response selection. This hypothesis is supported by functional imaging studies. A network including the inferior frontal cortex, the STN, and the pre-SMA in the right hemisphere could either brake or completely stop motor responses during a stop-reaction time paradigm. The STN may act by modulating when a response is executed, reducing premature responding, and, therefore,

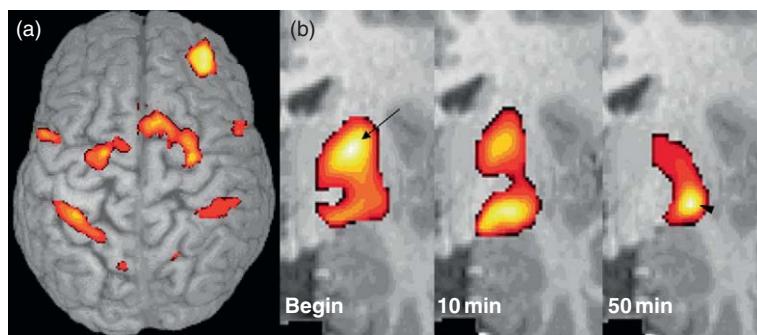

Figure 9 (a) Cortical areas activated during the early learning phase of a complex sequence of finger movement superimposed on a 3D surface render showing activation in bilateral pre-SMA, lateral premotor areas, ventral prefrontal cortex, associative parietal areas (BA 40), and the right dorsolateral prefrontal cortex. (b) Activation maps obtained in the putamen during the same task in the first run, and after 10 and 50 min of training superimposed on a coronal T_1 -weighted image. There was a progressive activation decrease in the dorsal part of the putamen (arrows) and an increase in a more ventrolateral areas (arrowheads) bilaterally. Adapted from Lehericy S, Benali H, Van de Moortele PF, et al. (2005) Distinct basal ganglia territories are engaged in early and advanced motor sequence learning. *Proceedings of the National Academy of Sciences of the United States of America* 102: 12566–12571.

may contribute to select the appropriate response, particularly when there are multiple competing responses.

Conclusion, Role of the Basal Ganglia

In summary, the BG are organized in distinct functional territories processing different types of information. Therefore, the BG have not only motor but also behavioral functions. These different functions are represented within distinct cortico-BG circuits, that is, the sensorimotor putamen in movement execution, the rostral striatum in higher-order aspects of motor control, and the ventral striatum in reward-based learning. Evidence also supports the notion that there exist some degree of overlap among corticostriatal circuits.

Within circuits, information is processed in three distinct pathways: direct, indirect, and hyperdirect pathways. A center-surround organization of information processing allows a temporally organized tuning of information by combining a large, divergent excitation and a centered focalized inhibition of BG output nuclei. This Go/No-Go organization of the BG would help coordinate decision-making processes by facilitating adaptive frontal motor commands while suppressing others. The Go pathway is activated by dopamine and helps facilitative responding, while the No-Go pathway is inhibited by dopamine and suppresses responding.

Therefore, a complex integration takes place in each of the BG nuclei that results in the elaboration of an output message that will be used for movement selection and planning, and for reward-based learning.

Glossary

Deep brain stimulation – Using electrodes

stereotactically implanted, current is delivered to precise targets the electrical activity of which is disturbed by a given pathology (Parkinson' disease, dystonia, dyskinesia, psychiatric disorders such as OCD or depression, epilepsy, pain, etc.) The purpose of the stimulation is to counteract these so-called bioelectrical abnormalities and thereby restore a situation near to normal in the underlying networks.

Error detection – A comparison process between the predicted and actual state of the planning process. It can be related either to the movement parameters or to the outcome of an action itself.

Goal-directed behavior – According to Brown and Pluck, a goal-directed behavior is construed as a set of related processes by which an internal state is translated, through action, into the attainment of a goal. The 'goal' object can be immediate and physical, such as relieving thirst, or long-term and abstract, such as being successful in one's job or the pursuit of happiness. By 'directed,' it is meant that the action is mediated by knowledge of the contingency between the action and the outcome.

Perseverative behavior – Inappropriate maintenance or repetition of a previous response.

Planning – Neuronal processes involved prior to the initiation of action and directly related to the achievement of a goal (see goal-directed behavior).

Representation – Global activity implemented within brain networks that encode features of the internal or external world. The question of the neuronal basis of representation is a key issue in neuroscience.

Temporal relation or timing – Temporal relation or timing, a method initiated by E.V. Evarts and his school to study the relationship between the neuronal activity of a central motor area and the structure of a precise movement recorded via mechanographic or electromyographic techniques. It was researched how a neuronal pattern of discharge is time-locked to the different cinematic and kinetic parameters of a motor act. The timing method has supported the concept of a hierarchical organization of the motor system with the naive quest of a putative conductor.

Introduction

Historical Considerations

One of the most important questions in science remains the origin of voluntary movement. While the sensorimotor organization of the spinal cord in movement generation was established in the beginning of the nineteenth century by the pioneering neurophysiologists François Magendie (1783–1855) and Charles Bell (1774–1842), the question of central (cortical) movement generation really arose in the last third of the nineteenth century. Paul Broca (1824–80), in France, and Hughlings Jackson (1835–1911), in England, proposed a cortical substrate for motor functions. First, Broca's description of a left frontal lobe lesion in a patient suffering from aphasia (or rather anarthria) showed that this region is essential for articulate speech. Second, Jackson noticed that there was a systematic spread of convulsions from one body part to the next during epileptic seizures, and proposed a 'somatotopically' organized cerebral motor mechanism. The experimental proof of such remarkable intuition arose experimentally from electrical stimulation of the cortex. By using a galvanic current, Fritsch and Hitzig succeeded in eliciting contralateral movements in the dog – providing evidence both for excitability of the cerebral cortex and its role in motor function (see **Figure 1**). Only 5 years later, Ferrier used faradic current to provide a very detailed motor map of the monkey brain spreading over the parietal and temporal lobe. However, the motor cortex in the precentral gyrus was located very precisely by Sherrington using low-intensity stimulation of the cortex in great apes. Finally, a complete functional map of the human primary motor cortex (precentral motor area) was provided by Penfield with his famous representation of body movement as a homunculus obtained by stimulation of the precentral area of conscious patients undergoing surgical procedures.

Paradigm Shift

Until the mid-twentieth century, most central nervous system (CNS) studies were based on stimulation, ablation, or cytoarchitectonia (the precentral gyrus is defined in Brodmann's nomenclature – area 4 – by the large pyramidal cells described by Betz) studies of region of interest. This led to the powerful, but somehow reductionist and

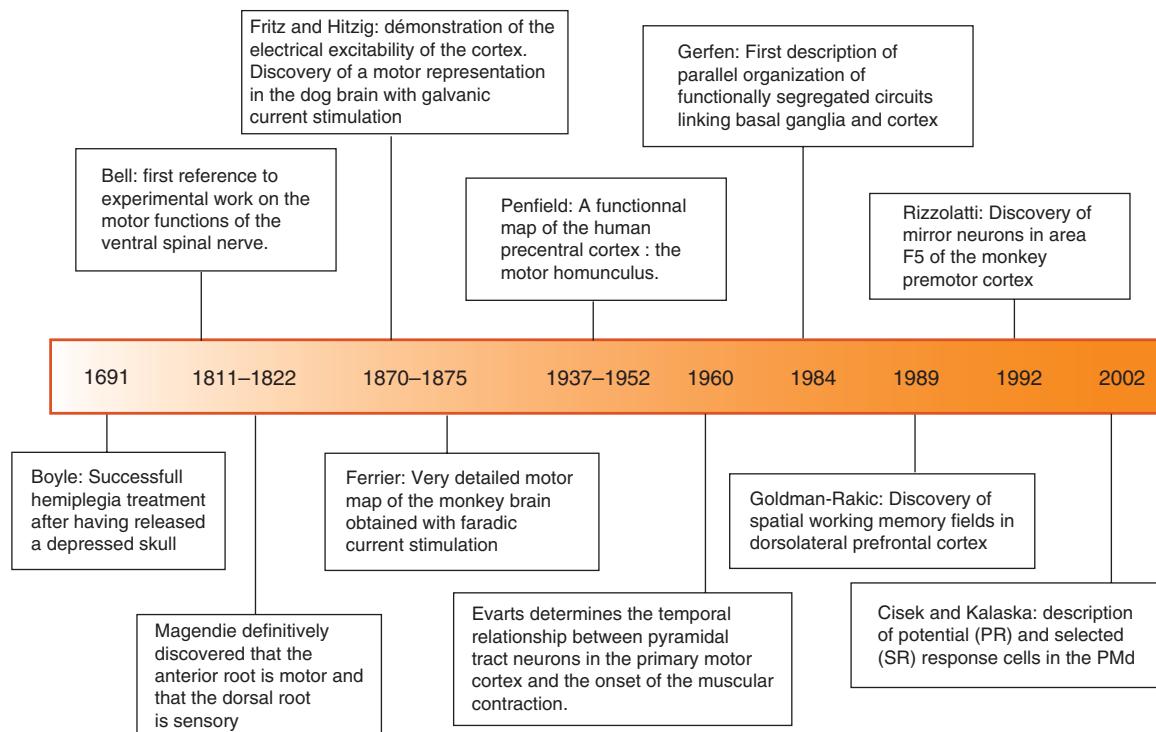

Figure 1 Timeline of selected key events contributing to an understanding of the frontal lobe function in motor/behavioral planning.

static, concept of localization. While in Jackson's view, the motor system is organized in a hierarchical manner, these tools did not allow the timing of brain activity in relation to movement to be studied.

As often occurs in science, a quantum leap came from a new technique – the development of extracellular recording of the spike activity of single neurons in behaving monkeys. This opened up the new field of 'behavioral neurophysiology.'

Thanks to the extracellular recording of neurons during movement performance, neurophysiologists have direct access to the output function of the cerebral cortex, thereby going beyond indirect methods like lesion and stimulation. Moreover, they provide access to the 'temporal relation' between neuronal discharge and movement. In order to determine when cortical motor neurons discharge in association with a voluntary movement, Evarts trained a monkey to depress a modified telegraph key (making a contact) until a light came on, and to release the key following light-onset (resulting in alternate flexion and extension movements). The simultaneous recording of neuronal and electromyographic (EMG) activity made it possible, for the first time, to determine the temporal relationship between them. Evarts found that corticospinal neurons discharge approximately 60–80 ms before movement onset. One of Evarts' pupils, W. Thach, found that the Purkinje cells of the cerebellum change their firing pattern well in advance of primary motor-cortex neurons. This provided the first proof that neuronal activity is involved

in internal generation of goal-directed movements or self-paced behavior. These studies greatly helped to demonstrate that motor-cortex neurons encode a variety of cinematic and kinetic parameters such as force, direction, and velocity. A question then arose as to the respective roles of central versus peripheral signals in the edification of cortical discharge patterns of the primary motor cortex (M1, area 4) and sensory cortex (S1, areas 3, 1, and 2) before and during movement. In monkeys, deafferentation by dorsal rhizotomy (C2–T7) of the trained limb produced major changes in activity of these two areas. S1 cells became silent while M1 neurons exhibited a drastic disorganization. Such clear-cut modifications demonstrated the powerful influence exerted by the peripheral feedback loop. Indeed, the latter affords the peripheral inputs linked to the actual motor act and allows their simultaneous computations with the wholly central activations originating from the cerebellum, basal ganglia, and prefrontal areas. Therefore, disruption of the peripheral afferents induces a severe disturbance in M1 and S1 during the final buildup, which normally encodes for harmonious motor messages. While some of these data led largely to the notion of the hierarchical organization of the motor system, others tended to show that the motor system is organized in a rather parallel manner.

Anatomical Substrates

Besides the primary motor cortex, additional motor regions were also defined on the basis of their response

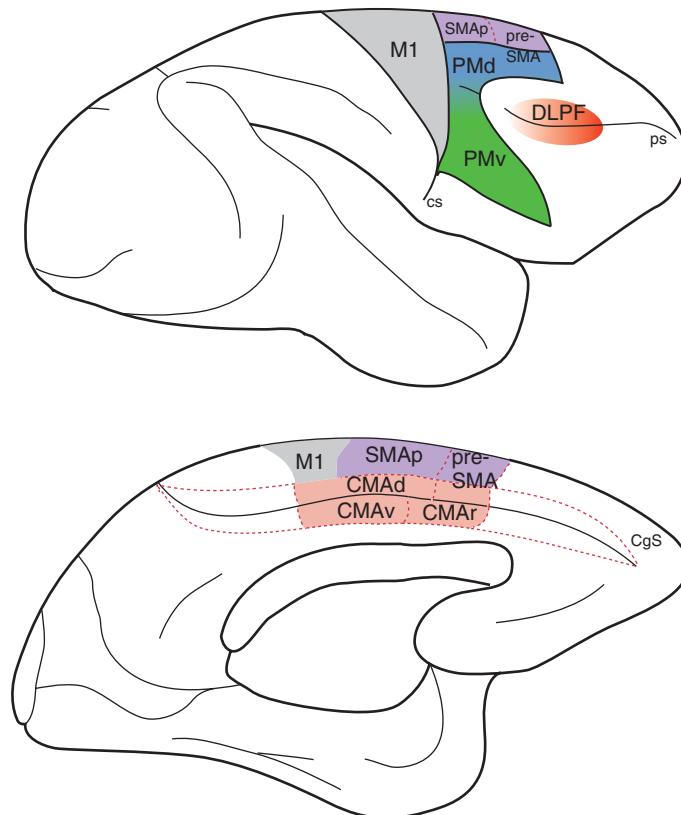

Figure 2 Motor areas in the frontal lobe of the macaque. Top: Lateral view of the left hemisphere. Bottom: Mediolateral view of the left hemisphere to show the location of the mesial motor areas. Abbreviations: CgS = cingulate sulcus; ps = principal sulcus; cs = central sulcus; M1 = primary motor cortex; PMd = dorsal pre-motor cortex ; PMv = ventral pre-motor cortex; SMAp = supplementary motor area proper; pre-SMA = pre-supplementary motor area; DLPF = dorsolateral prefrontal cortex; CMAd = dorsal cingulate motor area; CMAv = ventral cingulate motor area; CMAr = rostral cingulate motor area.

to microstimulation or their anatomical relation to the spinal cord. These premotor regions are classically subdivided into at least six independent subregions, namely: the ventral (PMv) and dorsal (PMd) premotor area, the supplementary motor area (SMA), and the rostral (CMAr), ventral (CMAv), and caudal (CMAc) portion of the anterior cingulate motor area (**Figure 2**). The output of these premotor areas has been shown to send direct connections to the spinal motoneurons. This suggests that the premotor areas are, in some respects, situated at the same level of hierarchical organization as the M1. This is well summarized by R. Dum and P. Strick who stated that “[...] each premotor area, along with the M1, may represent a separate source of ‘central command signals’ for the generation and control of movement.” Functionally, these premotor areas which are reciprocally interconnected with the dorsolateral prefrontal cortex (area 46) encode (in addition to simple activity in relation to movement execution) activity relative to a more abstract level such as reward-related activity, associative learning, mental imagery, or processing of perceived or memorized information.

In the following section, we describe some relatively recent developments in primate neurophysiology involving these areas that have greatly changed our approach to behavioral planning. We review the evidence and discuss new findings that throw light on how the cognitive processes preceding (self- or externally triggered) action are based on a mechanism transforming internal and external ‘representations’ into an action. We also demonstrate the complexity of such interactive processes through the prism of neurological and mental diseases.

Multiple Representational Systems in the Monkey Frontal Lobe

Representation of Potential Actions

A number of recent neurophysiological studies have shown that when decisions are made between overt actions, this process appears to involve many of the same brain regions subserving the planning and execution of movement. This challenges the classical cognitive view that splits brain function into three distinct serial stages:

(1) perceptual mechanisms are held to generate an internal representation of the world followed by (2) a cognitive process that evaluates this neuronal ‘world image’ in order to select (3) a plan of action. This decision is then finally relayed to motor systems for execution. In this perspective, the motor systems are viewed as devices that only implement the plans made by higher-level cognitive processes. This model assumes that decisions about action occur in an abstract decision-space independent of the details of the motor output itself, before engaging the motor system in planning and executing the chosen action. However, in 2005, Paul Cisek and John Kalaska, in Montreal, showed that when multiple reaching targets are presented, they involve the simultaneous activation of separate populations of neurons in PMd that encode parameters of the different reaching options before a final choice is made. They designed a task in which monkeys had to first memorize the locations of two color-coded potential movement targets (spatial cues (SCs)) and then use a subsequent nonspatial color cue (CC) to choose the correct movement target. They found PMd (mostly in the rostral part) neuronal activity representing the two potential motor outputs during the initial ambiguous spatial-cue delay period, and then a rapid change in activity after the presentation of the color cue that represented the selection of one action and the rejection of the other. This study was the first to show clear evidence for separate coexisting representations of competing reaching movement options during the period of evaluation of different choices prior to a final decision in populations of neurons that also encode the parameters (e.g., direction) of motor outputs. These theories unify the processes of movement selection and parametrization – contrary to the serial order of choosing an action and then encoding its parameters in standard ‘cognitive’ models.

Shared Representation

Another example of the intrinsic relationship between action and perception was provided with the discovery by Giacomo Rizzolatti and colleagues of mirror neurons in area F5 (within the PMv) and later in the rostral part of the inferior parietal lobule. These neurons became active before a monkey performed a movement directed to a reward, but they also responded when a monkey happened to see a researcher get the reward, even if the monkey did not move. In other words, these neurons provide a representation of a certain type of action irrespective of the agent performing it. Based on neuroimaging studies in the human, the hypothesis has arisen that such neurons play a role in learning by imitation and that, depending on the context, the mirror neurons can predict the next action in a series of actions. Ultimately these results suggest the role of mirror neurons in empathy, based on the idea that one strategy for

empathizing with others is by simulating aspects of their presumed emotional state within ourselves. It is likely that the impairment of the ability to interpret the actions and emotions of others in patients suffering from autism is linked to a dysfunctioning of these mirror neurons, which are much more widely distributed in the brain than suggested by the original F5 localization.

Rules Representation

In order to plan an action, subjects must maintain a clear internal representation of the instructions (rules) required to reach a goal or of the goal itself. Following studies providing evidence that prefrontal lesions in monkeys induced specific deficits in the delayed-response test, the concept of working memory was developed and extended to lesion studies in the human. In 1989, Patricia Goldman-Rakic definitively proved the neuronal basis of this working memory function in the dorsolateral prefrontal area (area 46). In her pioneering experiment, she recorded neurons in the dorsolateral prefrontal cortex of the monkey while the monkey performed an oculomotor delayed-response task. In the absence of available sensory information, she found that prefrontal neurons displayed elevated spike discharges throughout the delay period. Moreover, she found a clear directional tuning of this delay period activity, which led to the concept of ‘memory field.’ As stated in the 1989 seminal article: “Memory fields may be the cellular expression of a working memory process that allows mnemonic information to guide behavior.” The similarities existing between patients with prefrontal lobe lesions and those with attention-deficit/hyperactivity disorder (ADHD) exhibiting working memory impairment led to the suspicion of prefrontal impairment in such patients. Symptoms of inattention, distractibility, and restlessness fit particularly well with this hypothesis.

Outcome Representation

The planning process in goal-directed behavior relies on the ability to monitor the congruence between the actual outcome and the initial goal. In a recent study, Michelet *et al.*, using a Stroop-like visuomotor task in monkeys, studied the unitary neuronal activity of the anterior cingulate cortex (ACC; CMar: 24c) during performance evaluation. They found a high percentage of cingulate neurons modifying their firing frequency both during the attention and evaluation periods. During the latter period, however, changes in discharge rates were always much more pronounced for erroneous responses than for successful movements that induced reward delivery (**Figure 3**). Interestingly, firing activity during the evaluation period increased more in erroneously completed trials than in incomplete ones and when the reward was

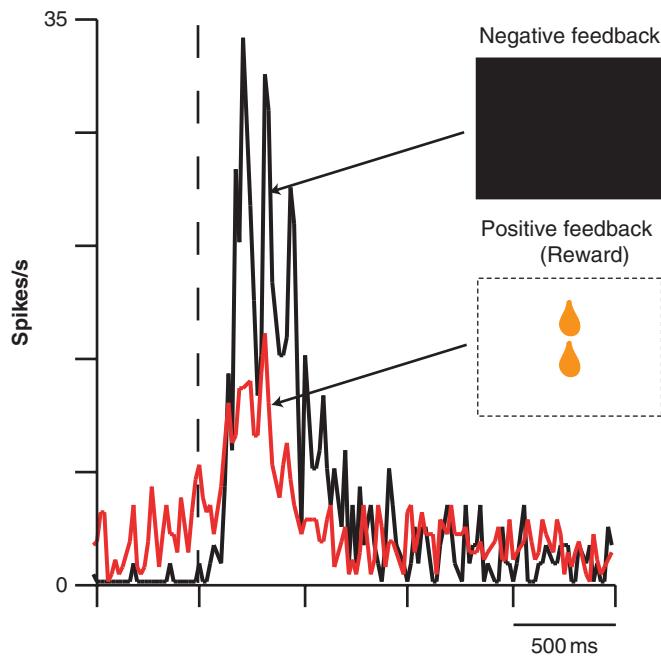

Figure 3 Histogram comparing firing activity of an individual CMAr neuron during the evaluation period following the negative and positive feedbacks. This neuron responded to both outcomes. However, firing rate increased more after negative (in black: error) than after positive (in red: success) feedback. This result confirms that CMAr plays an important role in performance evaluation and more particularly in error detection. Figure from Michelet T, Bioulac B, Guehl D, Escola L, and Burbaud P (2007) Impact of commitment on performance evaluation in the rostral cingulate motor area. *Journal of Neuroscience* 27(28): 7482–7489 (with permission from the *Journal of Neuroscience*).

delivered in an active rather than passive context, indicating that performance evaluation was conditioned by the degree of the animal's commitment to the task. It would thus seem that CMAr neurons could constitute a system for the evaluation of behavioral performance contingent on the subject's commitment to the task. Moreover, some neurons responded more markedly to the warning stimulus when a previous trial failed. In this case, the probability of a subsequent correct response increased. Such a neuronal apparatus could represent an error-compensation system that serves to adapt a subject's behavioral response following an unfavorable and unexpected outcome. Thus, ACC neurons encode a central representation of the congruence between expected and actual performance outcome (comparison process). The abnormal activity of these neuronal apparatus, which appear to take advantage of past errors, could contribute to the genesis of obsessive-compulsive disorders (OCD). Indeed, the heart of the obsessional process is the subject's underlying impression that 'something is wrong.' In other words, obsessions may be thought of as the permanent perception of a mistake and/or error in certain behavioral situations. Compulsions occur as behavioral responses that aim to relieve the tensions or anxiety generated by the situation. If obtained, this relief may be felt to be a form of reward. Nevertheless, it is only transient, thereby creating a feeling of considerable anxiety. This leads to

the immediate reproduction of the behavior in a cyclic manner on the basis of an internal motivational state through the expectation of a reward. Although it is undoubtedly simplistic, this phenomenological view is of interest because it suggests that the mechanism of error recognition malfunctioning is testable and that it could be used to study the physiopathology of the OCD.

Body Scheme Representation

Parkinsonian akinesia is a symptom in which patients suffering from a loss of dopaminergic neurons are unable to initiate any movement, while the corticospinal motor apparatus remains intact. It has been suggested that the underactivity of mesial frontal structures induced by dopamine depletion could constitute the functional substrate underlying akinesia in the Parkinsonian state. In order to test this hypothesis, Escola *et al.* trained rhesus monkeys to perform a delayed Go/No-Go motor task and recorded neuronal activity in the presupplementary motor area (pre-SMA) and the supplementary motor area (SMAp). Recordings were collected at different phases of treatment with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a neurotoxin that causes the progressive loss of dopaminergic neurons in the mesencephalic region of the brain. Neuronal activity was diminished and disorganized both during the instruction and the behavioral stages of the

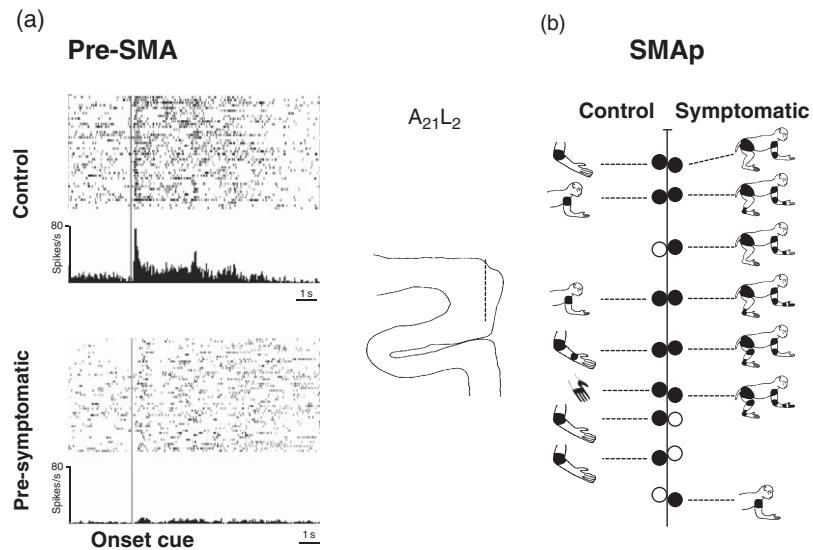

Figure 4 Input/output properties of the SMA before and after MPTP treatment: (a) Example of a Pre-SMA neuron which modifies its activity in response to the onset cue. Neuronal activity is represented in the form of a raster display (top, each point is an action potential, each line a different trial) and a histogram of firing frequency over time (bottom, bin-width 50 ms). (b) Somatosensory receptive fields of the arm regions of the SMAp in control versus symptomatic situation. Left: frontal section. The dotted line corresponds to the track (A₂₁-L₂) followed by a microelectrode successively lowered in control and symptomatic situation. Right: Somatosensory receptive fields observed for the neurons recorded (filled circle: responsive neuron; empty circle: unresponsive neuron) along the microelectrode track (vertical line). One must observe that in the control situation, responsive neurons possess few and focal receptive fields. Alternatively, in symptomatic situations responsive neurons exhibit numerous and diffusely scattered receptive fields. Reproduced with permission from Escola L, Michelet T, Douillard G, Guehl D, Bioulac B, and Burbaud P (2002) Disruption of the proprioceptive mapping in the medial wall of Parkinsonian monkeys. *Annals of Neurology* 52(5): 581–587; Escola L, Michelet T, Macia F, Guehl D, Bioulac B, and Burbaud P (2003) Disruption of information processing in the supplementary motor area of the MPTP-treated monkey: A clue to the pathophysiology of akinesia? *Brain* 126(Pt. 1): 95–114.

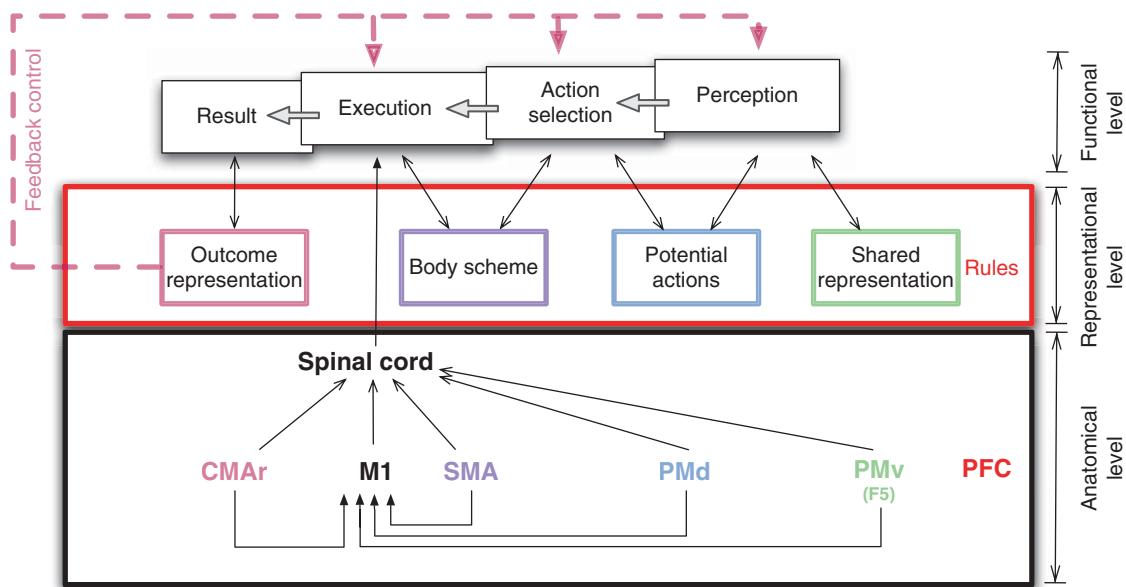

Figure 5 Hypothetical scheme of the planning process. This diagram illustrates the three levels of organization. Overlapping boxes at the functional level indicate that planning process is not a purely serial mechanism, while reciprocal arrows linking functional and representational levels illustrate the complex organization of behavioral planning. Colors and legends of anatomical levels as in Figure 2.

delayed motor task. All the different stages of the motor planning process are therefore likely to be affected: analysis of instructions, preparation, and initiation of movement. In both the pre-SMA and the SMAp, the progressive decrease in neuronal response paralleled the dopamine depletion (**Figure 4**). Firing frequency decreased sharply in both structures in the animal after the Go and No-Go signals at the moment when the monkey had to take the decision to initiate movement. These modifications in neuronal activity observed in Parkinsonian monkeys could reflect the inability of cortical neurons to trigger motor programs correctly in response to significant events. Furthermore, there is also a major impairment of the focused selection of proprioceptive inputs on the SMAp – a structure known to be involved in body schema representation (**Figure 4**). These two results are intimately linked because external information perception is constrained by motor schemas, that is, by the implicit knowledge within the CNS concerning the range of possible movements to be executed. The authors propose that the conjunction of these phenomena could impede motor planning and thus contribute to akinesia.

Conclusion

This article discusses the frontal areas which are interconnected by a complex network of projections that provide a series of internal representations involved in behavioral planning. These areas are organized both in a parallel and hierarchical way (see **Figure 5**). At the lowest level, the primary motor cortex can be viewed as the ‘cortical final common pathway’ in charge of the synthesis of all the information processes in the premotor areas. However, they send projections not only to M1 but also to the spinal cord. The exact role of these corticospinal pathways, which are as numerous as those in the classical pyramidal tract, remains to be elucidated.

Although discussion of the role of the basal ganglia is beyond the scope of this article, all the above-mentioned cortical structures are part of the so-called corticobasal ganglia loops (cortico–striato–pallido–thalamo–cortical loops). In this regard, they are intermixed in highly complex overlapping patterns, thereby contradicting the simple hierarchical view of the serial organization of motor systems. The divergence of cortical input to the striatum and reconvergence in the corticobasal ganglia pathway allows fusion between cognitive, motivational, and motor representations (binding). The intricateness of the (at least) three – sensorimotor, limbic, and cognitive – loops could explain the extensive overlap of cell-discharge patterns in these frontal areas, and the fact that it is almost impossible to attribute a single function to a unique area.

This could also explain not only the wide spectrum of pathologies related to the dysfunction of distinct parts of the circuits (from akinesia to OCD) but also their comorbidity. An absence of voluntary movement can be found in parkinsonian akinesia, akinetic mutism after bilateral anterior cingulate lesion, severe depression abulia (or ‘psychic akinesia’), and in catatonic schizophrenia. In contrast, both OCD- and PFDL-lesioned patients exhibit perseverative behaviors. It, therefore, remains difficult to make a clear distinction between neurological and psychiatric diseases. Most of these pathologies are thought to be related to an impairment of the midbrain dopaminergic system. The connection between both frontal (mesocortical) and striatal (nigrostriatal) areas strongly supports this hypothesis. Interestingly, these different neurological and psychiatric disorders related to dysfunctions of the corticobasal ganglia circuits may be alleviated by a recent and nonpharmacological therapy: deep brain stimulation (DBS). Even though the precise mechanisms of DBS (high-frequency stimulation (HFS)) remain unclear, it appears capable not only of thwarting local abnormal activities but also, and chiefly, restoring a dynamic near to normal in a given circuit. Thus, in Parkinson’s disease (PD), the HFS of the subthalamic nucleus (NST), a node of the sensorimotor loop, suppresses or strongly diminishes akinesia and rigidity. Furthermore, in OCD, HFS of the ventral striatum which is inserted in the limbic loop produces a clear-cut decrease in obsessive and compulsive symptoms.

Because frontal lobe function is mostly dedicated to allowing the planning of movement and deciding – or not – to move, it is not surprising that frontal lobe damage exhibits positive and negative symptoms of such function. Better understanding on this function will not only provide new avenues for treatments of brain diseases but will also provide insights into one of the most important questions in science since time immemorial: the concept of free will. This is particularly important in the twenty-first century during which new discoveries could even lead to the definition of new concepts in policy or economics as well as revision of laws, since man will have new insights into the moral intuitions concerning responsibility.

Glossary

Classical conditioning – The simplest form of associative learning of two stimuli in which an initially neutral stimulus (conditional stimulus, CS) is paired in close temporal proximity with an innately significant stimulus (unconditional stimulus, US) that reflexively elicits unlearned behavior (unconditional response, UR). Through CS-US association formation, the animal acquires a learned behavior (conditional response, CR) to the CS that generally resembles the UR (but not always), precedes (or anticipates) the US in time, and reaches a maximum around the time of US onset.

Contiguity – The notion that the temporal relationship between the CS and the US is critical in classical conditioning.

Contingency – The notion that the informational (or predictive) relationship between the CS and the US is critical in classical conditioning.

Eyeblink conditioning – A type of motor classical conditioning task in which animals produce a discrete eyelid closure to an initially neutral CS (tone, light, or vibrations) by virtue of its association with a US (such as an airpuff to the eye). The cerebellum and its associated brainstem structures are necessary for the acquisition, maintenance, and performance of a conditional eyeblink response.

Fear conditioning – A type of emotional classical conditioning task in which animals become afraid of a previously innocuous CS (tone, light, or a distinctive environmental setting) by virtue of its association with an aversive US (such as an electric shock). The amygdala has been implicated in the formation of conditional fear memories.

Prediction errors – The difference between the actual US (or reinforcement) and predicted US. Large prediction error values indicate an unexpected (surprising) US occurrence, whereas small prediction error values signify an expected (unsurprising) US occurrence.

and memory. This simplest form of associative learning was characterized independently by Russian physiologist, Ivan P. Pavlov, and American psychologist, Edwin B. Twitmyer, in the early twentieth century. In general, classical conditioning takes place when an initially innocuous cue, the conditional stimulus (CS), is repeatedly followed in close temporal proximity by a biologically significant cue, the unconditional stimulus (US), which evokes a reflexive behavior known as an unconditional response (UR). From the formation of a CS-US association, the organism acquires a conditional response (CR) to the CS that generally (1) bears a behavioral resemblance to the UR (but not in all instances as some CRs are different or opposite from their URs), (2) occurs just prior to the US, and (3) reaches a maximum magnitude around the time of US onset. These characteristics of the CRs are thought to serve as adaptive functions in the organism's future encounters with the same US.

For nearly 70 years, the critical factor in classical conditioning was understood to be the temporal association between the CS and the US – the notion of contiguity. In other words, classical conditioning was thought to take place when a CS was simply followed by (or paired with) a US. However, three coincidentally independent studies by Leon J. Kamin, Robert A. Rescorla, and Allan R. Wagner in the late 1960s revealed that the informational relationship (the notion of contingency), and not contiguity, between the CS and US is the critical element in classical conditioning. This shift ushered in modern thinking of classical conditioning. This article focuses on Kamin's *Blocking*, though readers can refer to Rescorla's and Wagner's influential works on *Contingency* and *Relative Validity*, respectively.

What Is Blocking?

The phenomenon of blocking indicates that if a US is already accurately predicted by one CS and if the addition of a new CS offers no new information about the US, then conditioning will not develop to the new CS despite its contiguous pairing with a US. In a typical blocking experiment, the subject is first presented with a CS (denoted *A*) paired with a US (*A+*) repeatedly (see **Figure 1**; experimental group). In the second phase, a different CS (*B*) undergoes compound conditioning with *A* and the same US (*AB+*). Later, when *B* is tested, virtually no (or very little) conditioning has accrued to

Introduction

Classical or Pavlovian conditioning, in which an organism learns a predictive relationship between two (or more) stimuli, is considered the basic building block of learning

Kamin's blocking design

Procedure	Groups			
	Experimental	Control 1	Control 2	Control 3
Phase I	A+		C+	A+
Phase II	AB+	AB+	AB+	AB++
Test	B→no CR	B→CR	B→CR	B→CR

Figure 1 Experimental design of a blocking experiment. A blocking procedure typically consists of serial phase I and phase II training sessions followed by a test session. The animals in the experimental group undergo extensive A+ conditioning in phase I, until a stimulus A (CS) reliably predicts the US. Control 1 group animals undergo no conditioning experience in phase I; control 2 group animals undergo the same amount of C+ conditioning as the experimental animals receive to A+. In phase II, experimental, control 1 and control 2 animals all undergo AB+ compound conditioning (where B is a new added stimulus for experimental animals; both A and B are new stimuli for both control 1 and 2 animals). During compound conditioning, the magnitude of the US remains unchanged from phase I for experimental and control 2 animals. Later, when conditioning to B is assessed, the experimental animals typically exhibit no or very little CRs (demonstrating that A has blocked conditioning to B), whereas CRs are observed in the control 1 and 2 animals. Control 3 demonstrates that if the intensity of the US increases from phases I (+) to II (++) , blocking does not readily occur because B now provides new information about US (i.e., increased intensity) during compound conditioning.

B. However, if A had no history of conditioning with the US (control 1), or if a different CS was conditioned with the US (C+; control 2) in the first phase, then B (as well as A) will accrue substantial associative strength during the AB+ compound conditioning phase and will produce a CR when later tested. Thus, the associative strength accrued to B during the compound (AB+) conditioning is inversely proportional to the magnitude of associative strength amassed by A previously, and it is not simply B's contiguous relationship with the US that determines whether or not conditioning will develop to B.

In contrast, if the magnitude of the US is increased during phase II compound conditioning (control 3; AB++), then blocking will not occur; in this case, stimulus B provides new information about the US (i.e., increased intensity), that is not predicted by A alone. Kamin suggested that for conditioning to occur, some quality of the US must be unexpected (or surprising). Since its discovery 40 years ago, blocking has profoundly shaped all modern learning theories and has been considered a quintessential element of cognitive processing in classical conditioning.

Theoretical Models of Blocking

In Rescorla's and Wagner's classic formal learning theory, the necessity of contingency in classical conditioning is an emergent property of US processing represented as $\Delta V_n = \kappa(\lambda - \Sigma V_i)$, where κ is a learning rate parameter (a constant), λ is the asymptote of conditioning with a given US (a constant), ΣV_i is the sum of associative strengths of all CS elements present, and ΔV_n is the change in the associative strength to a CS on trial n (a variable).

This simple equation (with only one variable!) accurately models and predicts a number of key phenomena in

classical conditioning, including blocking. In essence, the Rescorla–Wagner equation posits that the associative strength between the CS and US (i.e., V_i) is driven by errors between the expected US (V_i) and the actual US (λ). Thus, large ($\lambda - V_i$) values indicate that the US is relatively unexpected and surprising, whereas small ($\lambda - V_i$) values denote that the US is relatively well predicted by the CS. When a CS fully predicts the occurrence of a US, then $\lambda - V_i = 0$. Accordingly, blocking will transpire when the associative strength initially acquired by a CS (A) that was paired with a US (A+) reaches the asymptotic λ value. Subsequently, in phase II, because stimulus A already fully predicts the US, by virtue of acquiring all of its associative strength ($V_A = \lambda$), when a new CS (B) is introduced during the compound conditioning (AB+), stimulus B will not accrue any associative strength, as $\Delta V_B = \kappa(\lambda - (V_A + V_B)) = 0$, where $V_A = \lambda$.

Figure 2 illustrates the simulations of blocking using constants $\lambda = 1$ and $\kappa = 0.2$ as examples in the Rescorla–Wagner equation. In this case, phase I conditioning to V_A starts from 0 (before conditioning) and accumulates values of 0.2 (after first CS-US pairing), 0.36 (after second pairing), 0.488 (after third pairing), 0.5904 (after fourth pairing), 0.67323 (after fifth pairing), and so on, until V_A approximates the λ value of 1 (**Figure 2(a)**). In phase II compound conditioning, a complete blocking to stimulus B will occur when V_A is already at a λ value (**Figure 2(b)**). However, if V_A acquired 0.5λ value during phase I, then during compound conditioning, stimulus B will gain some associative strength because stimulus A cannot fully predict the US (**Figure 2(c)**). On the other hand, if stimulus A had no prior conditioning with the US (control 1, **Figure 1**), then during compound conditioning, both stimuli A and B (assuming they are equally salient) will acquire equal associative strength (**Figure 2(d)**). One can also see why complete blocking will not occur when

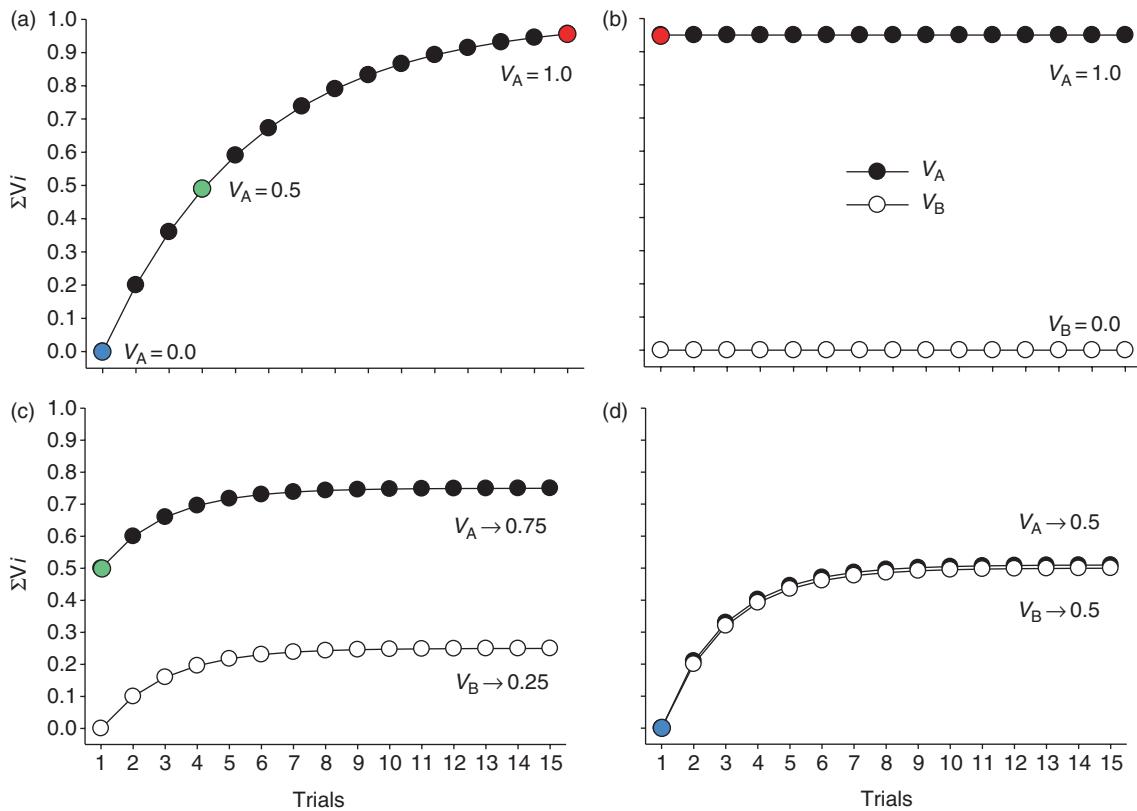

Figure 2 Simulation of the Rescorla–Wagner model of blocking as a function of stimulus A’s associative strength. (a) Stimulus A paired with a US acquires associative strength as a function of the number of CS–US pairings until V_A reaches the λ value of 1. (b) When V_A equals 1 at the start of AB+ compound conditioning, stimulus B will gain no associative strength. (c) When V_A equals 0.5 at the start of AB+ compound conditioning, stimulus B will gain some associative strength. (d) When V_A equals 0 during AB+ compound conditioning, stimuli B and A (of equal salience) will evenly share associative strength. (See the text for explanation.)

during phase II compound conditioning the magnitude of US was increased from λ to 2λ (control 3; AB++).

In addition to the Rescorla–Wagner’s US processing theory, there are other learning theories based on CS processing that can also account for blocking. For example, the CS processing theories of Nicholas J. Mackintosh and subsequently John M. Pearce and Geoffrey Hall postulate that the absence of surprising events (i.e., in the presence of a well-predicted US) reduces the associability of CSs to form new associations. By this view, blocking occurs during phase II because no surprising events occur after the compound AB+ presentation (in phase II; Figure 1), and consequently stimulus B rapidly loses associability, rather than any loss of US effectiveness. In certain situations, however, the US and CS processing theories make different predictions regarding blocking. For example, although the Rescorla–Wagner model predicts one-trial blocking, CS-processing-based theories do not. Conversely, CS processing models suggest unblocking (or disruption of blocking) when the magnitude of the US is decreased from phases I (A++) to II (AB+), although the Rescorla–Wagner model predicts blocking (i.e., B becomes a conditioned inhibitor).

With major progress in identifying neural circuits underlying particular types of learning, learning theorists have gained insight into the biological mechanisms of blocking. Below, we briefly present the involvement of the cerebellum, amygdala, and midbrain dopamine neurons in mediating blocking in different learning paradigms. For a neural circuit espousing a CS-processing account of blocking, readers are referred to the Baxter, Holland, and Gallagher study on the septohippocampal system’s role in an appetitive conditioning paradigm.

Eyeblink Conditioning and Blocking

The rabbit eyeblink conditioning paradigm, which was initially developed in humans, became a widely employed behavioral paradigm to investigate the general principles of learning theories and the neurobiological substrates of learning and memory. In typical eyeblink conditioning, a discrete CS (usually a tone or a light) is contingently paired with a discrete US (usually an airpuff to the eye or a mild electric stimulation to the paraorbital region) with particular temporal relationships between the CS and US.

Initially, the subject exhibits eyeblink URs only to the airpuff US. Over the course of repeated CS-US presentations, the animal develops eyeblink CRs to the CS that precedes the US in onset time, and peaks at about the time of US onset. Based on converging lines of evidence from lesion, recording, stimulation, pharmacological, genetic and brain-imaging studies, Richard F. Thompson and his colleagues identified the cerebellum and its associated structures as essential in eyeblink conditioning.

Notably, the US-processing view of the Rescorla-Wagner model is an emergent property of the anatomically based eyeblink conditioning circuit. The neural connections with particular relevance to blocking are: (1) the excitatory mossy fibers from the pontine nuclei to the cerebellum (CS information); (2) the excitatory climbing fibers from the inferior olive to the cerebellum (US information); and (3) the monosynaptic gamma-aminobutyric acid (GABA)-containing projections from the cerebellum to the inferior olive. Because GABA neurotransmitters exert inhibitory influences on their targets, it has been proposed that this cerebello-olivary pathway serves as negative feedback, specifically by gating the US information flow through the inferior olive en route to the cerebellum (the putative site of CS-US association formation). In support of this view, inferior olivary neurons show US-evoked neural activities during the initial stage of CS-US training (prior to the animal exhibiting any CRs), but not when the animal emits CRs during CS-US trials.

If the cerebello-olivary GABAergic projection serves as negative feedback by gating the US information from reaching the cerebellum, then the blocking effect in eyeblink conditioning can be understood as follows. According to **Figure 3**, blocking will occur when a CS (e.g., an

auditory CS_A) acquires sufficient associative strength to activate the cerebellum, which in turn inhibits the inferior olive (via the cerebello-olivary GABAergic pathway) from responding to a US. Because the input conveying the US information can no longer reach the cerebellum, it cannot support conditioning to a new CS (e.g., a visual CS_B) during the phase II compound conditioning. In validation of this view, Thompson and his colleagues demonstrated that preventing the cerebellum-to-inferior-olive inhibitory activity (by directly applying a GABA antagonist drug into the inferior olive) during the phase II compound tone CS and light CS pairing with the airpuff US – thereby releasing the inferior olive neurons from the CS_A-induced inhibitory control from the cerebellum – blocked blocking.

Fear Conditioning and Blocking

In typical fear-conditioning studies, initially neutral CSs (such as tones and lights) are paired with aversive USs (such as electric shock). After only a few CS-US pairings, the CS will rapidly become capable of evoking an ensemble of fear responses, including analgesia (the ability to inhibit/decrease sensitivity to nociceptive stimuli). The amygdala, the locus of fear conditioning, sends projections to the hypothalamus and brainstem nuclei that mediate the expression of various fear CRs. One conditioned fear response, analgesia, appears to play a role in mediating blocking in fear conditioning. The analgesia CR involves the conditioned fear-associated release of endogenous opioids (endorphins), due to amygdala's increased stimulation of the periaqueductal gray. It has been postulated that as fear conditioning progresses, the

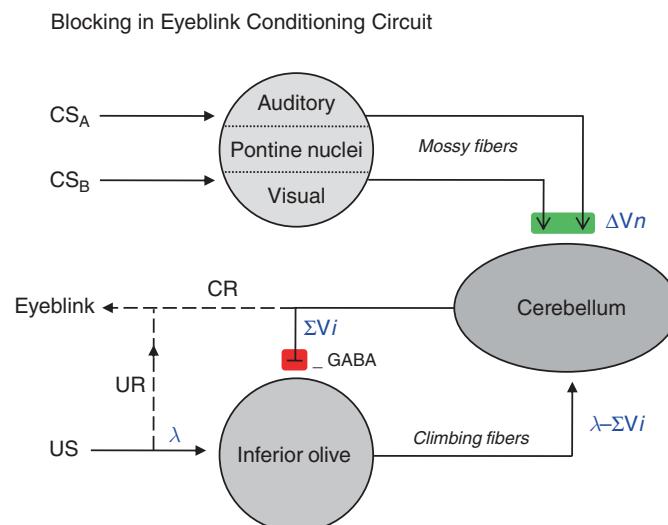

Figure 3 A simplified diagram of the essential neural circuit mediating eyeblink conditioning with the Rescorla-Wagner equation embedded. The conditioned stimulus (CS) and unconditioned stimulus (US) information are conveyed by the pontine nucleus and inferior olive, respectively, to the cerebellum where the CS-US association formation occurs. (See the text for blocking explanation.)

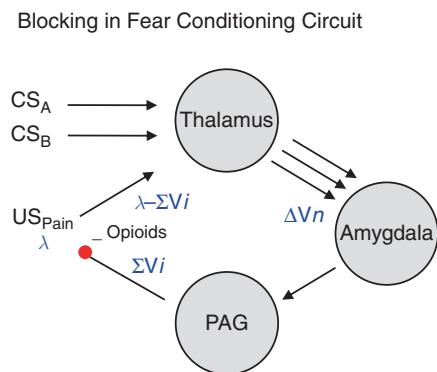

Figure 4 A simplified diagram of the fear conditioning circuit with the Rescorla–Wagner equation inserted. The conditioned stimulus (CS) and unconditioned stimulus (US) information is relayed from the thalamus to the amygdala, where fear conditioning takes place. (See the text for blocking explanation.)

effectiveness of the nociceptive US to support fear conditioning diminishes as the ability of CS to activate the amygdala increases, which in turn stimulates increased opioid release (Figure 4). Consistent with this notion, Michael S. Fanselow and Robert C. Bolles found that systemic injection of the opioid receptor antagonist naloxone during phase II compound conditioning can attenuate blocking. It is likely that naloxone, by opposing the analgesia CR to the first CS_A, prevents the CS-associated decline in the ability of the nociceptive US to support fear conditioning to CS_B during compound conditioning (*AB+*). However, the locus of naloxone's effects on blocking is unknown, and it remains to be established whether the US-evoked neural activities in the amygdala decrease as a function of fear conditioning.

Dopaminergic Midbrain Neurons and Blocking

Other brain structures appear to employ a similar negative feedback mechanism to those of the cerebellum and amygdala to regulate the US teaching input. For example, Schultz and his colleagues found that, in monkeys undergoing a cued delayed reward conditioning (an operant task), dopamine neurons in the substantia nigra (SN) and the ventral tegmental area (VTA) show phasic responses to the delivery of liquid reward US. However, once the animal learns that a light cue predicts the reward, the delivery of the reward no longer elicits phasic responses in dopaminergic neurons, but instead, the CS now elicits a dopaminergic response. Such negative feedback circuits in the midbrain may provide the neural instantiation of blocking.

Indeed, when dopamine neurons were examined in a blocking paradigm, the acquisition of shift in dopamine responses from the reward delivery to a second CS *B* (during *AB+* compound conditioning) did not occur

because the first CS *A* reduced the reward-evoked dopamine signal. The SN/VTA dopamine signals have been hypothesized to convey a prediction-error signal that enables the formation of cue–reward associations in forebrain structures. On a neural level, this system might be seen as analogous to that in the cerebellum (Figure 3), replacing the inferior olive with the SN/VTA and the cerebellum with the basal ganglia and neocortex (which receive dopaminergic innervations from the SN/VTA). These findings are also consistent with reports of disrupted blocking after manipulations of the dopamine system.

Summary

Evolutionarily, blocking (and other similar negative feedback processes) emerged because it serves an adaptive function in how animals process and attend to information in their environments. Because animals continually encounter a variety of stimuli in their environments, it is crucial for animals to respond selectively to those stimuli that reliably predict biologically significant events. Other stimuli that provide no new useful information should be filtered and discarded, otherwise the animal's nervous system will be constantly forming unnecessary associations with various stimuli in its surrounding, which may result in an information overload. This fact was succinctly stated by an American psychologist, William James, who stated: "Selection is the very keel on which our mental ship is built. And in this case of memory its utility is obvious. If we remembered everything, we should on most occasions be as ill off as if we remembered nothing."

Indeed, malfunctioning association mechanisms in the brain may contribute to psychopathological conditions such as schizophrenia. The behavioral phenomenon of blocking, by utilizing a heuristic negative feedback process, serves to circumvent redundant learning and conserve neural real estate.

Glossary

Allometry – The relationship between the size and shape in morphology, often employed to evaluate relative growth rates or size of a specific structure. For example, the relationship between brain size and total body size (either during development or across individuals/species).

Cerebrotype – Comparative brain structure defined by the relative composition of different brain components (i.e., telencephalon, cerebellum, etc.).

Neocortex (also called isocortex and neopallium) – This consists of the outer layers of the cerebral hemispheres, and is divided into the frontal, parietal, temporal, and occipital lobes

Phylogenetic methods – Statistical methods used to remove the effect of autocorrelation, or biases due to similarity between closely related species, from an analysis.

Phylogeny – The pattern of relatedness between species, and/or taxonomic groups, representing the evolutionary branching pattern of speciation leading to extant (living) species.

Taxon – A systematically defined group of organisms. A taxon can refer to different ranks of classification (i.e., species, genus, family, order, etc.).

Telencephalon – The most anterior segment of the vertebrate brain. It consists of cerebral cortex (dorsal telencephalon or pallium), basal ganglia (ventral telencephalon or subpallium), and olfactory bulb.

In large-brained groups, there has been a general trend toward encephalization, or increase in brain size, over evolutionary time. Understanding the functional significance of the brain and its architecture can explain why some taxa have evolved brains that are metabolically costly to develop and maintain. This article will discuss patterns of evolutionary change in brain size in vertebrates, how to compare brains across species, and the adaptive explanations that have been proposed for the evolution of large brains.

Evolutionary Changes in Brain Architecture

Vertebrate Brains and Evolutionary Trends

A segmented brain (with fore-, mid-, and hindbrain regions) is an early vertebrate innovation, and vertebrates possess an expanded and compartmentalized forebrain relative to other chordates. Thus, the earliest vertebrates had segmented brains with identifiable regions that are homologous to those in more derived and complex brains. Reconstructing these brains from fossil evidence is very difficult; in fish, as well as in amphibians and reptiles, the brain does not occupy the entire cranial cavity. However, fossil crania suggest that early vertebrate brains were small rudimentary structures similar to those found in the agnathans, or jawless vertebrates. For later vertebrate classes, such as birds and mammals, a number of fossilized specimens provide a picture of brain size and architecture of these early groups. Jurassic flying reptiles (*Pterodactyls*) and early birds (*Archaeopteryx*) had brains that were considerably larger than other extant reptiles and dinosaurs, but their forebrains were considerably smaller than modern birds. Similarly, Jurassic mammal-like reptiles and Paleocene mammals had brains that were roughly equivalent to modern-day marsupials; they were proportionately larger than contemporary reptile species, but, like modern insectivores, they had relatively small neocortices and large olfactory bulbs. In most recent groups, especially the homeotherms, brain size has increased over evolutionary time.

Although brain structure varies widely over vertebrates as a whole, individual taxa tend to have distinct cerebrotypes, and the architecture of the brain is scalable with size. The between-taxa variation in brain architecture has been interpreted as evidence for mosaic (individual brain components evolving separately) rather

Introduction

Brain size and structure vary widely across vertebrate groups. At one end of the spectrum are the primitive jawless vertebrates such as lampreys and hagfish with small, relatively simple brains. At the other end are the homeothermic, or warm-blooded, vertebrates (i.e., birds and mammals), with large, complex, and metabolically expensive brains. The difference in size of the two ends of the vertebrate continuum is marked: jawless vertebrates have brains that are approximately 0.05% of their body weight, whereas a pocket mouse has a brain that is about 10% of its body weight. Cartilaginous and bony fish, amphibians, and reptiles respectively have increasing brain size along the vertebrate continuum. In the larger-

than concerted (brain structures increasing in a scalable fashion) brain evolution. However, on closer inspection, brain evolution is not random, and there are some very predictable changes in architecture with increasing brain size over taxonomic groups.

The Vertebrate Forebrain

The forebrain, or telencephalon, is one of the areas that varies most between groups. Not only has the overall size of the telencephalon increased with brain size relative to the rest of the brain, but so also has the level of folding and number of gyres. The disproportionate increase in the telencephalon, and particularly the neocortex in mammals, means that the overall proportion of the brain that is composed of the neocortex varies dramatically across taxa (**Figure 1**). For example, in insectivores the neocortex is about 20% of the overall brain size, whereas in hominoids (apes) the neocortex is nearly 80% of the total brain. In contrast to the telencephalon, the proportionate size of the cerebellum is remarkably static across most mammals (~ 0.13). The reason for the disproportionate increase in the forebrain may be either adaptive (i.e., the forebrain is associated with higher, or executive, cognition) or developmental; during ontogeny the hindbrain is the first to develop and the forebrain is the last. Ontogenetically, it is easier to change late developing structures through heterochrony; delaying the termination of brain development will lead to the latest developing structures being relatively larger. Therefore, although it appears that the relative size of different brain components varies across species, on closer inspection, much of this pattern is driven by relatively larger-brained species that predictably have proportionately larger neocortices. This indicates that developmental constraints are important and that the brain does not develop in a truly mosaic manner.

In addition to overall size changes, the brain structure has changed in more derived groups: there has been an increase in overall neural density, and the ratio of white matter to gray matter has increased disproportionately. Additionally, many structures such as the neocortex, dorsal lateral geniculate nucleus (LGN) in mammals, and the vagal lobe of teleost fish have become highly laminated, which may allow efficient partitioning of information.

How to Compare Brains

Brain Size versus Architecture

Given that overall brain size has increased across vertebrate taxa, and that the proportional size of the neocortex has driven this trend, it seems logical to conclude that the larger the brain, the more powerful the computer. However, assuming a direct relationship between size and power is problematic for several reasons. First, larger brains are not necessarily more efficient than smaller brains. A good analogy for how this assumption might be flawed is the development of computer technology over the second half of the twentieth century. The difference in power and efficiency between early and modern computers is not a factor of size, but of the efficiency and density of the circuitry. Brains similarly vary in the size and density of their neurons and the connectiveness between different brain components. Therefore, total brain size may not reflect cognitive ability accurately.

Thus, when we compare brains from different species, it is important to consider variation in the architecture as well as the size. In fact, comparing the absolute size across brains is likely to be meaningful only where they have similar structures and composition. Distantly related groups have potentially undergone very different selective pressures. For example, bats must be aerodynamic and therefore have strong constraints on maximum brain size; neural structure in bats should be expected to be

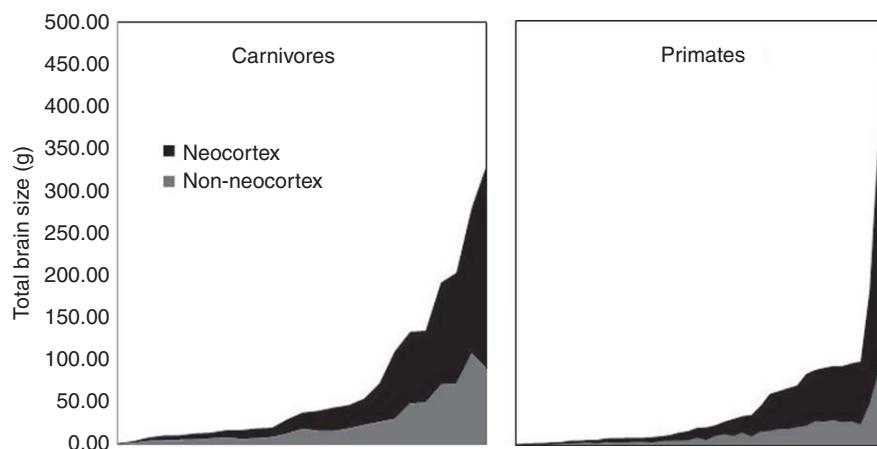

Figure 1 Proportional increase in neocortex volume with increasing brain size in carnivores and primates.

dense and compact. Relative to bats, a taxon such as cetaceans (dolphins and whales) has few constraints on maximum brain size. Marine mammals tend to have relatively exploded brains with very low neural density compared to small terrestrial mammal species. Therefore, it is reasonable to predict that in addition to overall size, network and neuronal density will be indicative of cognitive capacity. However, there is currently not enough comparative data on neuronal structure to look at the relative importance of density and neuron size versus overall brain size for cognitive ability.

A second issue is the allometric relationship between brain size and body size; brain size increases predictably by a factor between 0.67 and 0.75 with body size (**Figure 2**). Jerison proposed that the reason for this allometric relationship was that body volume to surface area increases at a $2/3$ exponential rate. Thus, the number of (neural) receptors and effectors should also increase at this rate. Alternative arguments have focused on metabolic scaling (also 0.75), which may allow larger animals to support more expensive cognitive architecture. If brain size is the result of metabolic or surface-to-volume ratios, then large brains may not have adaptive significance, but may be a result of released energetic constraints.

Given these issues, there have been a number of suggestions about how to measure relative cognitive capacity in animals. First, within closely related taxa, it may be appropriate to compare brain volume directly. If brains are structured in similar ways, then a direct comparison of volumes may be appropriate. Recent analyses of primates

have demonstrated that overall brain size is a better measure of cognition than relative brain sizes. However, across taxa, where body size and ecology vary widely, relative measures are probably more suitable.

Estimating Relative Brain Size

Jerison's solution to this problem was to calculate an encephalization quotient (EQ). An EQ is calculated by the ratio of the actual brain volume to the volume expected for its body size (i.e., $\text{bodysize}^{2/3}$). A similar measure is residual brain size, which is calculated by fitting a regression line through logged brain and body sizes. A residual value, or the distance between the regression line and each species point, gives a measure of relative brain size; those species with points above the line have larger brains than expected for their body size, whereas species that fall below the line have smaller brains than expected (**Figure 2**). Although this estimate is widely used, there are several criticisms. First, the species that are included will bias the regression line. Thus, a residual value is not absolute but relative to the species included in the analyses. Additionally, different taxonomic groups have different slopes and different intercepts (i.e., groups with large brains relative to body size will have a higher regression line than groups with small brains). For example, primates and carnivores have higher intercept values (larger relative brain sizes) than ungulates or insectivores. If a single line is fitted through multiple groups, the resulting residuals will be

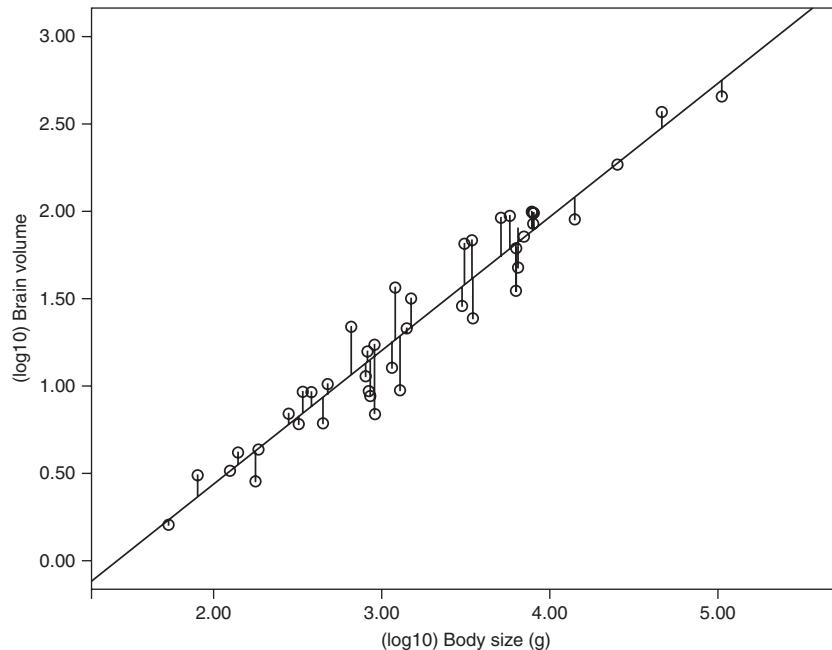

Figure 2 The relationship between brain size and body size in primates. The line represents a fitted regression, and the spikes, residual brain size of individual species.

nonnormally distributed; the group with larger brains will be clustered with high positive residuals, whereas the group with small brains will be clustered with negative residuals. A possible solution for these problems is to calculate regression lines for individual families rather than over mammals as a whole. Overrepresentation of closely related species, which are likely to be autocorrelated for both brain and body measures, can also bias the overall relationships between brain and body size. Phylogenetic methods can reduce the influence of autocorrelation between closely related species. Finally, the method used to calculate the regression line will affect the residual values. The conventional regression line, a least squares regression, underestimates the slope of the relationship and results in small-bodied species having negative residuals. Although using a reduced major axis eliminates this problem, most statistical packages use the least-squares regression methods (and thus, so do most comparative brain analyses). This is a particular issue when trying to control for phylogenetic relationships when estimating relative brain size.

The problem becomes more complicated when we wish to consider more fine-grained relationships between cognitive capacity and behavior. Not all parts of the brain are expected to be important in higher-level cognitive processing. For example, the medulla/brainstem is associated with controlling metabolic and maintenance functions of the body and the cerebellum is implicated in physical coordination. In contrast, the parts of the brain most commonly implicated in learning, decision making, discrimination, and memory are parts of the telencephalon, especially the hippocampus and neocortex. If specific areas of the brain are linked with higher cognition and behavioral complexity, then absolute or relative measures of these parts should be more enlightening than direct or relative measures of overall brain size. Thus, neocortex volume and neocortex ratio, the ratio of the volume of the neocortex to the rest of the brain, can be used as comparable measures of executive brain size. In summary, there are a multitude of methods to compare brain size using both absolute and relative measures. The best approach depends on both the question and the species used in the analysis.

Evolutionary Explanations for Brain Size Increase

Brains are incredibly costly to develop and maintain. Adaptationists, who seek functional (fitness benefits) explanations for the existence of traits, argue that costly traits will not be maintained unless their adaptive benefit outweighs their costs. Given that brains are so costly, it seems intuitive that growing a large brain must offer some kind of cognitive advantage. Additionally, some

vertebrate taxa have seen increases in brain size concurrent, or at least associated, with rapid speciation leading to adaptive radiations, such as within the passerines.

This section presents the major arguments for brain size evolution in vertebrates, starting with the nonadaptive developmental hypothesis, then the ecological, and finally the social hypotheses for encephalization. Despite the recognition that brain size is likely to have adaptive significance, there are surprisingly few attempts to relate measures of brain size with cognitive function or performance on cognitive tasks. One exception is the recent collation of various experimental cognitive paradigms administered across primate species during the twentieth century. Species performance on these tasks is positively associated with measures of brain size (especially total brain size). Thus, there is some evidence for there being a cognitive benefit for having large brains. However, this does not provide an adaptive explanation for brain size increases.

Developmental Hypotheses

Beginning in the 1980s, comparative studies of brain size in birds and mammals identified numerous life-history correlates with brain size. Species with larger brains tend to have delayed development, reach reproductive maturity later than small-brained species, have fewer offspring, and typically have longer life spans. Many of these associations may be primarily driven by body size, as larger-bodied animals have larger brains and slower life histories. However, for a given body size, species that have large brains have higher relative basal metabolic rates (BMRs) than species with smaller brains because brains are metabolically costly to maintain. It therefore appears that species with large brains need to be able to energetically support them. Martin extended this argument further by suggesting that the available maternal energy and gestation period exert the strongest constraints on fetal and, hence, adult brain weight. However, the question remains whether these life-history variables are causes or consequences of large brains. If large brains are an adaptive response to environmental challenges, then it follows that the life history and physiology of large-brained species will need to be able to support the demands of growing and maintaining a large brain.

Ecological Hypotheses

Behavioral flexibility should allow individuals to respond to unpredictable environments and to use novel resources. There have been a number of efforts to quantify behavioral flexibility. In 1997, Lefebvre and colleagues compiled a database of innovative or novel behaviors recorded in the literature for different bird

species. Their index of innovativeness is positively correlated with brain size in birds and has since been extended to primates. Wyles' behavioral drive hypothesis suggests that novel behaviors spreading through a population can change (or potentially release) selection pressures. Thus, Nicolakakis and colleagues argue that the correlation between species richness in birds and relative brain size is the result of behavioral drive leading to adaptive radiations in behaviorally flexible species.

There are a number of studies that have shown macro-ecological patterns that are associated with relative brain size. Shultz and colleagues identified relative brain size as a predictor of long-term population trends in UK farmland birds. Species with larger relative brain sizes have decreased less than species with small relative brain sizes. Sol and colleagues extended this logic demonstrating that both invasion success and migratory propensity are associated with relative brain size; large-brain species are more successful at invading novel habitats in both birds and mammals. Additionally, species that migrate, and hence avoid unpredictable environments, have smaller relative brain size than resident species that are able to survive extreme seasonal variation in resource availability and climate. Additionally, resident species are more innovative and have been documented as using more novel behaviors than migratory species. These studies suggest that larger-brained species are more behaviorally flexible and can adaptively change their foraging strategy in novel and unpredictable environments.

For primates, ecological hypotheses have centered on the need to track resources that vary over time and space. Frugivorous species have larger relative brain size than folivorous species; larger-brained species also tend to have larger home ranges than smaller-brained species. This has been interpreted as an indication that the variable nature of fruit resources (both over space and time) has imposed a cognitive demand on individuals which need to track resource availability. However, there are several inconsistencies with this logic. First, there are a number of relatively small-brained frugivores that are sympatric with primates, and thus experience the same ecological pressures (e.g., forest duikers, flying lemurs, squirrels, and viverrids). Thus, it does not seem essential for frugivorous species to be large brained. Second, Dunbar and Shultz have partialled out the relative contribution of different traits to brain size and have shown that high-quality fruit diets are more likely necessary to support the high metabolic demands of large brains rather than be the driving selective pressure increasing brain size.

Social Hypotheses

In the late 1970s, several primatologists suggested that the apparent intelligence of monkeys could be the result of their complex social environment. This concept was

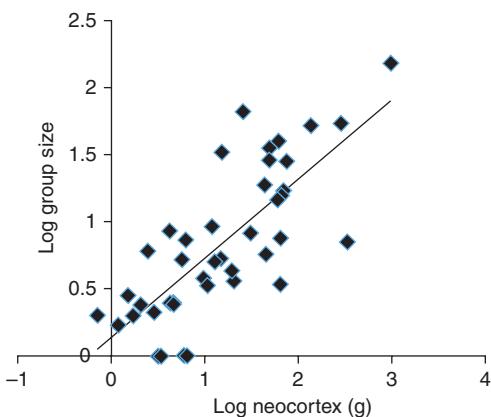

Figure 3 The relationship between neocortex size and group size in primates.

developed in the social brain hypothesis, which proposes that the evolution of large brains characteristic of primates has been a response to complex sociality. There is a strong correlation between primate relative brain (and neocortex) size and the size of social groups (**Figure 3**) and grooming cliques. The relationship has been interpreted to indicate that individuals in larger groups need to monitor, maintain, and remember more relationships.

Byrne and Whiten suggested that the cognitive demands of living in a social group may be more linked to cheating and detecting cheating than just monitoring relationships; they termed this Machiavellian intelligence. As a test of the hypothesis, Byrne and Corp collated data on deception rates in primates and demonstrated a positive relationship with relative neocortex size. Although Byrne and Whiten's hypothesis is not in opposition to Dunbar's social brain, it does put a slightly more malevolent twist on primate intelligence.

Primates are not the only social animals and the group size relationship with brain size should generalize to other taxa; however, several studies have shown that it does not. In fact, in nonprimates, large brains appear to be associated with stable and enduring relationships, such as between pair-bonded partners or between members of small cohesive groups, rather than overall group size. A potential explanation for this pattern is that many social species occur in large, unstable aggregations rather than bonded groups. It is only individuals in stable and bonded groups that need to coordinate activities and monitor relationships. Although brain size does not appear to be linked to cooperative breeding in birds, relative brain size is associated with stable pair bonding. Pair-bonded individuals need to monitor their reproductive partners to maintain territories, avoid cuckoldry, and synchronize vigilance and parental care.

A related, but slightly different take on the social intelligence hypotheses is the potential benefit of social learning. Individuals that can effectively exploit and

utilize the knowledge of others can avoid a costly trial-and-error learning process, and adaptive behavior can spread quickly through populations. Populations of many animals show cultural behaviors which, on the surface, do not appear to be adaptive, but are consistently maintained in a population. A lot of interest has been focused on cultural differences in chimpanzees; as culture is seen a distinctive feature of human societies, the logic that it is seen as cognitively advanced appears to be logical. However, some of the best examples of cultural behavior come from fish and birds. Many of the cultural differences between chimpanzee populations can be interpreted as adaptations to local resources and environmental conditions. Although it is not reasonable to state that there are no cultures in primates, interpreting population differences in a cultural context does not really highlight the cognitive demands or adaptive significance of these behaviors.

Reconciling Social and Ecological Hypotheses

In essence, all of these hypotheses focus on an individual's ability to make flexible adaptive decisions in the face of unpredictability. One approach to reconciling the ecological and social hypotheses may be to look at an animal's environment as hierarchically structured, with environmental variability, resource availability and distribution forming the first layer of complexity and inter- and intraspecific interactions forming higher tiers of complexity, which interact and compound the initial ecological problems that all individuals need to solve. A solitary animal needs to maintain its energy balance by finding enough food of appropriate nutritional quality. Thus, the animal needs to be able to locate appropriate food, decide which items to include in its diet, how to optimally use patches, and how to allocate its time to various maintenance activities. However, individuals do not live in isolation, and have to avoid predators, locate mates, minimize competition over resources, and they need to make strategic decisions about how to balance predation risk, reproduction time, and resource allocation. However, when social groups become more stable (why would they), then all resource-acquisition decisions need to be made in the context of what other group members are doing.

Human Evolution and Brain Size

Although humans have brains that are much bigger than those of other primates, early hominids had brains that were little bigger than modern apes. Therefore, there has been much speculation about what has driven the increase in brain size in later species. Hominids such as *Australopithecus afarensis* evolved bipedal locomotion, with no concurrent increase in brain size. In fact, it was

over a million years later that there was a marked increase in brain size. So what factors could have driven the brain size jump seen in the genus *Homo*? It is unlikely to have been driven by tool use, as evidence for manufactured tools appears later in the fossil record. Ecological arguments also do not seem to hold; the seasonality of environments where hominids were found does not tightly correlate with brain size changes. Dunbar and Aiello suggested that increases in group size, similar to the relationship shown in primates, could explain the increased demand on cognitive ability. Moving from a forest or woodland environment into one where predation risks are high could provide an initial pressure to increase group size. Savanna-living primate species are found in larger groups than their forest counterparts. Coordination, relationship maintenance, and information transfer in such large groups would not only have been cognitively demanding, but may have also been the impetus driving the evolution of language.

Where to Next?

One of the prevailing criticisms of comparative brain studies is that we are yet to identify strong links between relative brain structure size and cognitive function. Thus, it is essential to relate cognitive performance across taxa to brain architecture. Additionally, the relative importance of size versus internal network structure (connectivity) and neuronal density needs to be compared across species. There is evidence from humans that intelligence and brain structure are associated and heritable. However, little is known about the relative effects of the environment on brain size and structure. Hippocampus size has been shown to be sensitive to environment, with spatial learning leading to increased size. Whether the flexibility seen in the hippocampus is a general phenomenon across the telecephalon is unknown. Thus, although there are a number of associations between brain size and behavior, the causal nature of these relationships needs further investigation.

Glossary

Apical dendrite – Branched projections located at the apex of a neural cell that receive and conduct signals from other neural cells.

Conductive coil – A series of one or more loops of conductive wire that compose a critical hardware component in MRI machines; it is used to create a magnetic field and/or to detect a changing magnetic field by the voltage induced in the wire.

Dipole – A pair of electric charges or magnetic poles of equal magnitude but of opposite sign or polarity and separated by a distance. Electric dipoles contribute to the generation of a current, which contributes to the generation of a magnetic field (c.f., electromagnetic, conductive coil).

Dura mater – The outermost, toughest and most fibrous of the three membranes covering the brain. It lies beneath the skull and skin, and contributes obstruction to signals generated in neuronal cells.

Electromagnetic – The property by which a change in an electric field induces a magnetic field, and vice versa. This property is what underlies the ability of a conductive coil to produce or detect changes in a magnetic field (c.f., conductive coil), and of a neuron to produce a measurable magnetic field (e.g., by MEG, c.f., dipole).

Gray matter – Tissue in the brain that consists mostly of neuronal cell bodies and capillaries, appears gray in color and lies primarily at the outer surface of the brain (Figure 1(a)).

Hemoglobin – Iron-containing oxygen-transport protein in red blood cells. Hemoglobin oxygenation increases when neuronal cells are active, contributing to the blood-oxygen level dependent (BOLD) signal measured by fMRI.

Nuclear – Relating to the properties of an atomic nucleus. Nuclear properties, such as resonance or stability, are critical to imaging technology (e.g., MRI and PET respectively).

Perfusion – The delivery of arterial blood to capillaries in biological tissue such gray matter of the brain.

Pyramidal neurons – A type of neuronal cell that serves as the primary excitation unit in the human brain.

Radioactive isotope – An atom with an unstable nucleus, characterized by excess energy. In PET, radioactive isotopes that emit positrons are utilized, whereas in SPECT radioactive isotopes that emit a single unit of energy (or photon) are employed.

Resonance – The tendency of a system to oscillate at larger amplitude at some frequency more than at others. Changes in frequency change the oscillation, or spin, of atoms in brain tissue, which produces a measurable signal that is captured in MRI.

Radiofrequency – Frequency or rate of oscillation within the range of about 3 Hz to 300 GHz (used to produce and detect radio waves).

White matter – Tissue in the brain that consists mostly of myelinated (lipid or “fatty” covered) axons, that appear white in color, comprising connecting tracts between regions of gray matter (Figure 1(a)).

Introduction

Brain imaging refers to techniques that employ an interaction between brain tissue and various forms of energy (e.g., electromagnetic or particle radiation), rather than physical incision, to capture positional data about the structure and function of the brain. Such data are used to create corresponding brain maps. Structural images delineate brain tissues such as white versus gray matter, vasculature, and bone, based on their physical properties (tissue density or nuclear resonance characteristics). Functional images capture physiological activities in the brain (metabolism, blood flow, chemical composition, absorption) typically coupled to neuronal firing. Functional imaging has two possible aims. In clinical applications the goal is typically to differentiate normal physiological activities in a healthy brain from those in perturbed states (e.g., stroke, Alzheimer’s disease). In cognitive neuroscience the goal is to understand how brain function mediates human cognition and behavior (e.g., memory, language, and vision). Attaining these goals depends on the nature of the measured signal, spatial and temporal resolution, and practical constraints such as invasiveness and cost of each technique.

Brain Imaging Techniques

Brain Structure

Magnetic resonance imaging

The most powerful method of structural imaging today, largely replacing X-ray-dependent computed tomography (CT) in research applications, is magnetic resonance

imaging (MRI). MRI is based on nuclear magnetic resonance (NMR), the tendency of certain nuclei to resonate when placed in a magnetic field, independently discovered by Felix Bloch and Edward Purcell in the 1940s. In MRI a strong electromagnet, typically 1.5–4.0 tesla (T) for human imaging, is first used to produce net nuclear magnetization in hydrogen atoms in the body. Radiofrequency pulses are then applied at the resonant frequency of the hydrogen atoms, which displaces them into a higher-energy state (i.e., out of alignment with the net magnetization). As the protons then return to their original state they release energy, creating an oscillating magnetic field that can be picked up (via electromagnetic induction) by a conductive coil placed in the field. This signal is localized spatially by using a combination of magnetic field gradients in different planes to produce unique spin properties across the brain that can be used to reconstruct the spatial location of the signal source. The contrast in MR images is obtained by

modifying the timing of both radiofrequency pulses and signal acquisition to take advantage of natural differences in physical properties of the different tissues, such as the time needed for the tissue to return to the net magnetic field after excitation. Typical MR images (**Figure 1(a)**) capture detailed three-dimensional (3D) structure of the brain distinguishing between tissues such as gray and white matter, cerebrospinal fluid, bone, fat and air, as well as being able to detect the presence of abnormal tissues such as tumors or cysts.

One advantage of MRI is its extreme flexibility in the types of signals that it can measure. Diffusion-weighted MRI (e.g., Diffusion Tensor Imaging or DTI) is sensitive to the movement of water molecules over time. The measurement of directional diffusion signals allows characterization of white matter structure, which has allowed the development of MRI-based tractography methods for imaging white matter connectivity. When

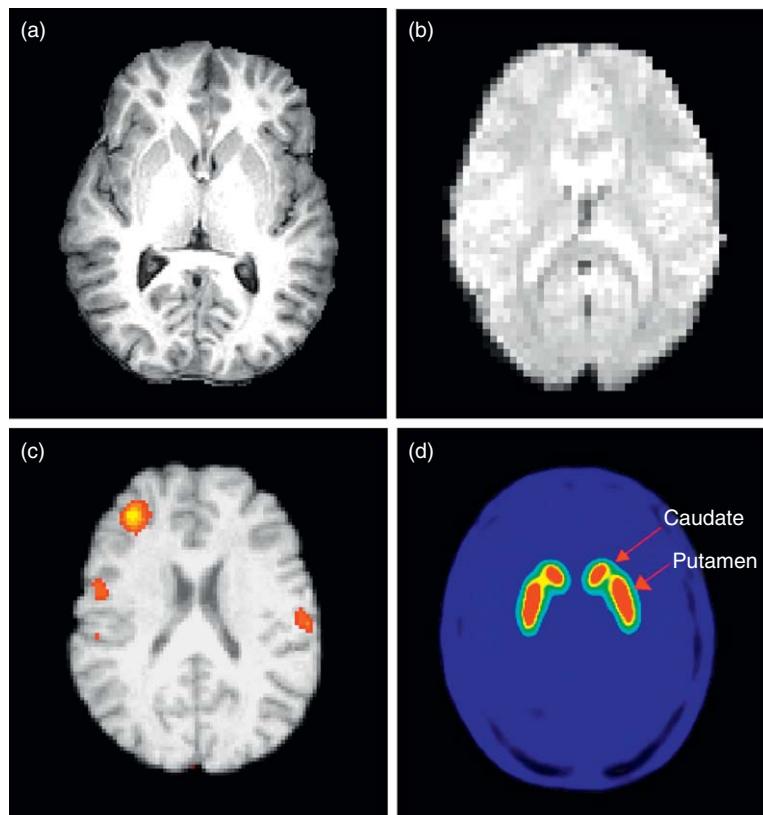

Figure 1 Maps of the brain vary with the type of signal detected. In magnetic resonance imaging (MRI) (a) the signal typically arises from variation in magnetic properties of hydrogen atoms across different brain tissues, producing high-resolution (~1 mm) structural images that delineate structures such as white vs. gray matter, deep nuclei, bone and ventricles. MRI can also be used to detect brain function by measuring the oxygenation level of blood hemoglobin (b). The resulting images are of lower resolution (~3 mm) at the gain of higher temporal resolution. Comparisons of the resulting images across tasks or states reveal the locations of task-specific changes in brain metabolism. Localization of these changes is accomplished by overlaying the activation maps onto a structural image (c). An alternate measure of brain function is shown in figure (d). Here the binding potential of D2-like dopamine receptors for the radioactive tracer [¹⁸F]fallypride is revealed using positron emission tomography (PET). The density of the receptors increases (hot colors like red and yellow) in caudate and putamen structures of the basal ganglia compared to other parts of the brain (blue). Figure (d) has been provided courtesy of E. London, UCLA.

used to measure overall diffusion, it is very sensitive to changes that occur early in stroke and other neurological disorders. MRI spectroscopy measures regional concentration of specific metabolites, which can signal neural cell integrity and energy metabolism. MRI can also be used to measure blood flow and characterize brain perfusion, which is a sensitive measure for stroke and other cerebrovascular disorders. Finally, one of the most powerful applications of MRI is to measure brain function by measuring changes in oxygenation of hemoglobin in the blood.

Brain Function

Electro- and magnetoencephalography

Electroencephalography (EEG), first described by Hans Berger in 1924, and more recent magnetoencephalography (MEG), first introduced by David Cohen in 1968, measure electrical signals resulting directly from post-synaptic potentials in the apical dendrites of pyramidal neurons of the cortex. Such potentials produce currents running along the length of the neuron that summate across neuronal assemblies due to the parallel configuration of such neurons (i.e., creating electrical dipoles). This summation produces a measurable voltage (V) potential at the scalp surface, measured by EEG. Perpendicular to these currents arises a magnetic field that also summates across neurons and is measured by MEG. In EEG changes in scalp voltage potential are measured by electrodes attached to the scalp. Changes in voltage (approximate range of 10–100 μ V) can then be recorded across time at each of the electrodes. In MEG, magnetic fields at the scalp are measured using a superconducting quantum interference device (SQUID) containing highly sensitive detectors that translate the magnetic field back into current values. SQUIDS are necessary because the summed magnetic fields produced by pyramidal neurons are small, \sim 10 fT (femtotesla), while noise in daily urban environments (i.e., cars, power lines) averages between 10^6 and 10^9 fT. In both modalities the resulting signals can be used to monitor brain activity across time. Distinct frequency profiles are associated with states of sleep, alertness, and awareness during anesthesia. These signals can also be observed during a time window associated with a cognitive function of interest. For instance, in EEG, low-frequency negativity can be observed immediately preceding a motor response. Subsequent properties of this potential, such as laterality differences across the scalp, can further differentiate between the cognitive expectation of an event and preparation of a motor response. In both EEG and MEG, additional information may also be obtained from the frequency domain of the temporal signal.

Positron emission and single photon emission computed tomography

The advent of nuclear medicine in the 1940s and 1950s and subsequent developments in production of radioactive isotopes and gamma ray detectors have contributed to emission computed tomography modes of brain imaging, including positron emission tomography (PET) and single photon emission computed tomography (SPECT). They are used to image blood flow and/or metabolic processes in the brain by measuring radiation energy emitted from radioactive isotopes that are intravenously injected, and subsequently distributed by the circulatory system of the brain (Figure 1(d)). In PET, isotopes can be created to measure blood flow (e.g., $^{15}\text{O}_2$), blood volume (e.g., ^{11}CO), or metabolic operations such as glucose metabolism or dopamine synthesis (e.g., ^{18}F). As these isotopes are circulated in the brain, they release positrons that collide with an electron, annihilate and release two gamma rays traveling in opposite directions. Coincidence detectors determine the source of the collision and the number of collisions occurring, providing information about location and concentration of that compound in the brain. From this information, a 3D image of the metabolic effects on the radioactive isotope in the brain can be reconstructed. For instance, glucose labeled with ^{18}F has been effectively used to measure increased glucose metabolism in visual and auditory sensory cortices in response to visual versus auditory stimuli respectively, and in motor cortex during finger tapping movements. Changes in metabolism across various areas of the cortex can also be tracked, for instance, as a function of metabolic maturation during development or with the progression of disease. A similar process applies to SPECT; however, single photon emission isotopes (e.g., ^{123}I , ^{111}In) are used instead of positron-emitting isotopes and the detectors are gamma cameras designed to measure single photon emission rather than coincidences. Unlike PET, SPECT isotopes have been developed primarily for measurement of cerebral blood flow changes, not metabolic processes. Thus while this technique can detect the effects of a stroke on blood flow patterns, it cannot detect functional changes in which blood flow is less affected than metabolism, such as altered synthesis of the neurotransmitter dopamine in Parkinson's disease.

Functional magnetic resonance imaging

Although MRI has been in use since the 1970s and has many applications in structural imaging, its application to measuring brain function was not possible until 1990 when Seiji Ogawa and colleagues demonstrated that the oxygenation state of blood hemoglobin modulates MRI signal around large veins. This finding resulted in development of MRI sequences sensitive to changes in blood flow in the brain (Figure 1(b)), without the need

for any exogenous contrast agent to be injected (e.g., PET, SPECT). In fMRI, the contrast arises from the effects of deoxygenated hemoglobin on the magnetic field. As demonstrated by Ogawa, when blood hemoglobin lacks oxygen it has magnetic properties that disturb the effects of magnetization in its vicinity and thus lowers the measured signal. In contrast, when hemoglobin is oxygenated, it has less effect on neighboring molecules and thus produces a net larger signal during an MRI scan. The utility of this finding to measuring brain function is that both blood flow and local hemoglobin oxygenation increase in response to neuronal activity, thus increasing the local MRI signal. This is referred to as the blood-oxygen-level-dependent (BOLD) signal; while there are other ways to measure functional activity using fMRI, BOLD fMRI is by far the most popular method. The BOLD response provides a robust but indirect measure of brain activity and, like PET, can detect active regions during perceptual and cognitive tasks in both healthy and diseased brains (Figure 1(c)).

Applications: Determining Factors

Spatiotemporal Resolution

Imaging techniques vary in both spatial and temporal resolution, which constrains the types of questions that they can answer within their imaging domain. For structural imaging, spatial resolution is the primary concern (since structures change over the course of months to years), whereas functional imaging requires high spatial and temporal resolution (since neuronal function occurs over milliseconds at a spatial scale of microns). Functional imaging modalities fall into two categories: those that directly reflect neuronal activity (EEG/MEG) and those that measure physiological processes associated with neuronal activity (fMRI/PET). These categories are also defined by tradeoffs between spatial and temporal resolution. The former (EEG/MEG) provide excellent temporal resolution (0.01 s) but low spatial resolution (\sim 10 mm), whereas the latter provide better spatial resolution (fMRI: 1–5 mm, PET: 4–8 mm) at the cost of temporal resolution (fMRI: 1–6 s, PET: 60–1000 s). These differences differentiate how the two categories of methods are applied. EEG and MEG are well suited to examine the dynamics of brain function because they provide continuous and temporally precise measures of neuronal activity. One application of such data is for monitoring of brain states. For instance, the EEG signal is useful in diagnosing the quality and type of sleep that an individual engages in during the course of a night, or in monitoring the alertness of an individual in an anaesthetized state. Both EEG and MEG can also be used to analyze the dynamics of brain function. For instance, the processing sequence

of an audiovisual stimulus can be obtained by comparing the timing of signal over visual versus auditory cortices following stimulus onset. The questions that EEG and MEG can answer are thus tied to the idea of when processes happen and only coarsely related to where they happen. In contrast, PET and fMRI can answer the question of “where?” better than the question of “when?” neuronal activity occurs. Both techniques provide spatial resolution under 10 mm, with fMRI potentially providing resolution down to 1–2 mm. This implies that these techniques are more accurate in localizing where within the visual and/or auditory cortex the audiovisual stimulus is processed. If the visual stimulus involves motion, for instance, it will produce the strongest activity in region V5/MT of the visual cortex relative to other visual processing regions such as V1 or V4. Unlike EEG or MEG, these techniques do not dissociate which perceptual modality was processed first, visual or auditory, because such processing occurs at the time scale of milliseconds, well below that of either PET or fMRI.

Practical Considerations

The utility of imaging methods, particularly in the functional imaging domain, is also influenced by two practical considerations: invasiveness and cost. The invasiveness of a technique has the effect of distinguishing between clinical and cognitive neuroscience applications. This is apparent in the comparison of PET and SPECT with EEG, MEG, and fMRI. Whereas the former use radioactive isotopes, and thus are more invasive, the latter use intrinsic signals to identify function. Reliance on radioactive isotopes has two effects, both of which make the method unsuitable for cognitive neuroscience applications. First it increases health risk, which is less easily justifiable by the benefits of basic research relative to clinical applications. Second, invasiveness has the effect of constraining the amount of data that can be acquired. This is undesirable because the neural signals related to cognitive processes are often relatively small, and many repeated observations are required to maximize the power and interpretability of the experimental results. In contrast, sampling is restricted in both PET and SPECT because safety concerns about side effects of radiation limit the number of times that an individual can be tested and second because the number of scans obtained within a session is constrained by the distribution time and half-life of the isotope. For instance, for ^{15}O with half-life of 2.03 min, approximately 60 s are required for the isotope to circulate throughout the brain and 10 min required between dosage injections (i.e., 5 half-lives) for most of the isotope to be eliminated from the body between scans. In a 60 min session no more than six scans can be administered with 60 s temporal resolution.

EEG, MEG, and fMRI are not limited in the amount of data that can be collected on an individual, and thus are more suitable to cognitive neuroscience applications.

Finally, cost also has a role in the utility of imaging methods. For instance, whereas PET is considerably more accurate than SPECT, the latter is cheaper and uses more easily accessible isotopes. Its availability makes it a more common tool in clinical settings. EEG and MEG are less disparate in quality, but the necessity for SQUIDS as detectors in MEG makes it much more costly in comparison to EEG. Consequently, EEG is more prevalent than MEG in both clinical and research settings. MRI, in contrast, is relatively common in both clinical and research settings, making it both a popular and accessible tool.

Challenges

Limits on Resolution

The preceding discussion raised the concern of an apparent tradeoff in spatial versus temporal resolution among brain imaging methods. Both temporal and spatial resolution are constrained by the nature of the signals that they measure. In EEG, the current generated by neuronal population spreads passively from its source, being distorted and diffused by the dura, scalp, and skull, such that exactly reconstructing the source of the signals is impossible. In fMRI changes in neuronal activity are measured indirectly through the BOLD response, which occurs primarily in larger veins that are downstream of the true neuronal response. Technological developments in the techniques themselves will not greatly improve the resolution of these techniques. Rather, new developments in the type of signal measured may offer an alternative approach. For example, recent advances in MRI suggest that it may be possible to measure the magnetic fields produced by neuronal activity, akin to the signal measured in MEG. This approach may present perhaps the best resolution to date: millisecond temporal resolution similar to EEG and MEG while maintaining the spatial resolution of fMRI. However, these signals are exceedingly small and to date they have not been measured reliably in the human brain.

An alternate approach to optimizing resolution is to combine technologies either through simultaneously recording from different modalities, or by using the data from one modality to improve the interpretation of another. MRI images can improve EEG spatial resolution by facilitating reconstruction of realistic head models to estimate conductivities throughout the scalp, skull, and dura. Such models can then be integrated into deblurring algorithms designed to decrease the attenuating effects of these structures on the EEG signal. Due to the complementary nature of the signals recorded, simultaneous recording from EEG and MEG can improve the sampling and thus spatial resolution of the underlying neuronal activity. It is also possible

to acquire EEG data simultaneously with fMRI data, but it is very technically challenging. An important caveat to these strategies is that the techniques be compatible in measured signal. For instance, although an apparently useful approach would be to combine EEG and fMRI recordings to integrate over space and time, the signals measured by these methodologies correspond to different processes (neuronal current vs. changes in blood deoxyhemoglobin) and their co-occurrence is not easy to interpret. Integrating across different sources of information within a modality, such as structural and functional MRI images, is more straightforward; for example, high-resolution MRI structural images are often used to localize the sources of activity in low-resolution fMRI images (**Figure 1(c)**). Registration algorithms can align the two data sets in space and across time, allowing researchers to infer the location of a lower resolution (3–4 mm) BOLD signal on a higher resolution (1 mm) MRI structural image. Similarly, diffusion imaging and fMRI can be combined to define the bounds on functional regions by comparing the parameter of activation in a given region as measured by fMRI, with the connections that it makes to another region as measured by DTI.

Functional Localization and Inference

Another challenge in functional neuroimaging concerns functional localization (i.e., matching brain activity to cognitive function). This is complicated by the presence of interactions between regions; measurements of activity in a single region are potentially incomplete in describing how the brain performs a given function. To demonstrate, the fusiform face area (FFA) in the inferotemporal visual cortex shows a stronger activation in response to faces than other stimuli, supported by the presence of face-selective cells in this region, and shows decreases in activity in patients with prosopagnosia, an inability to recognize faces. The activation patterns of the FFA thus suggest that it is involved in face perception. Upon closer inspection however, it has become clear that the FFA also responds to stimuli other than faces (e.g., objects and birds) (**Figure 2**) and patients with prosopagnosia show abnormal activation patterns in regions other than the FFA (e.g., inferior occipital cortex), questioning the selectivity of this region for face perception. Moreover, face-selective cells have been found in other parts of the brain, including temporal and occipital cortex, prefrontal cortex, and amygdala, suggesting that other parts of the brain may also be critical to face perception. Thus, understanding activation in FFA alone may be insufficient to understanding this function.

This conclusion is supported by recent proposals that accommodate the above inconsistencies by considering the FFA as one contributor to a network of regions that together result in face perception. For instance, one recent

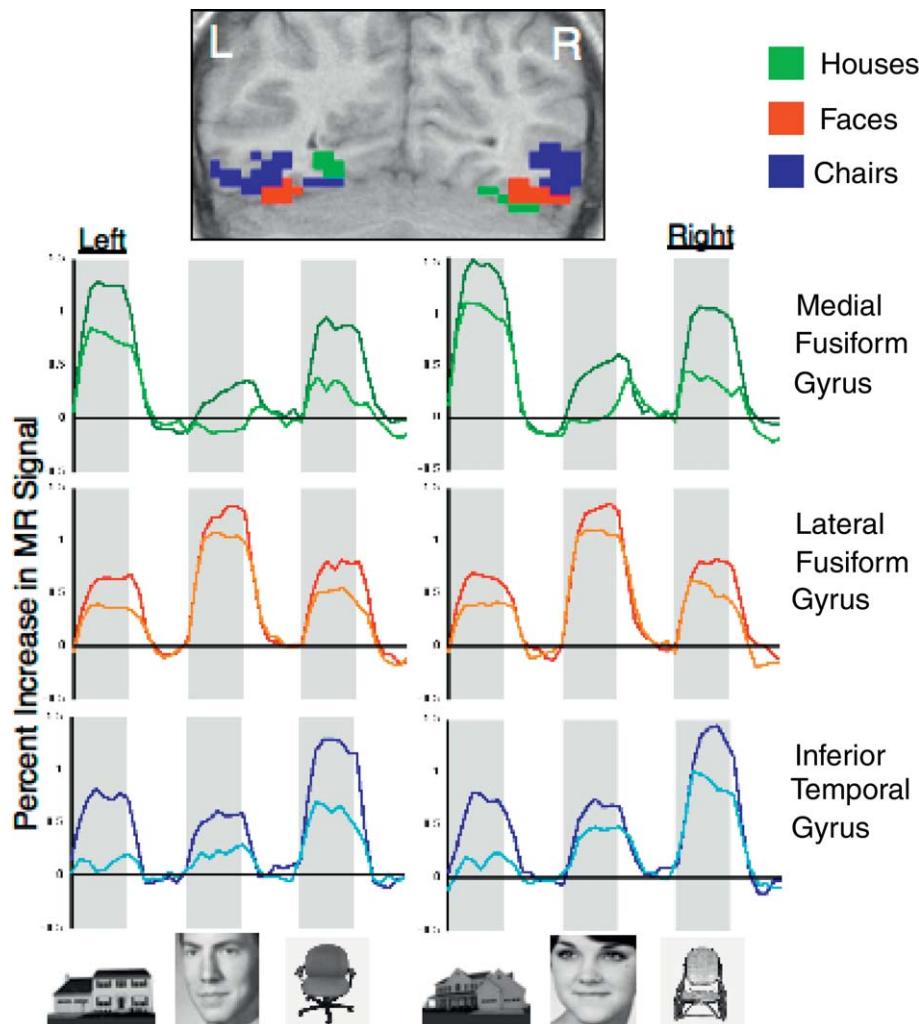

Figure 2 The lateral fusiform gyrus (red/orange in top figure and middle row graph) shows a greater response to faces than to other stimuli, indicating its involvement in face processing. However, the selectivity of this region for faces is not exclusive as the region also responds to other stimuli such as chairs and houses. Similarly, nearby medial fusiform gyrus and inferior temporal gyrus respond to faces as well as to other stimuli. These data suggest that face processing includes multiple regions in the brain, not only the fusiform gyrus. Reproduced with permission from Ishai A, Ungerleider LG, Martin A, Schouten JL, and Haxby JV (1999) Distributed representation of objects in the human ventral visual pathway. *Proceedings of the National Academy of Sciences of the United States of America* 96: 9379–9384. Copyright (1999) National Academy of Sciences, USA.

model suggests that the role of the FFA in face perception is to distinguish between faces. In addition, the role of cells in the temporal and occipital cortices may be to identify speech patterns and gaze associated with faces, in the prefrontal cortex to identify the semantic goal guiding the need for face perception, and in the amygdala to facilitate identification of facial expressions. The integration of activity across multiple regions, rather than only in FFA, captures the function of face perception. Not only does such a scheme accommodate the presence of face selective cells in regions other than the FFA, but it also explains variability in selectivity of FFA for faces. The role that FFA plays in distinguishing unique faces may be applicable to distinguishing between other stimuli (e.g., objects) given, for instance, a different set of

interactions with other regions in the brain. The example of FFA and face perception demonstrates that understanding brain function may be better served by considering activity across a network of regions rather than within a single region and thus implies that cognitive functions likely correspond to integrated functional networks of regions rather than to activity within individual regions.

Understanding brain function is therefore contingent on understanding functional networks, which requires the integration of experimental and analytic techniques. Recent advances in multivariate analytic approaches have made possible the identification of distributed networks of regions that show similar activity patterns and changes in activity patterns across tasks, participants, or time. Interactions between regions and their direction of

influence can be assessed through causal models. This is beneficial in distinguishing which regions modulate activity in another region by determining, for instance, the strength of interactions between other sets of regions. As an example, activity in the prefrontal cortex may increase the connection strength between FFA and amygdala when the individual's goal is to determine which of their colleagues is in a bad mood, but between FFA and temporal cortex when locating a colleague with a distinguishing accent in their speech. In addition, networks can be assessed by evaluating the types of activity in various regions (e.g., sustained activation after viewing a face or a short burst of activity at the onset of the face) that can determine the individual roles of regions (e.g., remembering a face or detecting a face, respectively), by correlating network activity to behavior and by evaluating the effects of disruptions to a network on both activity in other regions and behavior. Finally, a complementary approach to localizing function may be to better categorize the types of underlying cognitive processes that are involved in cognition. This goal requires the development of an ontology of the basic units of cognition; it could then be used to interpret network brain activity by the degree to which individual units are engaged in a task. Ultimately, how the brain produces mental activity is determined not only by which regions are active but also by their interactions across space and time, and understanding these interactions remains challenging for brain imaging.

Glossary

Directional tuning – A preferred movement direction that results in maximum discharge of a primary motor cortex cell.

Electrocorticography (ECoG) – The measurement of electrical activity produced by the brain as recorded from electrodes placed on the epidural or subdural surface of the cerebral cortex.

Electroencephalography (EEG) – The measurement of electrical activity produced by the brain as recorded from electrodes placed on the scalp.

Microelectrode arrays – These arrays contain multiple recording sites through which intra-cortical neural signals, namely action potentials and local field potentials, can be acquired. They can also be used to deliver electrical stimulation to the brain.

Volitional control of neural activity – A term introduced by E. Fetz in the 1970s, referring to the capacity for a subject to voluntarily control the firing rate of a given neuron (e.g., bring it to a designated target value) provided the feedback is delivered.

A brain-machine interface (BMI, also referred to as brain-computer interface, BCI) is a direct communication pathway between the brain and an external artificial actuator, such as a computer or a robot. This novel experimental paradigm contends that a user can perceive sensory information and enact voluntary motor actions through a direct interface between the brain and an artificial actuator in virtually the same way that we see, walk, or grab an object with our own natural limbs. Specifically, BMIs are meant to play a major role in the near future as they could lead to significant advances in restoring the sensorimotor functions for patients suffering from spinal cord injuries, stroke, and other neurological disorders. Instead of reconstructing the connectivity and functionality of damaged nerve fibers by repairing the damaged tissues, BMIs will allow to bypass the lesion, creating an artificial link between healthy brain structures and the system to be controlled. These could be the natural limbs of the patient under functional electrical stimulation (FES), a prosthetic device, or any virtual object that is part of a computer interface.

A BMI is generally comprised of four parts: first, a recording device captures neurophysiological signals

from the brain. Then, a decoding algorithm converts these signals into a semantic variable representing an action to be performed. These commands are streamed to the artificial actuator that will execute them. Finally, feedback is provided to the user in order to close the control loop (see [Figure 1](#)). It is usually provided as visual feedback, but other schemes can be implemented, which are discussed later.

Research in BMIs has flourished in the last decade, with impressive demonstrations of rodents, non-human primates, and humans controlling robots or cursors in real time through single-unit, multiunit, and field-potential signals collected from the brain. Next, we review the main aspects of the four building blocks of a BMI system, namely, recording technologies, decoding algorithms for estimation and control, and feedback mechanisms. We focus more on cortical BMIs that employ neuronal ensemble activity. A discussion on the future directions concludes the article.

Recording Technologies

Three main recording technologies dominate the BMI spectrum: electroencephalography (EEG), electrocorticography (ECoG), and cortically implanted microelectrodes arrays.

EEG is the measurement of electrical activity produced by the brain as recorded from electrodes placed on the scalp. EEG is a very popular recording method because it is relatively inexpensive, fast (~ 15 min to set up), and noninvasive. This technique allows rapid application of BMIs in human subjects, leading to the creation of an online cooperative database of EEG data for BMI. The low spatial resolution and signal-to-noise ratio (SNR) are main drawbacks of EEG measurements since the sources of the recorded electrical signal are far away from the recording site.

Low spatial resolution and SNR result in limited performance and make online single-trial performance difficult. Most of the published works using EEG are offline studies in which a large number of trials must be averaged for the SNR to be sufficient for use in a BMI system. Few groups are succeeding at online control studies with single trials, such as the wheelchair control work of Millan and colleagues.

Two classes of EEG-based BMIs can be distinguished: asynchronous and synchronous BMIs. Asynchronous

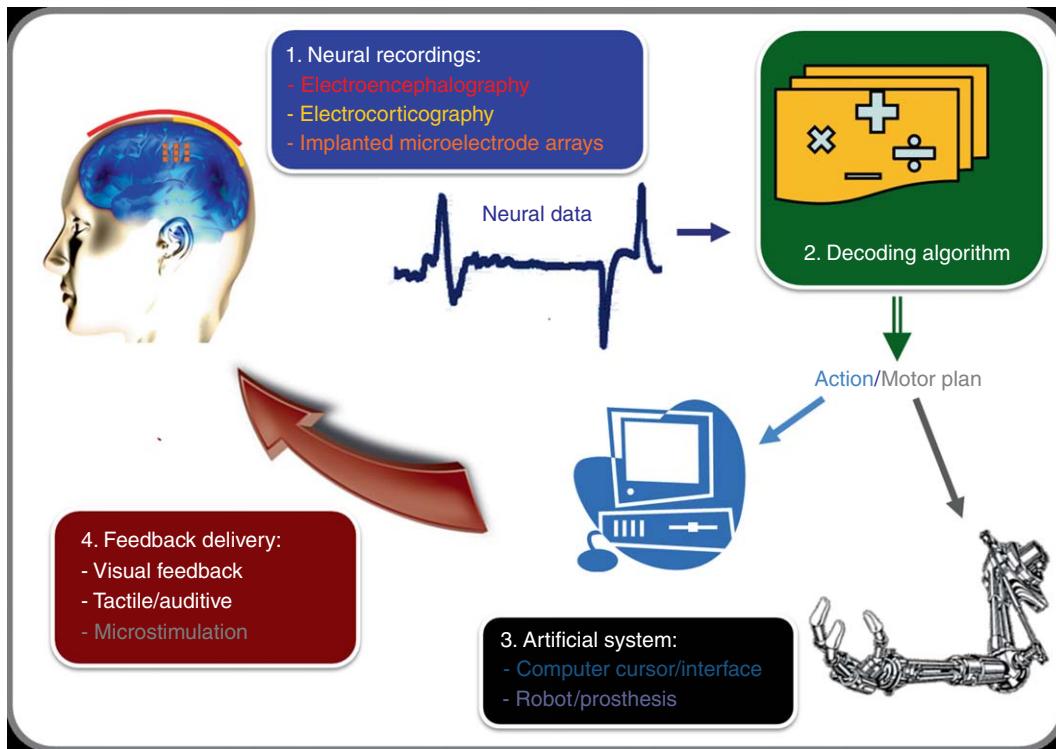

Figure 1 The BMI loop. The four main building blocks of a closed-loop BMI system: recording system, decoding algorithm, device to be controlled, and feedback delivered to the user.

systems will look for changes in amplitude, frequency, or phase of natural rhythmic signals of the brain, linked to the volitional activity of the subject. For example, the amplitude of μ -rhythm (8–12 Hz) is modified not only when a subject performs a movement, but also when he or she imagines it. After proper training, subjects learn how to control this rhythm to perform a specific action; a recent study showed an impressive demonstration of a brain-actuated wheelchair. Synchronous systems aim at detecting specific events in the EEG signals, which are caused by stimuli perceived by the subject (ERPs: event-related potentials). Specifically, P300-type ERPs (meaning that the measured EEG potential occurs 300 ms after the stimulus) caused by visual, tactile, or auditory stimuli have been used to control computer-based tasks. One advantage of synchronous systems is that they do not require any training period from the user, since ERPs are an innate feature of the brain. However, several repetitions of the stimulus are needed in order to extract the information from noisy signals. Improvements may come from source localization methods, which allow better discrimination among events using spatial information.

The nature of the signals recorded through electrocorticography (ECoG) is similar to EEG, since it measures electrical potentials resulting from the spatial average of a large area of the brain, and hence utilizes a large group of neurons. However, the fact that the

recording electrodes are placed under the dura leads to higher spatial resolution in ECoG than EEG (respectively, tenths of millimeters vs. centimeters), broader bandwidth (0–500 Hz vs. 0–50 Hz), higher characteristic amplitude (50–100 μ V vs. 10–20 μ V), and far less vulnerability to artifacts, such as EMG or ambient noise. The main drawback with respect to EEG is the invasiveness of the procedure as it requires opening the skull, and in the case of subdural implants, also opening the dura mater. In addition, similar to EEG, ECoG can be used either in an asynchronous or synchronous manner. Schalk and colleagues showed recently an application of asynchronous ECoG to two-dimensional cursor control with good success rates. In this study, ECoG features, such as spectrum amplitude at specific frequencies and electrode locations, were used to drive the cursor in one or the other direction.

Microelectrode arrays form a much more invasive physical interface, but they permit collection of spiking data from neural ensembles. To date, this is the only recording technique with the ability to reconstruct the intended movements of the subject with high accuracy. Microelectrode arrays are chronically implanted in frontoparietal areas of the brain, such as the primary motor cortex (M1), the dorsal premotor cortex (PMd), or the posterior parietal cortex (PPC). Single-unit and multiunit activities are recorded on each electrode. The activity of

each recording site must be sorted in real time for use in a BMI paradigm; units with a clearly distinguishable waveform are isolated. An instantaneous spiking frequency, or spike count for a given time bin, is derived for each cell, and then used as input by the decoding algorithm. Of great concern with implanted microelectrode arrays is their stability, both in short and long periods of time. In the short term, one must confirm, from one day to another, that the same cells are used by the decoder. This is not granted, since microelectrodes can move into the brain, leading to changes in the observed waveforms, or to a below-threshold SNR. In the long term, the brain tends to protect itself by creating a layer of scar tissue around the electrodes, leading to a slow decrease of the SNR. Thus far, studies have reported high-quality recordings up to 18 months after surgery.

Estimation and Control of Movement Parameters from Neural Data

The role of the decoding algorithm is to transform the neural activity into a control signal for the prosthetic device. The usual procedure to build a decoder is to first have the subject perform the task manually while spike activity and motor parameters are being recorded (also referred to as ‘manual control’), followed by training of the decoder with the chosen algorithm. The trained model is then used to generate predictions of motor parameters from neural data recorded online (also referred to as ‘brain control’). Various types of modeling approaches have been tested in previous studies. Among them, three different types of linear models have been widely used to predict the movement based on spike activity: the population vector algorithm, multidimensional linear regression methods such as the Wiener filter, and dynamic filters such as the Kalman filter.

The population vector algorithm used in several BMI studies was proposed by Georgopoulos and colleagues in the 1980s. They originally observed that M1 neurons were broadly tuned to hand-movement direction, noting that each neuron had a preferred direction for which it exhibited maximal firing rate. In this algorithm, the preferred directions of individual neurons are independently determined during a training phase. Then, in the online phase, the preferred directions of individual neurons are weighted by their instantaneous firing rate. The sum of the weighted preferred directions defines the population vector which estimates the current movement direction. The movement speed can be inferred from the magnitude of the population vector.

Regression models use behavioral variables, such as hand position or velocity, as a weighted linear combination of neuronal activity. The filter weights are determined using a multidimensional linear regression.

The spike count for each neuron is typically binned and regressed at several time lags, that is, for a movement prediction at time t , neural data from time t , $t-1, \dots, t-l$ will be used, where l is the number of time lags. This allows the model to capture time-delayed dependencies between neural activity and movement that exist across different cortical areas. Similar approaches using non-linear elements, such as artificial neural networks, have also proved to be efficient.

The models described thus far, can be viewed as attempts to directly approximate the mapping from neural firing rates to movement. In contrast, most models of neural encoding express the neural activity as function of a stimulus. This motivated other groups to use dynamic filtering models, where an explicit generative model of neural firing rate is used. In the Kalman filter framework, one can model the hand behavior as the system state, and the firing rate as the observation (measurement). The observation is a linear function of the state at time t , assumed to be a linear function of state at time $t-1$, plus Gaussian noise. The linear relationships between consecutive states and between state and observation are estimated from training data using least-squares estimation, thus building the Kalman model. The Kalman filter is derived from the model, allowing online estimation of the state (behavior) based on the observation (neural data). Recently, more sophisticated decoding schemes have been proposed based on hidden Markov models and Bayesian inference approaches.

Data acquired during the manual task are generally divided into two sets: a training set and a test set. The test set is used for evaluating the prediction performance of the decoding algorithms. The metric commonly used to evaluate the performance of a decoder is the squared correlation coefficient between the predicted movement and the actual movement. This performance is often referred to as the ‘offline performance’ of the decoding algorithm because it does not imply any real-time prediction of the movement, nor any feedback to the user.

Once the motor parameters are estimated, the next step in the BMI loop is to control the prosthetic device. Cortical BMI demonstrations can be divided largely into two categories: continuous control of position or velocity, or discrete control of more abstract information, such as intended targets, intended actions, and the onset of movements. The former are typically referred to as motor prosthetics, whereas the latter are referred to as communication prosthetics.

Feedback Delivery

A crucial part of a BMI system is the feedback signal that is sent back to the user so that the brain can adapt the firing rate of the recorded neurons and reduce the error in

the control signal. This is also known as ‘biofeedback’, demonstrated by Fetz and colleagues in the late 1960s. Previous BMI studies have mostly relied on visual feedback to close the loop. Whether using a synchronous or asynchronous BMI, controlling a cursor or a robot, visual feedback provides excellent information about the prosthetic device to the user, at virtually no cost. However, visual feedback may not be enough for proficient control of a prosthetic device in the long term. It is well known that peripheral tactile and proprioceptive information are fundamental for controlling our own limbs. For a neuroprosthesis to feel as a natural extension of the body, it presumably must be instrumented with sensors that can provide such information to the brain. These sensory signals could also take advantage of the BMI paradigm, and be directly delivered to the brain. Intracortical micro-stimulation (ICMS) is a method for delivering sensory stimuli to the central nervous system. Previously, ICMS work has sought to deliver artificial sensory stimuli to the somatosensory, visual, and auditory cortices. In the long term, when it comes to motor prostheses, ICMS aims to reproduce a wide range of sensory functions performed by the human limbs, such as proprioception and touch.

Discussion

BMI research has implications for both neuroengineering and systems neuroscience. In the former, neuroprosthetic systems will play a major role in restoring communication and sensorimotor function for patients suffering from spinal cord injuries and other neurological disorders. On the other hand, BMIs are also a powerful tool for studying sensorimotor learning and control, as well as cortical plasticity. In the BMI paradigm, the experimenter has full control of the motor transformation linking the neural activity to the behavior, or the sensory transformation linking a behavioral or external event to neural activity. For example, sensorimotor maps can be arbitrarily changed by the experimenter, allowing the neural adaptations to environmental changes to be studied in a controlled way.

When it comes to comparing decoder performance using different modeling approaches, it is important to realize the fundamental difference between open-loop and closed-loop BMIs. In an open-loop BMI, neural data and behavioral data are recorded, and the goal is to build a decoder that maximizes the prediction power (e.g., correlation between predicted and actual movement). The problem can be seen as a pure statistical learning issue. However, a good predictive power in an open-loop BMI does not guarantee good performance of the BMI system in closed loop. This is because the recorded neurons may behave differently when performing the BMI task as opposed to when performing the manual task. In

fact, it has been shown that the directional tuning of neurons is subject to change when switching from the manual task to the BMI task. One possible explanation for these changes in the firing properties of the cells is learning; as the subject adapts to the BMI task, the behavior of the neurons involved in the BMI task also changes. Nevertheless, a good performance of the decoder in open loop is still important because it will provide a ‘first guess’ during the closed-loop operation, where performance increases with practice.

The fact that neurons behave differently during BMI control as compared to manual control suggests that there is a ‘BMI space’ of motor control. During a closed-loop BMI experiment, the activity of the cells entirely determines the motor behavior. And conversely, to perform a given motor action, neurons must behave in a specific way. Thus, the subject must volitionally modulate the activity of the neurons to achieve the desired task. This fundamental principle for BMI was proposed by Eberhard Fetz in the 1970s.

Future Directions

Several questions concerning BMI research are currently being addressed by the scientific community. For instance, understanding the learning process during closed-loop BMI is crucial. Building a computational model of this process could help determine which type of decoder would enhance the learning process: for instance, decreasing the duration of a subject’s adaptation to the BMI task, or increasing final performance of the BMI.

Another challenge for BMI research will be to show the ability to finely control high-dimensional robotic actuators. To date, BMIs have focused on extracting kinematic data from neural signals during reaching or grasping tasks. Pure motion control, however, lacks the information required for interaction with a real environment, where the dynamic interaction of forces and torques between the robotic system and the environment play crucial roles. For instance, in the human body, the neuromuscular system naturally modulates mechanical impedance (i.e., intended inertia, damping, and stiffness) to achieve proper interaction with the environment. Ultimately, and particularly when dealing with rehabilitation prostheses, BMI systems must provide a similar degree of control when interacting with the environment. To achieve this goal, decoding algorithms may need to include modules that account for the viscoelastic properties of muscles. For example, instead of directly predicting end-point kinematics of the hand, the BMI could predict the muscle activity based on neural recordings, and then use these predictions to drive a musculoskeletal model of the arm. This will provide access to other types of variables concerning the

movement, such end-point force or stiffness. Indeed, such biomimetic algorithms constitute an elegant way to solve the decoder problem; ideally, every component of the natural motor-control loop would be modeled and implemented in the BMI system. However, while the biomimetic approach is appealing, computational issues may arise: for example, the human arm is driven by more than 30 muscles, each of which exhibits complex, non-linear behavior. Building such a large musculoskeletal model, estimating its parameters, and running it online is not a straightforward task. Software tools that specifically target such applications will be crucial for progress in the field.

As more recording technologies, decoding methods, robotic devices, and feedback schemes become available, it is important to consider BMIs as modular systems. Each one of the four essential components can be seen as a module that could potentially be replaced by another one that performs the same function (e.g., computing kinematics from neural data) but in a different way. Each module by itself can be divided into submodules to be inserted or removed as desired. This modular approach will address each issue separately, in hopes of leading to greater improvements in the field.

Glossary

Cortical mapping – Invasive mapping technique that consists of the application of electrical pulses to the cortical surface during or after open surgery to reveal eloquent functional regions.

DTI (diffusion tensor imaging) – Brain mapping technique that allows noninvasive imaging of white matter tracts' organization through the depiction of microscopic movements of water molecules in the brain tissue.

fMRI (functional magnetic resonance imaging) – Brain mapping technique that highlights noninvasively the cortical areas related to specific cognitive processes during a task of interest, through the local hemodynamic response to neuronal activity.

Hemispherotomy – Surgical procedure that consists of disconnecting a whole diseased hemisphere, while leaving intact the blood supply, leading to a situation of isolated contralateral functional hemisphere.

Hemisphereectomy – Surgical procedure consisting of removing a whole diseased hemisphere.

IAT-Wada test – The intracarotid amobarbital test (IAT) was proposed by Wada and Rasmussen in the 1960s. This invasive test relies on anesthetizing one cerebral hemisphere by injecting a short-acting barbiturate while proposing specific language and memory tasks to assess hemispheric dominance in patients.

aetiology of epilepsy. Only in the early twentieth century did Jackson define a seizure as "an occasional, an excessive, and a disorderly discharge of nerve tissue on muscles," also recognizing that seizures could alter consciousness, sensation, and behavior. One century later, many brain mapping techniques have become available to explore the cognitive symptoms that epileptic adults and children encounter. Strongly settled on neuropsychology, recent studies have brought major findings to understand language and memory impairments in epilepsy. This article aims at summarizing important contribution of brain imaging in adulthood epilepsy on these two cognitive fields. Recently, similar research in childhood epilepsy has already drawn promising data to better understand abnormal cognitive development in epileptic children.

Epilepsy and Language

Scientific and medical interest for language networks in epilepsy has emerged from the challenges of surgery of pharmacological intractable epilepsy in adulthood. Meanwhile, these researches have been very useful to understand neural substrates of normal language functioning. Both electrical cortical language mapping and the intracarotid amobarbital test have been widely used to map language cortical organization in patients. They revealed that, contrary to traditional assumption, language efficiency requires integrated neural network within and beyond Broca's and Wernicke's areas. For instance, the left inferior frontal gyrus sustains both phonological skills and semantic processes, while temporal and parietal regions contribute to speech sound processing and word recognition. However, as these techniques remain invasive, magnetic resonance imaging (MRI) appears as an alternative noninvasive, reliable, and complementary technique to explore language networks organization.

It is thus with regard to the disease called sacred: it appears

to me to be in no way more divine nor more sacred than other diseases, but has a natural cause from the originates like other affections. Men regard its nature and cause as divine from ignorance and wonder, because it is not at all like to other diseases. [...] The brain is the cause of this affliction. (On the Sacred Disease, Hippocrates, 400 BCE).

It has been a long way until medical and scientific communities established the neurophysiologic

Clinical Rationale for Language Mapping in Epilepsy

While 60% of epileptic adults positively respond to anti-epileptic drugs, some are considered for surgical treatment (resection of the epileptic zone) to minimize putative risks on cognition of repeated seizures and/or life-long medications. In adulthood, early onset of seizures is associated with less pronounced left hemispheric dominance. Indeed, a larger number of epileptic patients showed bilateral activations or right dominance suggesting that repeated insults lead to substantial reorganization. As no anatomical landmark is reliably associated with potential functional reorganization, an extensive preoperative functional assessment of language is necessary to identify: (1) hemispheric dominance for language and (2) intra-hemisphere organization of specific language skills. The main clinical point is the postsurgical outcome and therefore to find reliable preoperative prognostic factors. We propose an overview of recent work that has explored these issues.

Methodological Considerations

First, it is noteworthy that language functional magnetic resonance imaging (fMRI) protocols are multiple according to different goals and contexts (e.g., cognitive question to be tested in a group of healthy subjects versus individual analysis in cognitively disabled epileptic patient to discuss the surgical procedure and prevent postoperative deficit), making generalizations inappropriate. In clinical settings, the most commonly used ‘verb generation’ paradigm requires the subject to find and generate a corresponding verb for each presented noun (usually printed in the center of a black screen). Verbal fluency has also been reported in many early studies. Of simple technical implementation, these tasks however need the patient to perform substantially. In addition, these studies require the patient to perform the task silently, to avoid head motion artifacts, but this results in increased difficulty and possible cognitive confounds. Herein, several clinical teams prefer to involve epileptic patients in less-demanding tasks. Passive listening, naming, silent repetition, and many kinds of semantic decision tasks have been proposed, with or without controlling for performance during imaging sessions. Moreover, fMRI protocols require the choice of an adequate reference condition to be contrasted with recorded fMRI signal during language functioning. Reported works alternatively used rest or control tasks involving viewed symbols or tones. These varying parameters do contribute to apparent inconsistent findings among studies. In addition, strength of the scanner magnetic field (i.e., 1.5 or 3 T), voxel and cluster sizes, preprocessing techniques (i.e., smoothing, image normalisation, and motion

correction), and statistical thresholds are all to be considered with attention. Finally, in epilepsy context, ongoing medication has to be remembered not only when looking at individual maps but also when comparing groups (patients and/or controls).

Hemispheric Dominance for Language

Early language fMRI studies have focused on ‘language laterality,’ as surgeons need to know whether the left hemisphere they have to operate on is indeed dominant for language, like in almost healthy right-handed people. As IAT-Wada test has long been the ‘gold standard’ to test for language dominance (despite strong intrinsic limitations: rough assessment over a few minutes of numerous language subprocesses), several fMRI studies have compared both approaches to validate fMRI. Calculating a laterality index (LI) (with $LI = [V_L - V_R]/[V_L + V_R] * 100$, where V_L and V_R represent the volumes of activations in left and right hemispheres), authors have demonstrated a strong concordance between fMRI and Wada test (from 67% to 100% depending on the studies). For instance, one study reported that 78% of their 50 right-handed patients were left dominant for language, whereas 16% showed bilateral language organization and 6% were right lateralized. Another work has investigated covert word generation in 100 epileptic patients. Instead of calculating LIs, the study visually inspected patterns of activations of each individual and rated the images as typically (left) or atypically (right or bilateral) lateralized. According to fMRI, 71 were left dominant and 29 showed atypical lateralization. Data suggested good concordance between the techniques since 91% of scans gave conclusions similar to that of the Wada test. It is noteworthy that most of the patients with clear lateralization (82%) showed bilateral activations, demonstrating that language substrates are bilateral even if there is greater activation in one hemisphere. Importantly, LI values differ according to the language task. Expressive tasks such as overt fluency and word generation tasks are best lateralized and usually give better concordance between fMRI and IAT-Wada test. However, these tasks predominantly involve frontal regions while the tissue to be resected is frequently located in the temporal lobe (at least the temporal pole in temporal lobe epilepsy). To elicit temporal lobe activations, one team used a reading ‘responsive’ naming task requiring the subject to name an object described by a single written phrase. In addition to inferior and middle frontal activations, the authors reported posterior temporal lobe implication in this task. Nonetheless, the lateralization power of the temporal activation during perceptive tasks is lower than that of the frontal activation during expressive tasks.

Rather than considering the whole brain for LI calculation, several authors have focused on regions of interest

(ROIs) and showed that concordance rates were higher for frontal ROIs when compared with temporoparietal ones, independently of task designs. Interestingly, an effect of the presentation modality has been suggested in one study. Indeed, the results suggested that semantic visual decision tasks gave more lateralized patterns in frontal regions than auditory tasks.

Altogether, these findings strengthen the need for multitasking fMRI protocols in the preoperative work-up of epilepsy patients in order to ascertain language dominance at the individual level. When rigorously performed and analyzed by well-trained teams, fMRI appears now as a reliable noninvasive replacement of the Wada test for the assessment of language dominance in patients.

Intra-Hemispheric Cortical Organization of Specific Language Skills

Beyond the issue of language dominance in surgical candidates is the possibility of intra-hemispheric reorganization due to epileptic seizures and/or structural lesions. Thus, the question becomes: if language dominance has not shifted from the left to the right hemisphere, has there been any functional reorganization in the surrounding tissue or in remote ipsilateral regions? Cortical language mapping is considered the ‘gold standard’ to answer that question, leading to the localization of critical areas underlying specific skills. The stimulation of a critical language area in an awake subject leads to a disruption of the corresponding function (speech arrest, paraphasias, anomia, etc.). Thus, visual naming has been demonstrated to involve posterior inferior temporal cortex, posterior superior temporal gyrus, or mid- to posterior superior temporal cortex. However, this invasive approach remains technically challenging, and the extent of the cortical surface tested is limited by operative field constraints and length of testing. When studying the putative intra-hemispheric reorganization of language neuronal substrates in adulthood epilepsy, authors found intra-hemispheric differences between patients and controls, with patients activating the basal ganglia and cerebellum more than controls. A few studies have compared intra-operative stimulations and fMRI in short series of adults, revealing that the sensitivity of fMRI varied from 38% to 100%, and the specificity from 65% to 97%. However, one must remember that the underlying mechanisms of both techniques are drastically different. While fMRI shows all neuronal networks involved in a specific task, it does not take into account the hierarchy between participating regions. An activated region, therefore, may not be functionally critical for the language task under study (i.e., it could be part of the resection, without inducing permanent language deficit). Conversely, invasive cortical stimulation shows small

areas critical to language, but does not highlight the whole underlying network. To date, those techniques thus appear complementary, with fMRI used in a first step to highlight the lateralized network, and help localize the cortical regions to be subsequently tested by stimulation.

Predicting Postsurgical Outcome

fMRI constitutes a challenging opportunity to predict postoperative outcome after seizures foci resection. Indeed, while naming is frequently impaired after surgery of the dominant hemisphere, left-temporal lobe epilepsy patients with early age at onset appear to be at lower risk to experience postoperative language decline when compared with patient with later onset. Researchers have assumed that it was a consequence of early language network reorganization (shift) in the former group. In addition, presurgical good performance in naming has been found to predict poorer outcome, suggesting that the resected tissue remained functional. Recently, scientists explored the prognostic value of fMRI in patients undergoing left anterior temporal lobectomy. Patients performed a semantic decision fMRI paradigm both before and after surgery. The authors found that the language lateralization in the temporal lobe was predictive of naming postoperative decline, that is, the stronger the left lateralization, the worst the postoperative naming performance. In a similar approach, another team recently emphasized the utility of looking at anatomical connectivity lateralization in addition to functional asymmetry. Using diffusion tensor imaging (DTI), they observed that dominant anterior temporal lobe epilepsy patients had less dominant and greater nondominant intra-hemispheric connections when compared with controls. Moreover, they found a negative correlation between the lateralization of connections and the postoperative naming performance. That is, the patients with more extensive connections on the resected dominant side had the greatest language decline. Even though encouraging, more imaging studies are needed to understand postsurgical risks on language abilities in adulthood epilepsy.

Neurodevelopmental Plasticity

Nowadays, surgery is more frequently discussed in cases of young patients with drug-resistant epilepsies, because epileptic insults have a strong negative impact on neurological and neuropsychological development. On the other hand, the peculiar plasticity of the immature brain may limit these alterations. Several studies have been conducted in pediatric patients with severe epilepsy using pre- and/or postoperative language fMRI. In 1997, Hertz-Pannier and colleagues reported a first-language

fMRI study involving 11 children and adolescents with intractable complex partial seizures. The functional paradigm consisted of silent word generation beginning by a given letter or belonging to a given semantic category. Beyond the great concordance between IAT and fMRI in this population, the authors showed that functional MRI could be used in pediatric patients with good compliance in order to assess language dominance noninvasively.

Several surgical teams have proposed either hemispherotomy or hemispherectomy techniques to control for severe infantile epilepsy syndromes that involved a whole hemisphere. However, one may wonder how people could speak with a single cerebral hemisphere. Using a similar fMRI approach, Hertz-Pannier and colleagues examined the postsurgical mechanisms of neurodevelopmental plasticity in a young boy with intractable left seizures in the context of Rasmussen's encephalitis. This boy had developed normal language abilities before the onset of seizures. The presurgical fMRI investigation (using semantic verbal fluency) when he was 6 years and 10 months old revealed clear left lateralization of language functions. After left hemispherotomy at the age of 9 years, the boy experienced profound aphasia and alexia. Language outcome was spectacular with good recovery of receptive language and slower but almost complete recovery of expressive language and reading at 18 months postoperatively. Postoperative fMRI conducted at the age of 10 years 6 months revealed a shift of language-related network to the contralateral healthy hemisphere for both receptive and expressive tasks (word and sentence generation, story listening), in right regions homologous to the previously left activated areas (inferior frontal, temporal, and parietal cortex). Importantly, these right regions had not been found activated preoperatively. This unique study demonstrates the possible reorganization within preexisting bilateral but asymmetric language network in childhood. Furthermore, these findings argue in favor of the possible relatively late disconnection of the dominant hemisphere in cases of intractable epilepsies (earlier studies had proposed the age of 6 years as the limit). Recently, scientists reported the importance of specific regional activations for language recovery. Studying six hemispherectomy adolescents and young adults, they demonstrated that activations within Broca's area and its right homologous differed from those of normal controls. Patients with best outcome showed activation of both pars triangularis and orbitalis of Broca's area, whereas pars opercularis alone seemed unable to sustain efficient language. The authors suggested that distinct subregions within Broca's area and their right homologs subserve language, and that their variable activation may determine functional outcome.

Further fMRI studies are however needed to extend such findings to larger samples through early and late childhood.

Epilepsy and Memory

Historically, research on memory impairments in epilepsy has marked an important step with the famous case of patient HM, in whom bilateral amygdalo-hippocampectomy for intractable epilepsy had led to profound amnesia. Indeed, bilateral temporal damage may disrupt memory function and more specifically episodic memory. Fortunately, both improved patient selection and understanding of memory organization with the help of advances in functional imaging nowadays contribute to avoid such clinical outcome. Henceforth, it is well established that the hippocampus is involved in both novelty detection and multimodal information association. It is supposed to differentially sustain episodic encoding and retrieval according to its parts (anterior for encoding and posterior for retrieval). Several studies of healthy subjects demonstrated that hemispheric memory dominance differed with the type of encoded information: words preferentially activate the left hippocampus, faces and objects the right hippocampus and visual complex scenes activate both left and right hippocampi. Otherwise, frontal lobes also have an important implication in episodic memory processes and hemispheric specialization has been suggested, with the left frontal lobe rather sustaining episodic encoding, and the right one rather involved in retrieval.

In this article, we first report functional imaging studies that outlined hemispheric dominance for episodic memory in adulthood epilepsy. To date, published research has mainly been conducted in temporal lobe epilepsy. Subsequently, increasing literature has revealed possible alterations in specific skills within episodic memory functions. Therefore, we summarize those up-to-date studies that rely on structural mapping and neuropsychological investigations. Finally, we mention future directions for fMRI episodic memory research in childhood epilepsy.

Hemispheric Lateralization of Memory in Adulthood Epilepsy

Increasing literature is currently published concerning episodic memory substrates in adulthood epilepsy. Similarly to language functions, these studies principally aim at demonstrating whether fMRI could reliably replace the IAT-Wada test in assessing patient's hemispheric dominance for memory. During encoding of a verbal memory task, researchers found a lower activation in the left parahippocampal gyrus contrasting with a stronger left prefrontal activation in left temporal epilepsy patients when compared with healthy controls. A few years later, scientists designed an fMRI paradigm with encoding of complex visual scenes, faces, and

abstract drawings. They found asymmetrical hippocampal activations with good concordance with the IAT-Wada test. However, one team found more discordant results with a good agreement between both techniques only in patients with right temporal epilepsy. Recently, this team has examined the differential effects on memory lateralization of left versus right seizures and studied the duration of epilepsy as a possible factor of cerebral plasticity. Using a scene-encoding paradigm, the team found right-lateralized activation in the left onset epilepsy group. By contrast, right temporal epilepsy patients did not show significant increase in the degree of lateralization, suggesting a differential influence of left and right insults on memory neural reorganization. The authors also demonstrated a strong relationship between the degree of memory lateralization and mnemonic performances. Indeed, left epileptic patients performed more poorly than right ones, but greater left lateralization was associated with higher scores in both groups. Their findings strengthened previous results showing that left hippocampal lateralization was associated with better scores of verbal memory, whereas right lateralization was correlated to better nonverbal memory performance. However, neither age at onset nor duration of epilepsy was found related to the laterality indices.

Recently, researchers examined the relationship between the lateralization of language and memory-related activations. Left and right onset epilepsy patients performed an fMRI encoding and retrieval of word-pair associates, and the authors analyzed memory-related activation patterns of the hippocampi, as well as inferior frontal and temporolateral areas, which are linked to language functions. Similarly to the study mentioned above, they found more pronounced right lateralization of hippocampal activation in left epilepsy patients than in right ones. No such group differences were detected in frontal and temporolateral areas, suggesting that patients can show a shift of memory functions without substantial reorganization of language functions. However, this work did not use a specific fMRI paradigm to investigate language dominance. Future research may benefit from combining memory and language functional mapping.

Predicting Postsurgical Outcome

Even though the risk of memory decline after surgery on the temporal lobe is of major concern, few studies have been published. One study, which used presurgical activations during scene encoding to predict patients' postoperative performance, found that asymmetrical activation in the hippocampal, parahippocampal, and fusiform gyri was correlated to postsurgical outcome, that is, lower activation in the epileptic temporal lobe was associated with a smaller change (either decline or improvement) in memory performance postoperatively. Recently, researchers assessed the

preoperative value of fMRI to predict modality-related memory impairments following either left or right anterior temporal lobe resection. Main data revealed that patients with greater activation ipsilateral to the seizure focus compared to the contralateral side experienced greater memory decline after surgery, regardless of modality. That is, patients with more left lateralized presurgical activations had more difficulties in the verbal modality. Reciprocal results were obtained regarding the nonverbal modality. Interestingly, the authors did not detect significant correlations between hippocampal volume and memory decline (while controlling for side and modality). Such findings question both the relationship between functional and structural aspects of the neural substrates of episodic memory and the reliability of structural analyses to predict surgical outcome.

Recent Studies on Episodic Memory in Epilepsy

Several architectural models are now available to understand human memory functioning in adulthood, and more specifically, encoding, long-term consolidation, and retrieval of episodic information. Among available theories of episodic memory is Tulving's conception, in which episodic memory refers to "memory for personally experienced events" and especially includes the "autonoetic awareness of one's experiences in the continuity of subjectively apprehended time that extends both backward into the past [...] and forward into the future." The studies mentioned above did not integrate these crucial aspects in their episodic memory assessments. To date, only two brain mapping studies have been conducted in adulthood epilepsy to understand specific memory impairments concerning autobiographical memory or recollection as opposed to familiarity retrieval. The first study has measured the volumes of medial temporal lobe structures (e.g., hippocampus and parahippocampal cortices) and correlated them to memory performance. The authors showed that, when compared with controls, patients with left and right medial temporal lobe resection were impaired in retrieving personal past events and justifying them with spatial and temporal phenomenological details. These impairments concerned all periods of patients' life. The correlations between medial temporal lobe structures volumes and memory scores suggested that these structures are involved in reliving the episodic context of personal past events (i.e., recollection). The second study reported a specific memory retrieval profile in a woman who underwent surgical resection of left anterior temporal lobe structures for the relief of epileptic seizures. The resection spared the hippocampus, but included the parahippocampal cortex. Four different experiments comprising recollection-based versus familiarity-based retrieval showed that she performed normally in recognition tasks and provided much recollection-based answers

but that she was impaired when her answers were based on familiarity. Altogether, these findings outline the functional specialization of medial temporal lobe structures (i.e., hippocampus for recollection and context retrieval; parahippocampal gyrus for familiarity). Furthermore, the findings emphasize the need for developing such approaches using fMRI in order to better understand the everyday-life memory troubles of patients with various epilepsies and mnemonic complaints.

Future Directions to Assess Episodic Memory Impairments in Childhood Epilepsy

Due to ongoing deleterious processes of epileptic seizures on the immature brain, it has long been argued that epilepsy leads to global or undifferentiated cognitive deterioration. In the past 15 years however, it has been recognized that childhood epilepsy, and more peculiarly temporal lobe epilepsy, can cause specific memory impairment in otherwise normally developing children. Therefore, the putative reliability and validity of fMRI to assess neural memory networks in drug-resistant epileptic children is a recent preoccupation. This may partially explain nonexistent fMRI reports on episodic memory in childhood epilepsy in the scientific literature to date. However, several neuropsychological and methodological limitations also have to be considered. First, little is currently known about normally developing neural networks of episodic memory and the scarce recent findings need to be replicated. Second, involving children in episodic memory fMRI paradigms requires the child to understand complex and effortful task demands. Moreover, fMRI investigation of episodic memory requires good compliance, and minimal head motion, which can be difficult to obtain from epileptic children, notably if they experience additional slowness, attention, or intellectual deficiency. Furthermore, both number of stimuli and time duration in the magnet remain an important problem, as appropriate detection of local hemodynamic response constrains the experimenters to multiply stimulus presentation to reach statistical significance of activations (especially in medial temporal lobes).

Consequently, it is necessary to develop playful and motivating paradigms (i.e., no lists of long words but rather colored images), in concordance with theoretical knowledge about behavioral memory development (in terms of quantity of information, time processing, and attention for instance) and global intellectual efficiency at a given age in order to better understand episodic memory development from early childhood to late adolescence. Then, researchers would be able to determine specific memory reorganization in childhood epilepsy, taking cerebral development and onset and frequency of epileptic seizures and medication into account.

Conclusion

Brain mapping in epilepsy constitutes a robust fashion both to study complex cognitive skills, such as language and memory (and better understand their normal functioning), and to grasp the dynamic time course of epileptic seizures' impact on neural plasticity. Strongly related to the clinical issue of pre-/postsurgical outcomes of patients suffering from drug-resistant syndromes, these techniques bring complementary data to map the cortical networks in individuals (cortical mapping and fMRI; fMRI of language and memory). From now onwards, coupling imaging techniques and sophisticated neuropsychological designs may improve our knowledge concerning brain–behavior relationships during brain development and in adulthood.

Glossary

Arterial blood pressure – The arterial blood pressure maintained in the circulatory system. Mean arterial blood pressure ranges from 80 to 110 mmHg in C57BL/6J and 6N mice when recorded throughout the circadian cycle under stress-free conditions at constant room temperature (21°C) in the home cage. Peak values during fear memory recall reach ~140 mmHg in mice.

Autonomic nervous system (ANS) – Part of the peripheral (visceral) nervous system that is subdivided into the parasympathetic (PNS) and the sympathetic nervous system (SNS).

Bradycardia – The decrease of heart rate with regard to reference (baseline) values.

Conditioned contextual fear – Fear elicited by an array of various specific sensory stimuli (e.g., background noise, illumination, smell, and surface texture such as the shock grid) that remind of a particular environment, where fear was previously experienced.

Conditioned cued fear – Fear elicited by an explicit sensory cue such as light or a tone stimulus.

Conditioned stimulus (CS) – The initially neutral stimulus that elicits the conditioned response after the association of the CS with the unconditioned stimulus (US) has been made.

Heart rate – The rate (frequency) at which the heart beats as generally determined as average value across a defined time interval or assessed instantaneously, for example, based on the time interval between successive RR waves of the ECG complex. The maximum physiological range of heart rate is 400–800 beats per min (bpm) at constant room temperature (21°C) in C57BL/6J and 6N mice.

Radio-telemetry – Technique for remote (wireless) recording of various measures and used to monitor arterial blood pressure and ECG in man and mouse.

Tachycardia – The increase of heart rate with regard to reference (baseline) values.

Unconditioned stimulus (US) – The sensory stimulus that serves as either negative or positive reinforcer to form the association with the future conditioned stimulus (CS).

Introduction

General Introduction

Since the fundamental studies by Ivan Petrovich Pavlov on classical conditioning, a form of associative learning, especially eyeblink and fear conditioning, is extensively used to investigate the neural and molecular substrates of learning and memory. Fear conditioning results in the establishment of nonspecific emotional responses acquired after brief training. These emotional responses are also elicited by innate fear. By contrast, eyeblink responses are specific somatic motor responses that require extensive training, because they are not easily acquired. The gradual development of these eyeblink responses along many trials is preceded by cardiovascular adjustments.

Fear conditioning is a behavior test in which the conditioned stimulus (CS), an initially neutral sensory stimulus such as tone, light, or a specific environment (context), comes to evoke a fear response (conditioned response; CR) because it was previously paired with a noxious unconditioned stimulus (US), commonly an electric foot shock, that elicited the unconditioned response (UR). Based on associative learning, the CR will be elicited by the CS in the absence of any adverse stimulation as predictor of the US. Thus, the CS serves as psychological stressor evoking fear. Since dysregulation of fear pathways is thought to underlie affective disorders, the role of brain areas in the control of emotional responses, ranging from fear learning via its expression to reconsolidation and extinction of fearful memories, has recently gained enormous interest. Experiments are predominantly performed using behavioral readouts with a focus

on freezing, a species-specific defensive response in rodents that occurs as active suppression of ongoing behavior, an evolutionary adaptation to avoid visual attraction of potential predators. As independent concomitant measure to behavioral readouts, cardiovascular readouts (heart rate and blood pressure) have gained considerable interest to complement and improve our understanding of the neural circuitry involved in different phases of emotional learning and memory across different species, and to identify mechanisms by which affective disorders contribute to elevated cardiovascular risk. Comorbidity of cardiovascular and affective disorders is well characterized and cardiac risk is increased under conditions of emotional challenges such as psychological stress exploited by fear conditioning. Thus, cardiovascular responses, a subset of autonomic adjustments, serve as important physiological parameters with high temporal dynamics. The understanding of the brain–heart interaction with regard to basal cardiovascular function and stimulus-induced adjustments has become an area of research generally referred to as *Neurocardiology* with investigations employing CNS manipulations and its effects on autonomic function (neurovisceral integration), including learning-induced plastic changes. This research heavily depends on animal models for specific pharmacological and/or genetic interventions. Recent noninvasive human studies have focused on imaging techniques in combination with cardiovascular measurements and emotional tests, including fear conditioning.

Emotion and the Cardiovascular System

The cardiovascular system is crucially involved in the preparation for fight and flight – a concept introduced by Walter Cannon. Based on environmental challenges such as predatory threats, organisms need to adjust their physiological state by increasing metabolic supplies to prepare for the necessary anticipatory response to promote survival. This response is under high evolutionary selection pressure, and thus can be investigated across a wide range of animal species. In mammals, physiological adjustments, mediated by the autonomic nervous system, provide for valuable readouts indicative of changes of the emotional state in the absence of, for example, properly quantifiable behavioral measures. In general, an increased cardiac output is achieved by elevating heart rate and blood pressure via reduction of tonic parasympathetic (PNS) and activation of sympathetic nervous system (SNS) activity. Elevated cardiac output is achieved not only through heart rate increase but also through concomitant decrease in atrioventricular (AV) node conduction delay of cardiac excitation and increased contractile force. In addition, the peripheral blood flow is altered with reduced supply to intestinal organs and increased blood flow to the musculature and brain for an

optimal defense reaction. In view of the strong effect of aversive stimuli on cardiovascular adjustments, it is not surprising that the focus of research has been on aversive forms of URs (learning-independent; innate fear or anxiety responses) and CRs (associative learning-induced; based on fear conditioning). Experiments on appetitive conditioning have been performed in rats, monkeys, and dogs, and, if at all, the magnitude of generally observed tachycardia is relatively small when compared with that observed in aversive conditioning. In general, the cardiovascular effects are blocked by peripherally acting β -adrenergic antagonists, thereby indicating regulatory effects mediated by the activation of the SNS. For that reason the focus of this article will be on neural substrates underlying aversive conditioning predominantly based on research in rodents.

Methods and Limitations

While straightforward methods exist to measure cardiovascular parameters in humans, the outcome of animal studies crucially depends on the experimental conditions. Unspecific stressors influence experiments in animals even more than in humans. Examples of stressors are restraining, recording conditions using externally placed electrodes, and interference by the experimenter. Blood pressure methods under semi-restrained conditions using tail-cuff systems in rodents are essentially inadequate to determine physiologically relevant cardiovascular adjustments in a defined behavioral setting. With the development of implantable miniaturized radio-telemetry techniques (Figure 1), remote recording of cardiovascular parameters in freely moving mice and rats has become a standard method. A major disadvantage of radio-telemetry is the considerable surgical demand followed by sometimes long-lasting recovery periods that are necessary for full recovery of small animal such as mice, before actual experiments can be performed.

The invaluable advantage of the radio-telemetry approach is that physiological measures can be obtained even under experimental conditions with restricted possibilities for behavioral assessment such as experiments in the home cage in which all unspecific stress can be avoided. In this way, valid baseline data can be obtained that are needed for the assessment of autonomic adjustments under physiological conditions. Environmental challenges such as novelty exposure are emotionally demanding for mice, and easily elevate baseline heart rate. Based on elevated heart rate values, physiological response magnitudes may be diminished when elevations are expected because species-specific maximum physiological levels exist (~ 800 bpm in mice). Another complicating issue in cardiovascular assessment is that physical activity contributes to autonomic changes paralleling effects that are generally observed during aversive

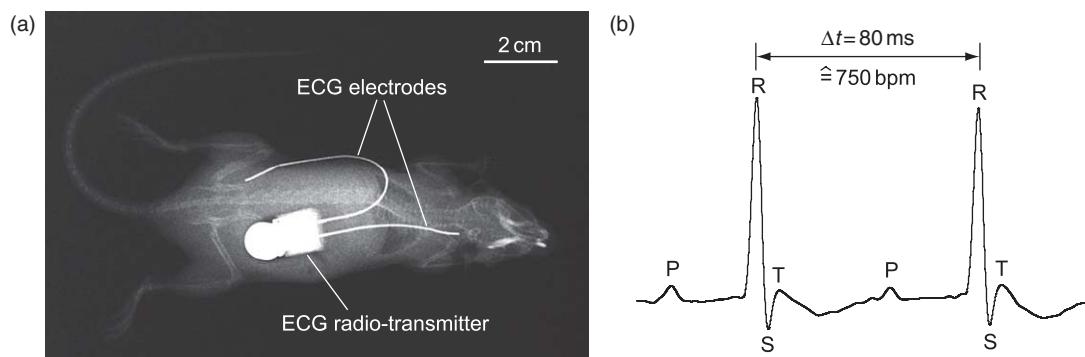

Figure 1 X-ray image (dorsal view) of a mouse with intraperitoneally implanted ECG radio-transmitter and subcutaneously placed electrodes positioned for a type II ECG recording (a) and optimal ECG signal of the same mouse (b) with the conversion of the RR interval of the ECG complex (with individual wave forms P-T) into heart rate (given in beats per min (bpm)).

emotional challenges. Therefore, it is crucial to determine whether autonomic effects are attributable to fear or anxiety, or simply to increased locomotor activity.

Cardiovascular measures are predominantly presented as time-averaged values reporting an increased or decreased heart rate and/or blood pressure without specific information on the underlying short-term dynamics. The dynamical features especially of heart rate variability (beat-by-beat variation) provide useful information on the interdependent activity, the sympathovagal balance of the sympathetic and parasympathetic subdivisions of the autonomic nervous system. Heart rate variability serves as important index of pathological changes and is used to diagnose cardiovascular risk in man. Studies that have focused on relative heart rate and/or blood pressure changes as opposed to absolute values often ignored the impact of interventions on basal physiological function. Thus, future research carefully needs to address the effects of local interventions on baseline function using sensitive and physiologically relevant (e.g., nonlinear) measures since small cardiovascular changes may have statistical significance, but their physiological relevance is limited. Nonlinear measures identified an important contribution of tonic parasympathetic activity to long-range correlation of heartbeats in their temporal sequence indicating the central role of the central nervous system to the dynamical features. Nonlinear (scale-invariant) measures have superior sensitivity in forecasting cardiac risk states in man in the absence of electrocardiogram (ECG) alterations and allow for translation of results across different mammalian species.

Conditioning-Specific Cardiovascular Responses in Different Species

Differences in cardiovascular fear responses exist in various species beyond the well-described allometric relation between body size and heart rate that are linked

to absolute heart rate values in mammals and birds, that is, the larger the animal the lower its basal heart rate. Ambient temperature has a strong impact on baseline heart rate in mammals, since ambient temperature affects the metabolic needs to maintain body temperature. These effects are especially prominent in small animals such as mice with a relatively high baseline heart rate due to higher metabolic needs to maintain body temperature as a consequence of their large surface area to volume ratio compared with larger animals. The closer the ambient temperature is to that of the thermoneutral zone of a species, the lower the baseline heart rate will be due to reduced metabolic activity to sustain body temperature, and the larger stimulus-induced adjustments may become.

In humans, rats, and mice, generally tachycardia and blood pressure increase are common responses to a conditioned or unconditioned stressor. Interestingly, the dynamical properties of heart rate and blood pressure adjustments in mice (fast and slow, respectively) are opposite to that reported in rats, where fast blood pressure increase and slower increase of heart rate occur. The conditioned fear-induced tachycardia in mice occurs after a single tone-shock presentation when CS (tone) and US (foot shock) are presented during training in the delay mode, that is, CS offset coincides with US onset. In mice the beat-by-beat fluctuation of heart rate illustrates the highly dynamical properties of this physiological function: extremely fast heart rate changes (half-time $t_{1/2} \sim 3 \text{ s}$) and relatively large response magnitudes occur, while the concomitant blood pressure increase is considerably slower (half-time $t_{1/2} \sim 52 \text{ s}$) when mice are re-exposed to the tone-CS in the home cage 24 h after training (Figure 2). The heart rate response is thus characterized by high heart rate variability under baseline stress-free conditions (pre-CS phase). When heart rate is increased to maximum level during CS (tone) presentation, the variability is substantially reduced (Figure 2(a)). Thus, heart rate and its

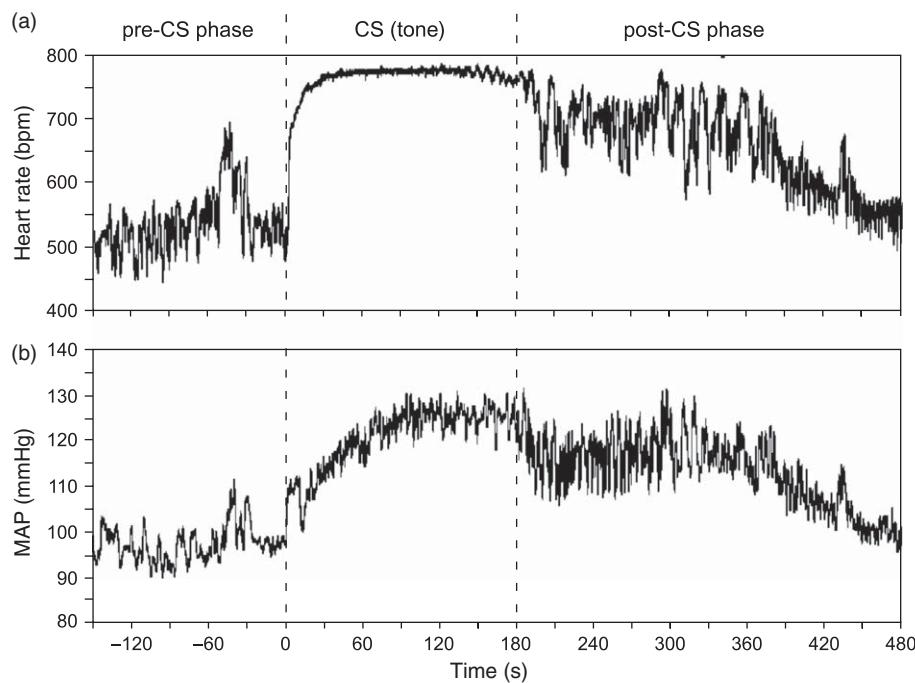

Figure 2 Typical heart rate (a) and mean arterial blood pressure (MAP) responses (b) during expression of fear conditioned to an auditory cue in a C57BL/6N mouse. Heart rate is characterized by high variability under baseline stress-free conditions (pre-CS phase) that is substantially reduced during CS (tone) presentation, since heart rate and its variability are inversely related. The temporal dynamics of conditioned fear-induced adjustments are fast for heart rate and relatively slow for blood pressure. The apparently increased noise in the MAP values during the first part of the post-CS phase is due to moving artifacts that have an impact on the blood pressure waveform recorded by a blood pressure radio-transmitter with the pressure catheter placed in the abdominal aorta. The tone-CS (180 s duration) was presented in the home cage 24 h after training with six paired tone-CS/US presentations.

variability are inversely related. The conditioned tachycardia occurs only under specific training conditions demonstrating its dependency of the association of the CS with the US on its contingency relation (Figure 3). The relatively mild and transient heart rate increase (~ 60 bpm) at tone onset in mice that did not form an aversive association has been interpreted to reflect attention processes (Figure 3).

The conditioned tachycardia acquired after a single-paired CS-US presentation (delay conditioning) during training is prevented by systemic injection of the protein synthesis inhibitor cycloheximide (Figure 4(a)) indicating that memory consolidation, needed to establish long-term memory 24 h after training, is impaired. Furthermore, nonreinforced re-exposure to the CS (tone) once daily in the home cage leads to a gradual extinction of the conditioned tachycardia (Figures 4(b) and 4(c)).

Rabbits display fear-induced heart rate decrease (bradycardia, as an adaptive strategy when playing dead (Thanatosis) during ultimate predatory threat) and blood pressure fall, indicating species-specific differences in the dynamical properties of various conditioned cardiovascular responses. Similarly, a tone-CS-induced profound bradycardia is observed in bats. The bradycardia response

in rabbits is relatively low in magnitude but allows one to record dynamical changes with regard to transient adjustments to repeated CS presentation at high rate.

Central Autonomic Network

The central autonomic network (CAN) has been characterized in considerable detail using various anatomical/histological techniques. It is not surprising that the CAN has considerable overlap with the central fear pathways. Various labeling techniques identified the CAN from brainstem to forebrain areas that are involved in direct and indirect regulation of the autorhythmicity of the primary and secondary pacemaker centers in the heart, the sinus node, and the AV node, respectively. A simplified schematic overview of the CAN and its peripheral action on the cardiovascular system is presented in Figure 5. In the following sections the effects of local interventions on the function of individual brain areas of the CAN will be described. The CAN will be followed from cortical areas via efferent connections to areas in the lower brainstem and their effects on conditioned cardiovascular responses will be described. Effects on unconditioned (innate) cardiovascular responses will be

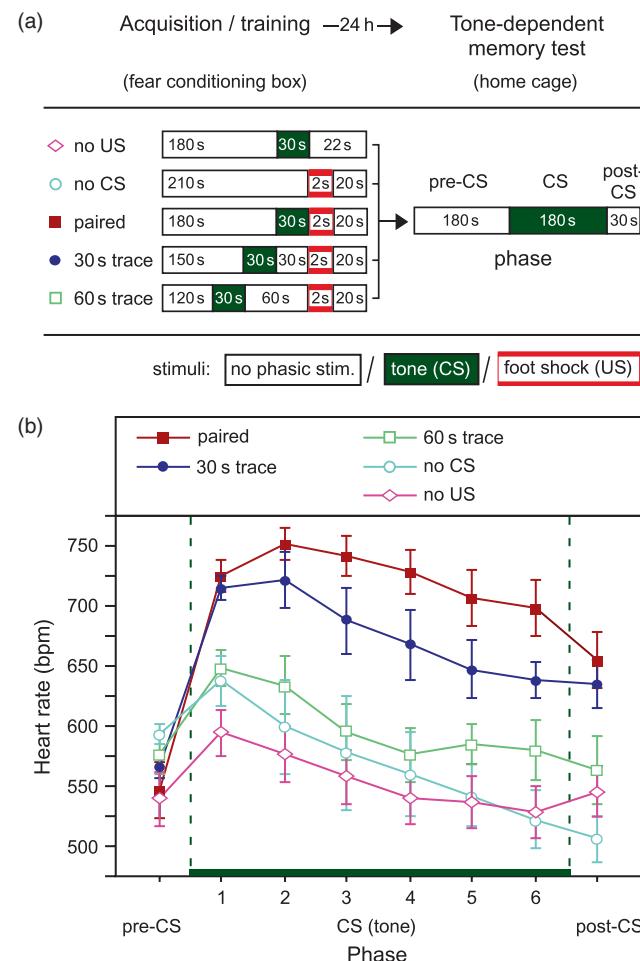

Figure 3 Training sequences (a) and averaged heart rate responses of C57BL/6N mice in the retention test (b) during re-exposure to the tone as a function of the training sequence. Mice were subjected to five different training sequences (no US, no CS, paired, 30 s trace, and 60 s trace) and 24 h later re-exposed to the tone in the home cage (a). A strong tachycardia was observed in mice only if they were trained with CS and US presented in a paired or at 30 s trace interval, whereas the three other groups responded with a mild and transient tachycardia that is interpreted to reflect an attention response (b). Mice that show the strong tachycardia also exhibit conditioned freezing responses to the tone-CS (data not shown). Modified with permission from a publication of Neuroscience and Biobehavioral with reviews from Elsevier.

included to differentiate the specific contribution of these brain areas to innate versus learned cardiovascular adjustments.

Forebrain Areas Involved in Conditioned Cardiovascular Adjustments

Higher cognitive centers are involved in the processing of environmental information such as conditioned stimuli that trigger cardiovascular adjustments via efferent outputs. These adjustments alter the tonus of both the sympathetic and parasympathetic branches of the autonomic nervous system. In the following section we discuss the specific brain areas involved in the adjustments of cardiovascular responses elicited by conditioned fear by altering basal function in preparation to cope with a potential threat.

Prefrontal cortex

The prefrontal cortex (PFC) plays an important role in executive functions, including decision making and stress controllability. Thus, the PFC is involved in behavioral flexibility and in extinction of fear responses. Of particular interest (from the viewpoint of autonomic involvement) is the ventromedial portion of the PFC in humans and the medial PFC in rodents. The medial PFC is comprised of the anterior cingulate, prelimbic, and infralimbic cortices. Anterior cingulate lesions attenuated conditioned heart rate decelerations in comparison to posterior cingulate or sham lesions, but enhanced the magnitude of the bradycardiac component of the orienting reflex in rabbits. Electrical stimulation revealed effective sites for eliciting heart rate and blood pressure changes in rabbits only in the anterior cingulate cortex. Here, relatively large (70–100 bpm) heart rate decelerations were accompanied by relatively small (1–5 mmHg)

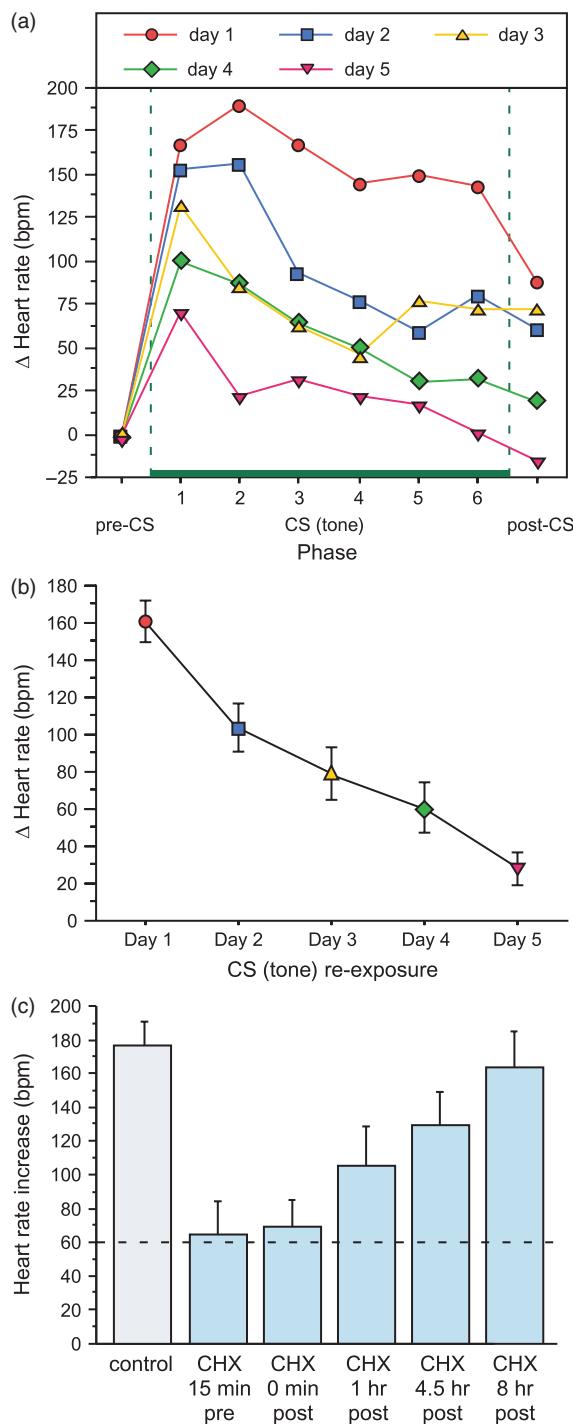

Figure 4 Effects of extinction and protein synthesis inhibition on heart rate responses as index of fear conditioned to an auditory cue. Repeated (daily) nonreinforced re-exposure to the 180-s tone serving as CS in C57BL/6N mice causes a decrease of the conditioned tachycardia along six consecutive 30-s intervals (a) and the grand means of the 180-s tone-CS period shown in (b). Impairment of consolidation processes by the protein synthesis inhibitor cycloheximide (CHX) attenuates the tone-CS induced tachycardia to the heart rate increase (~60 bpm) observed in nonconditioned mice (c). Pre and post refer to the timing of drug injection with regard to training. Modified with permission from a publication of Neuroscience and Biobehavioral with reviews from Elsevier.

blood pressure changes. Increase of regional blood flow occurs in the right anterior cingulate cortex during emotional challenge and covaries with mean arterial blood pressure in human subjects. The infralimbic part of the PFC projects to various brain areas that are implicated in autonomic regulation. Lesions and transient inactivation of the medial PFC before training reduce conditioned freezing, tachycardia, and blood pressure in various species from rats to rabbits when they are re-exposed to both conditioned explicit (tone) and contextual cues. Transient inactivation studies suggest that the medial PFC plays a role in encoding and/or consolidation of contextual fear conditioning. Moreover, experiments with pretest inactivation of the PFC indicated a role of the ventral (infralimbic) portion of the medial PFC in expression of cardiovascular fear response. However, the effects were not specific to CRs because reduced cardiovascular responses were also observed to unconditioned emotional stimuli suggesting a more general role in the expression of aversive emotional responses. Stimulation of the medial PFC neurons elicits cardiovascular effects as observed in conditioning experiments. Pharmacological interventions investigating the role of sympathetic and parasympathetic outflow showed that the medial PFC predominantly controls the sympathetic nervous system. This view is consistent with an increased selective attention and elevated sympathetic activity upon magnetic stimulation of the PFC in humans presented with emotionally challenging pictures such as angry faces.

Insular cortex

The insular cortex is part of the CAN. When stimulated by implanted electrodes in the anterior and posterior insular cortex, bradycardia was observed in rabbits. Lesioning of these areas, however, did not abolish but only mildly attenuated the conditioned bradycardia in rabbits. The role of this brain in conditioned fear responses in other species requires further investigation.

Hippocampus

Evidence exists for a role of the hippocampus in conditioned cardiovascular responses indicative of conditioned contextual fear. CA1 neurons of the hippocampus project predominantly to prelimbic and infralimbic areas of the PFC. The ventral hippocampus projects to the amygdala and is involved in emotional memory and anxiety. Post-training and pretest inhibition of dorsal hippocampal function decreased cardiovascular fear responses. Additionally, dorsohippocampal lesions abolished bradycardic responses in rabbits during conditioning only when CS and US were presented in a trace but not delay mode. This finding is consistent with the role of the dorsal hippocampus for the encoding of fear memory to explicit cues in trace conditioning experiments.

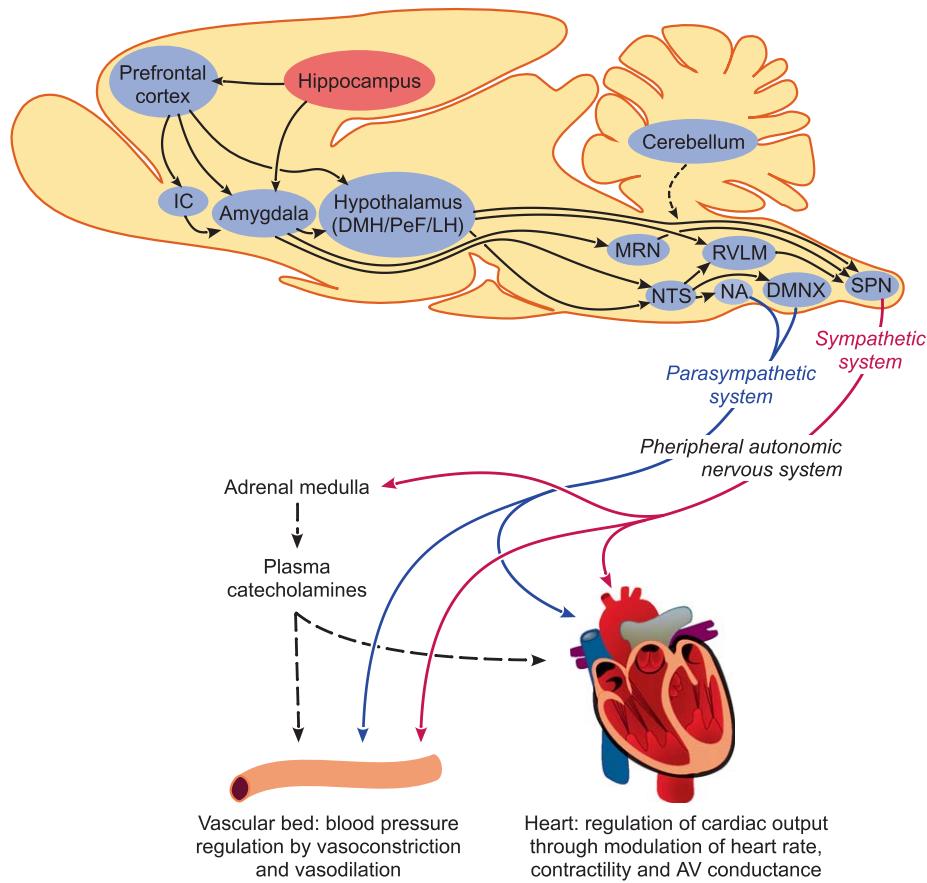

Figure 5 Simplified schematic diagram of prominent central autonomic pathways involved in conditioned cardiovascular adjustments. Blue ellipses denote brain areas that are part of the central autonomic network, whereas the hippocampus (red ellipse) is implicated in cognitive modulation of the central autonomic network depicted on the sagittal section of a rodent brain. The thin blue line from the parasympathetic system to the vascular bed indicates its low contribution to vasoconstriction and -dilation. Besides fast neural regulation via central and peripheral autonomic pathways, slower stress hormone release (catecholamines from the adrenal medulla) also contributes to cardiovascular regulation. AV: atrioventricular; DMNX: dorsal motor nucleus of the nervus vagus; DMH/PeF/LH: dorsomedial/perifornical lateral hypothalamus; IC: insular cortex; MRN: median raphe nucleus; NA: nucleus ambiguus; NTS: nucleus tractus solitarius; RVLM: rostral ventrolateral medulla; SPN: sympathetic preganglionic neurons of the spinal cord.

Amygdala and extended amygdala

The amygdala is an assembly of functionally different subnuclei. Information processing of an auditory cue such as tone that serves as CS requires auditory afferents projecting to the thalamus and, depending on the complexity of e.g. discriminatory learning, also auditory cortex function. From the thalamus and the auditory cortex information is then relayed to the amygdala with the basolateral amygdala (BLA) important for CS-US association and thereafter to the central nucleus (CNA) for fear expression.

In rats with lesioned BLA the normally observed heart rate responses to a tone-CS were absent when tested 1 and 24 h after training, while CS-induced heart rate effects were still observed during training suggesting an important role of the BLA for learned rather than innate fear responses. However, the BLA is under tonic gamma aminobutyric acid (GABA)ergic inhibition. Removal of this inhibition by local antagonist injection (dysinhibition)

increases anxiety- or panic-like behavior and elicits cardiovascular activation in rats.

The medial nucleus of the amygdala receives input from the main and accessory olfactory bulb and is involved in cardiovascular responses to innate fear responses, for example, those triggered by olfactory cues such as the fox feces compound 2,5-dihydro-2,4,5-trimethyl-thiazolidin (TMT) in rats (sustained blood pressure increase). Similarly, alarm pheromones (detected in the Grüneberg ganglion) trigger innate freezing responses in mice and are also expected to elicit cardiovascular responses indicative of fear.

Electrolytic lesions of the CNA inhibit the conditioned bradycardia in eyeblink conditioning in rabbits and both the conditioned cardiovascular social stress responses and the conditioned fear-induced blood pressure increase in rats. Stimulation of CNA neurons through chronically implanted electrodes elicits cardiovascular responses in awake but not anesthetized rats. These responses resemble those observed in emotional

conditioning. CNA lesions blunt the cardiovascular responses to unconditioned stimuli. Different projections from the CNA to hypothalamic and brainstem areas (see below) mediate the expression of learned and innate behavioral and cardiovascular responses indicative of fear.

The role of the bed nucleus of the stria terminalis (BNST), a part of the extended amygdala, in conditioned behavioral and cardiovascular responses is controversial. No effects on blood pressure changes were observed in rats with neurochemical lesion of the BNST when using conditioned auditory fear cues. In contrast, attenuated tachycardia and blood pressure increase to conditioned contextual cues was observed in rats following pretest inactivation of the BNST. These results suggest an anxiety-like role of the BNST in the expression of conditioned cardiovascular fear responses. This difference may be related to a more general anxiety-like role of contextual versus explicit unisensory cues and warrants further investigation.

Hypothalamus (perifornical area, dorsomedial hypothalamus, and paraventricular nucleus)

The hypothalamic defense area, the dorsomedial/perifornical lateral hypothalamus (DMH/PeF/LH), has long been identified to be crucial for the expression of conditioned but also unconditioned cardiovascular responses indicative of fear. Projections from this area to the caudal part of the periaqueductal gray (PAG) are essential for the somatic component of the defense response such as freezing, the active suppression of ongoing behavior in fear conditioning, as a default response to avoid visual attraction of predators. Sympathetic regulation of the cardiovascular fear and anxiety response occurs directly through projections from the DMH/PeF/LH to sympathetic preganglionic neurons (SPNs), and indirectly via the rostral ventrolateral medulla (RVLM) and the median raphe nucleus (MRN).

Cerebellum

The cerebellar vermis is involved in cardiovascular regulation during movement and posture changes. Eyeblink conditioning experiments demonstrated that the cerebellar vermis is also involved in conditioned bradycardia in rabbits. Vermal lesions impair heart rate conditioning. During emotional challenge an increase of regional blood flow occurred in the cerebellar vermis that covaried with mean arterial blood pressure changes in human subjects. Patients with cerebellar lesions did not show the conditioned bradycardia by fear as observed in controls. The pathways mediating the conditioned bradycardia are not well understood. Different cardiovascular modules in the cerebellum have been described that project to the parabrachial nucleus but may include other brainstem areas.

Brain Areas Involved in Basal Cardiovascular Regulation

Basal cardiovascular regulation is a complex physiological process that depends on feedback systems, including the baroreflex from the periphery to the central nervous system. Forebrain areas provide modulatory inputs to various brain areas which in turn provide outputs to specific areas involved in the adjustment of cardiovascular functions to meet the demands in preparation for, for example, fight and flight. Maintenance of basal cardiovascular function is attributed to hypothalamic and lower brainstem areas. Interference with the function of brain areas will always have an impact on both conditioned and unconditioned (innate) autonomic adjustments indicative of fear responses.

Although ibotenic acid lesions of the ventrolateral PAG cause a strong reduction of the freezing response of rats to conditioned auditory and contextual cues, the concomitantly occurring blood pressure increase is unaffected. These findings demonstrate the dissociation of projections from the CNA via the hypothalamus to different brainstem areas for the control of conditioned (but also unconditioned) behavioral versus cardiovascular responses. The dorsal and median raphe nuclei (MRN) are the principal source of serotonin and project to virtually all brain areas. Descending MRN neurons are involved in cardiorespiratory regulation and descending projections to the spinal cord participate in blood pressure control with serotonin playing a critical role in vagal outflow. The rostral ventrolateral medulla (RVLM) is the primary regulator of the sympathetic nervous system, with projections to the sympathetic preganglionic neurons (SPNs) in the spinal cord that are essential for the blood pressure response. The nucleus tractus solitarius (NTS) is the primary input area for the baroreflex modulation to maintain blood pressure within the physiological range. The nucleus ambiguus (NA) is involved in heart rate control and also in central regulation of blood pressure. Vagal preganglionic neurons originate from the NA and the dorsal motor nucleus of the nervus vagus (DMNX).

Implications for Affective Disorders

The beat-by-beat fluctuation of the heart serves as an index of the brain state. The cardiac time series, the beat-by-beat variation of heart rate, collectively reflects the total efferent nerve traffic of the autonomic nervous system. Dysregulation of the fear circuitry is implicated in the pathology of affective disorders from anxiety disorder to posttraumatic stress disorder. An improved understanding of the role of individual brain areas in central autonomic regulation and its contribution to

dysregulation is of high relevance in view of the comorbidity of affective and cardiovascular disorders. Fear conditioning therefore is an extremely useful model to investigate the role of specific brain areas in different processes from encoding via consolidation to reconsolidation and extinction of learned cardiovascular responses. The comparison with URs allows the dissection of contributions of these brain areas for learned versus innate responses.

Berntson and colleagues drew three main conclusions on anxiety and cardiovascular reactivity of patients suffering from anxiety disorders. (1) Anxiety disorders are frequently associated with altered autonomic function, although these alterations may vary considerably across different categories of anxiety disorders, and among individuals within a given category (personality traits). (2) Autonomic reactions often mirror the pattern of exaggerated affective/behavioral response, rather than reflecting a primary abnormality in autonomic regulation. (3) Enhanced autonomic reactivity is most often apparent in phasic responses to specific stimuli or contexts, rather than in basal measures. In view of these conclusions, it is hypothesized that forebrain areas such as the PFC may contribute to exaggerated cardiovascular responses due to lack of inhibitory control of emotional centers such as the central nucleus of the amygdala. This control has been reported to occur via the intercalated nucleus of the amygdala. It remains to be determined whether this pathway, for which behavioral and electrophysiological evidence exists, is also involved in the control of the extinction of cardiovascular responses elicited by conditioned fear. Hypofunction of the PFC, particularly the infralimbic area, appears to be associated with increased susceptibility for affective disorders such as posttraumatic stress disorder. Changes in neural excitability and epileptic-like hyperactivity of the SNS or dysinhibition of the PNS in the CAN underlie the generation of fatal tachyarrhythmias. Transient inactivation of the amygdala prevents tachyarrhythmias elicited by psychological stress in pigs with compromised heart function. Tachyarrhythmias are implicated in sudden cardiac death based on episodic central autonomic dysregulation, and the risk for sudden cardiac death is increased during emotional challenge as documented in epidemiological studies.

The limited understanding of the exact role of specific brain areas stems from the complexity of the cardiovascular system and its function under physiological condition. We attempt to isolate contributions of individual brain areas to specific responses. Thereby, we often ignore feedback mechanisms that continuously contribute to dynamic heart rate and blood pressure regulation that play important roles in the maintenance of basal cardiovascular function and adjustments by emotional challenges.

Conclusions

Cardiovascular parameters are extremely useful to investigate especially emotional learning-induced adjustments that can complement and extend behavioral studies and improve our understanding of the neural substrates that partly differentially contribute to cardiovascular versus behavioral responses. Yet, there is a need for a more detailed understanding of the brain–heart interaction for the expression of learned and innate cardiovascular responses. To better understand the role of individual brain areas of the CAN for cardiovascular baseline regulation and stimulus-induced adjustments (partly through cognitive processes), a shift is required to physiologically relevant experimental conditions and analyses beyond the linear domain. This is necessary since cardiovascular regulation involves complex feedback mechanisms acting on multiple timescales from fast baroreflex feedback to slow circadian hormone fluctuation-related effects. The progress in the analysis of dynamic properties of cardiovascular measures by nonlinear measures will provide for invaluable new insights in neurocardiology, the translation of results across species, and an increased sensitivity of diagnostic power to identify pathological states of autonomic dysregulation in affective disorders. Taken together, this will add to an increasingly complex picture of the tight coupling of brain and heart function.

Cerebellum: Associative Learning

K M Christian, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Published by Elsevier Ltd.

Glossary

- Conditioned response (CR)** – A learned behavioral response to a conditioned stimulus resulting from an acquired association with an unconditioned stimulus.
- Conditioned stimulus (CS)** – A stimulus that does not elicit any overt behavioral response prior to associative learning.
- Expansion recoding** – The means of transforming, or expanding, a given input into a sparse or distributed representation to make the problem of pattern separation and recognition easier to solve.
- Somatotopy** – The correspondence between areas of the body and neural regions that exert control over or are responsive to stimulation of those areas.
- Unconditioned response (UR)** – The reflexive behavioral response evoked by certain stimuli.
- Unconditioned stimulus (US)** – A stimulus that elicits an innate or reflexive response.

the nature of the information acquired and the response itself. Certainly, sensorimotor systems are required, first, to transduce the information related to the critical stimuli and then, subsequently, to perform the sequence of actions reflective of the memory, but it is the integrative neural trace of the association itself that is the focus of learning-related research. Several structures have emerged as being the critical loci of plasticity underlying specific types of associative memory. For example, emotion-based memory often involves the amygdala and the amygdalar nuclei are critical for the acquisition of conditioned fear – a process wherein neutral stimuli become associated with a fearful event. Similarly, the medial temporal lobe is involved in some forms of associative learning as well as long-term storage of associative information. Structures within this region show changes in neural activity at time points that precede and/or coincide with the behavioral expression of newly acquired associations between visual stimuli, as well as novel spatial and temporal relationships between task-relevant environmental features. But, perhaps, the most exhaustive and complete description of the neural instantiation of memory in the mammalian brain is that involving a simple form of associative memory localized to the cerebellum – namely, classical conditioning of discrete reflexes to behaviorally neutral stimuli. That the cerebellum is involved in cognitive processes at all was met with some resistance originally, although it is now widely accepted that it is the essential neural substrate for the acquisition and expression of this associative memory.

Introduction

Associative learning is the process through which organisms acquire information about relationships between events or entities in their environment. It is expressed as the modification of existing behaviors, or the development of novel behaviors, that reflects the conscious or unconscious recognition of a contingency. It is the contingent, and contiguous, relationship among stimuli that is a hallmark of associative learning – a meaningful temporal or spatial proximity of A and B and the perceived consequent occurrence of B if A. As such, it is fundamental to our sense of causality and is the basis of much of our understanding of the external world. Associative learning also underlies the majority of our adaptive behavior when the association is recognized to have either positive or negative consequences. Adaptive changes in behavior can be triggered by both aversive and appetitive stimuli and can thus enable the organism to avoid negative outcomes or to increase the probability of obtaining a reward. This type of associative learning depends on the presence of signaled reinforcement.

However, there are many forms of associative learning, and the brain regions that support the acquisition and expression of these learned behaviors are determined by

Cerebellum in Motor Control

Historically, the cerebellum was viewed primarily as a structure that simply modulated or refined the execution of extant motor programs. Evidence for the involvement of the cerebellum in motor control came initially from studies of patients in the nineteenth and early twentieth century in whom cerebellar damage correlated with a loss of coordinated movement. Generally, it was observed that lesions to the cerebellum resulted in deficits in the movement of limbs ipsilateral to the site of damage. However, a myriad of movement-related abnormalities were reported, including extensor rigidity, dysmetria, and dysfunctions in motor-sequence execution, equilibrium, and gait control. Additional evidence for the role of the cerebellum in motor function came from studies in which

stimulation of cerebellar regions elicited movements. Although there was not a single, incontrovertible interpretation of how the cerebellum contributed to motor control, it was clear that this structure played a significant role in the coordination, timing, and execution of movements. This accurate, but somewhat limited, view of cerebellar function dominated and circumscribed research until the middle of the twentieth century. In addition, this view still holds considerable influence as evidenced by the many current descriptions of the cerebellum primarily as a facilitator of motor coordination. However, we now know that the cerebellum is capable of encoding new associations and plays a significant role in motor and nonmotor learning, as well as related processes including timing and attention. Parallel lines of evidence from anatomical, theoretical, and behavioral studies in support of this more expansive view of cerebellar function are detailed below.

Cerebellar Anatomy

Cerebellar Cortex

Since the development of an influential theory of cerebellar was based on a close analysis of the relevant circuitry, a brief overview of the anatomy is necessary to

ground any discussion of cerebellar function. The cerebellum is a deeply foliated structure in which a structurally uniform and functionally heterogeneous cortical layer overlies extensive white matter and deep nuclei. Sensory information is relayed to the cerebellum via the pontine nuclei and inferior olive. Axons from principal excitatory neurons in each of these structures terminate on neurons in both – the cortex and the deep nuclei (**Figure 1**). Pontine nuclei receive visual, auditory, and somatosensory information from cortical and subcortical regions which is transmitted via mossy fiber axons to cortical granule cells, the most numerous cells in the cerebellum. Axons of granule cells bifurcate in the upper layers of the cerebellar cortex and extend transversely through the dendritic arbors of the Purkinje cells to make synaptic contacts on the spiny dendrites. Climbing fibers carry somatosensory information from the inferior olive to deep nuclear cells and Purkinje neurons in the cerebellar cortex. Purkinje neurons have a distinctive morphology due to an extensive and planar dendritic arbor positioned orthogonal to the longitudinal axis of the folia. Purkinje cells receive up to 150 000 excitatory synaptic contacts from nearly the same number of parallel fibers. These cells also receive hundreds of excitatory synaptic connections from a single climbing fiber – the

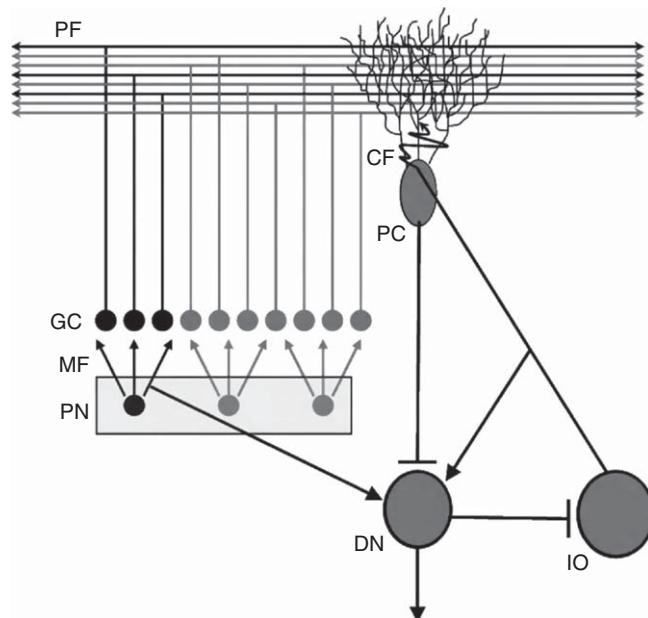

Figure 1 Simplified diagram of cerebellar circuitry (cortical interneurons have been omitted) to illustrate critical paths for integration of information required in associative learning. Two key sites of putative integration are the Purkinje cell (PC) and the deep nuclei (DN). Both receive inputs from the pontine nuclei (PN) and inferior olive (IO) which carry information related to the CS and US respectively. Mossy fibers (MF) and climbing fibers (CF) send collaterals to the deep nuclei, as well as primary projections to the Purkinje cell layer. CS information is believed to undergo expansion recoding via the granule cells (GC) within the cerebellar cortex. A simplistic illustration of this process is shown by the black-filled granule cells that send bifurcating axons, parallel fibers (PF), to synaptic targets on the extensive dendritic arbor of the Purkinje cell resulting in a sparse representation of contextual information. Climbing fibers contact a single Purkinje neuron, densely innervating the base of the dendritic tree. Arrowheads indicate excitatory connections and terminal bars indicate inhibitory projections.

ascending axon of a cell in the inferior olive complex. Climbing fibers wrap around the smooth segments of the Purkinje cell's dendritic arbor and a single action potential in an inferior olivary cell will elicit a massive postsynaptic depolarization resulting in a multiphasic action potential known as a complex spike. In addition to these excitatory connections, there are several types of inhibitory interneurons that form feedforward and feedback loops within the cortex. Purkinje cells are thus positioned to receive and process a wealth of sensory information in distinct synaptic patterns. The output of the cerebellar cortex is mediated exclusively through the Purkinje cells, which are γ -aminobutyric acid (GABA)-ergic neurons and form inhibitory synapses on neurons in the deep cerebellar and vestibular nuclei.

Deep Nuclei

There are three pairs of deep nuclei in the cerebellum: the fastigial, the interpositus, and the dentate. Functionally, the vestibular nuclei in the brainstem are analogous to the cerebellar deep nuclei and are generally included in a description of cerebellar circuitry. Roughly, these nuclei are organized from medial to lateral in correspondence with the innervating region of the cortex, the efferent targets, and somatic region of control – that is, the fastigial nuclei are the most medial and control the trunk of the body; the interposed nuclei (which exist as the globose and emboliform nuclei in some species) control proximal limbs; and the dentate nuclei, which are located most lateral, control distal limbs. The vestibular nuclei receive direct projections from the flocculonodular lobe of the cortex and are involved in eye movements, balance, and gait control. The deep and vestibular nuclei receive excitatory connections from the mossy fibers and inhibitory input from the Purkinje cells. Primary excitatory efferents from the deep nuclei innervate many cortical and subcortical regions including the spinal cord, reticular formation, vestibular nuclei, the red nucleus, primary and premotor cortex, and thalamic nuclei. Deep nuclei also send inhibitory projections to the inferior olive, creating a topographic feedback loop with the cerebellar cortex. In addition, the deep nuclei have a strict somatotopy and microstimulation of regions within the nuclei can elicit discrete movements.

Cerebellar Learning Theory

In contrast to many neural systems for which theories of function are developed incrementally to explain experimental results, a theory of cerebellar learning largely preceded any direct empirical evidence. In 1969, David Marr published a seminal paper proposing that one of the central functions of the cerebellum was to learn to

perform motor skills. Marr based his theory on the unique architecture of the cerebellar cortex – remarkable for its singular geometric regularity and simplicity. John Eccles had recently published a detailed account of cerebellar anatomy and this work – in conjunction with an earlier suggestion by Giles Brindley that the cerebellum functioned to encode new motor skills – inspired Marr to develop a computational theory of cerebellar learning. Importantly, Marr predicted that synapses within the cerebellar cortex were capable of plasticity through conjoint activation of parallel fibers and climbing fibers, and could thus store context-specific information. Although Marr predicted that this plasticity would take the form of a strengthened synapse, his theory was later extended by James Albus who posited, correctly, that the direction of plasticity would take the form of a learning-related depression in synaptic efficacy. Because Purkinje neurons are inhibitory and fire at a high rate spontaneously, a well-timed decrease in the synaptic drive could result in an adaptively timed disinhibition of the deep nuclei.

The cellular arrangement of the cerebellar cortex appeared to map perfectly onto the critical features of neurally inspired computational models of pattern recognition. In brief, expansion recoding mediated by the granule cells could transform information about the environment relayed from the pons into sparse patterns of activation in the parallel fiber–Purkinje cell synapses. In other words, the relatively vast numbers of granule cells, and thus parallel fibers, in the cortex could serve to create more unique, and therefore more easily separable, activity patterns by distributing information over a larger network of axons. Climbing fibers were then poised to act as a teaching signal to reinforce the encoding of these synapse-specific activation patterns. Massive depolarization induced by climbing fiber activity results in a complex spike and, subsequently, a brief cessation in Purkinje cell firing. Essentially, Albus proposed that the coincident activation of parallel and climbing fibers entrained the Purkinje cells to respond to specific patterns of activation with a transient decrease in activity so that, once learned, the activity patterns from the parallel fibers alone would be sufficient to suppress firing. This transient suppression could release the deep nuclei from tonic inhibition, resulting in the well-timed execution of a discrete movement. By viewing the cerebellum from a computational perspective as an information-processing machine, Marr and Albus developed a cohesive account of putative input–output functions that could support the encoding of novel associations at the neural level.

Critically, the associative nature of cerebellar-mediated learning was deeply embedded in the tenets of the computational theory. Because the theory required temporal proximity of parallel fiber and climbing fiber activation, it was now possible to interpret the Purkinje neuron as a cellular agent of coincidence detection. It was

this belief that the cerebellar cortex was a putative site of integration that was instrumental in transforming the view of the cerebellum from a simple motor-program facilitator to a site of intrinsic plasticity and that of the origin of directed behavior.

Over a decade later, the Marr-Albus theory of cerebellar learning gained significant empirical support with the discovery of long-term depression (LTD) at the parallel fiber–Purkinje cell synapse. Furthermore, it was shown that this plasticity could be evoked through the conjunctive activation of parallel and climbing fibers. Remarkably, the theoretical prediction based on the perceived similarity between abstract computational models and cerebellar anatomy was confirmed experimentally through electrophysiological recordings. This was a powerful convergence that elevated the status of the theory and contributed to its deep and sustained influence in the field of cerebellar research.

Cerebellar-Mediated Behavior

Aversive Conditioning

Around the same time as the discovery of LTD at cortical synapses, the initial reports of cerebellar involvement in the classical conditioning of a discrete motor reflex – the eyeblink response – appeared. Eyeblink conditioning is the paradigmatic example of associative learning in the cerebellum. As in all forms of classical or Pavlovian conditioning, eyeblink conditioning develops through an association of two previously unrelated stimuli – the unconditioned stimulus (US), which elicits a reflexive or unconditioned response (UR), and the conditioned stimulus (CS), which does not elicit an overt behavioral response. If the CS and US are repeatedly paired in close temporal proximity so that the CS precedes and predicts the occurrence of the US, the CS acquires properties sufficient to evoke a behavioral response. This acquired response – the CR – is anticipatory, reflects the organism's recognition that the US is imminent, and is triggered by the presence of the CS alone. In the most basic and commonly employed model of eyeblink conditioning, rabbits are trained with a tone or light CS which is paired with a periorbital shock or puff of air to the cornea as the US. In the standard delay protocol, the CS precedes the onset of the US and the two stimuli co-terminate. As learning occurs, CRs begin to appear during the interstimulus interval, eventually developing the appropriate timing to peak at the onset of the US. In a variant of this task – trace eyeblink conditioning – there is a stimulus-free interval between the offset of the CS and the onset of the US. Although trace eyeblink conditioning also critically involves the cerebellum, the introduction of a trace-interval requiring the animal to associate temporally distinct stimuli also requires the involvement of the

hippocampus. Because of its reliance on extracerebellar structures, trace conditioning is mechanistically distinct from delay conditioning. The discussion below is focused on the latter as it illustrates a form of learning in which the critical association depends solely on the cerebellum.

In 1981, Richard F. Thompson and colleagues published the first report that the cerebellum was involved in the acquisition of the novel association introduced during delay eyeblink conditioning. Lesions of the cortex and deep nuclei ipsilateral to the trained eye resulted in the abolition of learned behavior and prevented the acquisition of the conditioned eyeblink. Further refinement of cerebellar lesions and reversible inactivation revealed a critical and highly circumscribed region of the interpositus nucleus that was essential to the acquisition and expression of the CR. In addition, electrophysiological recordings from the interpositus nucleus revealed learning-related increases in neuronal activity that preceded the onset of conditioned behavior within a single trial and modeled the magnitude and temporal form of the behavior itself. Extensive research has now culminated in overwhelming evidence that the cerebellum – and in particular, the anterior lateral region of the interpositus – is the essential neural substrate for the memory trace in this form of associative learning.

Evidence from studies of human subjects and patients is in agreement with the findings from the nonhuman animal literature. Imaging studies have consistently shown cerebellar activation during acquisition of delay eyeblink conditioning. Lesions of the appropriate regions of the cerebellum – critically, the deep nuclei – prevents the acquisition of this associative memory trace. The role of the cerebellum in this form of associative learning appears to be evolutionarily conserved across species and supports the investigation of cerebellar function in this animal model. It is also important to note that even though eyeblink conditioning has been the most widely studied model, the results from these studies apply to the classical conditioning of any discrete behavior response with an appropriate US.

These empirical data from behavioral studies could be viewed as further confirmation of the predictions derived from the cerebellar learning theory. Specifically, the apparent integrative role of the cerebellum in associating distinct and previously unrelated stimuli was in accord with the observation of intrinsic plasticity and the requisite anatomical circuitry to deliver information related to the CS and US. Indeed, as was suggested in the formulation of the Marr–Albus theory, the sensory information related to the CS is relayed to the cerebellum via the pons, culminating in a pattern of activation in the parallel fibers reflective of the context. The pontine nuclei receive projections from auditory, visual, somatosensory, and association systems – both cortical and subcortical – and could thus support conditioning to a wide range of

stimuli. Empirically, it has been shown that appropriate lesions of the pontine nuclei can prevent expression of the CR in a modality-specific manner. Stimulation of the pons can serve as an effective CS and the results of many studies identify the pontine nuclei-mossy fibers as the essential CS pathway.

Similarly, evidence indicates that the climbing fiber system originating in the inferior olive supports the delivery of information concerning the US to the cerebellum. For eyeblink conditioning, the critical region of the inferior olive is the dorsal accessory olive – which relays somatosensory and nociceptive input from the spinal cord and cranial nuclei. One of the key predictions in the Marr-Albus theory was that climbing fiber activation served as an error signal to guide the physical imprinting of contextual information through the induction of plasticity in critical neurons. In this sense, the climbing fibers were thought to manifest the reinforcement that is integral to this type of associative learning. Consistent with this idea, lesions of the critical region of the inferior olive completely prevent learning if made before training and result in the extinction of the CR if made after training. Importantly, the US evokes activity in the inferior olive that decreases as the animal learns – that is, when the errors have decreased and the need for a teaching signal is lessened. As with the pontine-mediated CS circuitry, electrical microstimulation of this region serves as a very effective US. These results argue that the inferior olive-climbing fibers system is the essential US reinforcing pathway for the learning of discrete responses.

Although the anatomical mapping of CS and US signals to the cerebellum and its associated circuitry appears congruent to the suppositions made in the theoretical model, an important distinction remained – namely, that the Marr-Albus theory explicitly described the associative mechanism as existing exclusively in the cerebellar cortex. On the one hand, the data from eyeblink conditioning confirmed that the cerebellum was exemplary of a neural circuit primed to learn associations, while on the other, the emphasis on the cortex as the primary site of integration did not account for the critical role of the deep nuclei. As the research progressed in identifying the relevant circuitry for the learned association in the classical conditioning of the eyeblink response, the critical role of the interpositus was clear and unequivocal, while that of the cerebellar cortex is much less certain. Although the nature of cortical involvement in classical conditioning is not yet understood fully, data from studies using lesions, inactivations, and genetic manipulations suggest that the cerebellar cortex does contribute substantially to the development of the CR under normal conditions. Effects on the timing, amplitude, and frequency of the CR – as well as the rate at which the CR is acquired – have all been reported following cortical manipulations. However, one problem in identifying the role of the cortex in this

form of associative learning is that the organization of cortical regions does not share the well-delineated somatotopy of the deep nuclei. While stimulation and lesion studies have resulted in the identification of distinct regions of the deep nuclei that correspond to sites of peripheral stimulation, the cortex appears to have a redundant and fractured representation of somatic regions. This anatomical complexity hinders the straightforward investigation of cortical modulation of the classical conditioning of discrete reflexes.

Given the evidence suggesting the primacy of the interpositus in classical eyeblink conditioning, it is somewhat paradoxical that the most intense investigation has focused on the mechanisms through which the cortex may facilitate learning, while there remains a relative paucity of data describing synaptic changes in the interpositus. However, if understood in a historical context, this is not so surprising. With the theoretical and early empirical data in close agreement, it became generally accepted that cortical plasticity in the form of LTD could provide a plausible and likely mechanism for the emergence of the CR. In addition, it is true that since then a steadily increasing body of data has shown a correlation between learning deficits and compromised LTD in the cerebellar cortex. Genetic manipulations affecting cortical LTD can impair learning. However, mice in which Purkinje cells are selectively eliminated still exhibit significant, although dramatically impaired, learning in the absence of any cortical output to the deep nuclei. Interestingly, the associative memory derived from trace eyeblink conditioning depends on the cerebellar deep nuclei and extracerebellar structures but may not require the involvement of cerebellar cortex at all. In sum, the cerebellar circuitry can support the learning of new associations in this basic task but the site of integration is not restricted to the cerebellar cortex.

Predictions from the Marr-Albus theory were strikingly accurate in many ways but may have overstated the role of the cortex in cerebellar-mediated learning. Recently, however, there has been an increased focus on additional sites of plasticity in the cerebellum and changes in efficacy have been reported at mossy fiber-granule cell synapses, GABA interneuron-Purkinje neuron synapses, Purkinje neuron-nuclear cell synapses, parallel fiber-Purkinje dendrite synapses, climbing fiber-Purkinje dendrite synapses, and Purkinje neuron-nuclear cell synapses. Intrinsic changes in excitability have been identified in granule cells and nuclear cells. Due to the behavioral results implicating the deep nuclei in the formation of the associative memory trace, and the anatomical inputs that would support integration of the conditioning stimuli, one would expect plasticity to occur at synapses in this region. Evidence does suggest that eyeblink conditioning can increase the number of excitatory synapses between mossy fibers and the neurons in the

interpositus and there was an early report of LTP at the mossy fiber–nuclear synapses. Although the mechanisms through which the deep nuclei may encode the integrative memory trace have yet to be described in full, it is clear that the cerebellum and its related circuitry are both necessary and sufficient to support this form of associative learning.

Appetitive Conditioning

Building upon the research that demonstrated a role for the cerebellum in aversive classical conditioning, cerebellar contributions to other forms of associative learning have also been tested, with varying results. Appetitive conditioning employs reward as the reinforcing, motivational element in the learning task. To date, results from investigations of cerebellar involvement in appetitive conditioning have been mixed or negative. Pavlovian appetitive conditioning appears not to require the cerebellum. Even if procedural elements are controlled such that the performance requirements are the same for avoidance- and appetitive-operant tasks, it appears that the cerebellum is preferentially involved in acquiring the association in the aversive condition. Lesions to the cerebellum and deep nuclei can thus block avoidance learning in a bar-pressing task while having no effect on appetitive learning. In these instances, it would seem that the value, and perhaps the valence, of the reinforcer determine the degree of cerebellar involvement in learning the association. However, in an appetitive visuolocomotor task, rats with hemicerebellar lesions were delayed in the acquisition of a novel object–reward association. Nevertheless, lesioned animals were capable of generalizing feature discrimination to new object pairs, thereby demonstrating intact performance once the procedural strategy had been acquired. Similarly, results from studies of nonhuman primates have suggested that the cerebellum is minimally involved in the expression or retention of visuomotor associations.

That the cerebellum may not be required for maintaining or expressing some reward-based associations could be related to a transient need for the error signal mediated by climbing fiber activation. In other words, when animals are performing at near asymptotic levels, the utility and frequency of the error signal decreases to reflect a successful encoding of an appetitively based association, the expression of which may rely on extracerebellar structures. Performance degradation in an intact system would presumably reinstate the need for error-based teaching signals but long-term studies of cerebellar involvement in appetitive conditioning have not been done. It is therefore premature to speculate about the possibility of a time-limited role of the cerebellum in such tasks. And, as discussed above, the memory trace for aversive classical conditioning of motor reflexes requires

the ongoing involvement of the cerebellum – that is, insofar as it has been tested, there is no temporal window that constrains the essential role of the cerebellum. Furthermore, recent studies of human patients with focal cerebellar lesions have shown nearly the opposite effect. While patients were able to acquire information about reward contingencies in a probabilistic associative learning task, they were impaired in reward-based reversal learning and learning of a second reward-based task. While this is a promising area of future research, much work needs to be done to identify the nature and degree of the cerebellar contribution to associative learning with appetitive stimuli.

Conclusion

Although it is clear that the cerebellum can support associative learning, it is not yet clear whether the cerebellum is involved only in specific forms of associative learning and whether there is some fundamental property of the learning task that would signal cerebellar involvement. It does seem to be the case that the cerebellum is more significantly involved in aversive, as opposed to appetitive, conditioning. Strikingly, empirical results have largely confirmed the early predictions that the cerebellum is a neural machine primed to learn, and more specifically, to associate information of relevance to an organism in learning to negotiate its environment. However, it is not a generic learning machine capable of supporting any new associative memory trace. The mechanics of the intracerebellar circuitry that so inspired early theorists may be free of content in design but are not in practice. Information processing is constrained by the input to the system. The nature of the information received, in conjunction with the unique processing capabilities of the machinery, will largely determine the extent to which a neural system contributes to the encoding of memory in nonpathological conditions. Because the cerebellum receives afferent signals from widespread cortical and subcortical regions, further research is necessary to identify the extent of cerebellar-based learning. In addition, cerebellar modulation of nonmotor learning is also a topic of increasing relevance. Converging evidence indicates that the cerebellum is involved in many aspects of cognition such as linguistic processing, mental imaging, timing, verbal memory, working memory, and attention. It remains to be seen how well the traditional computational description of the cerebellum and its intrinsic circuitry will be able to account for this expanded view of cerebellar function.

This article has focused on classical delay eyeblink conditioning as it is the most extensively studied form of associative learning mediated by the cerebellum. It is important to remember, though, that eyeblink

conditioning utilizes only one cerebellar-based circuit of potential behavioral control. Nevertheless, the detailed overview of this form of learning is important to illustrate that the cerebellum is, in fact, a structure that can support the encoding of novel associations. Far from being a system employed only to refine the execution of coordinated movement, it has the circuitry necessary to integrate stimulus-specific information at the cellular level, as well as a capacity for modifiable synaptic connections – two features suggested to be constitutive of neural structures involved in associative learning.

Glossary

Bilateral advantage – Improved performance when the two hemispheres are simultaneously stimulated compared with monohemispheric stimulation. The distribution of processing across both hemispheres is thought to be advantageous, since it allows for the combination of all available resources. In this case, bilateral stimulation is advantageous, because the stimulus input is initially distributed over both hemispheres, which reduces the amount of callosal transfer.

Corpus callosum – It corresponds to the important white matter tract connecting the two halves of the brain. It represents the main interhemispheric commissure. The corpus callosum mediates interhemispheric communication mainly between homotopic cortical areas of the right and left cerebral hemispheres.

Hemispheric specialization – Mainly based on the observation of distinctive impacts of lateralized brain lesions on behavior and cognition, the concept of hemispheric specialization expresses the fact that each cerebral hemisphere has developed distinct specialized abilities for different aspects of behavior, perception, and cognition. Initially thought to occur at a functional level (music, language, etc.), hemispheric specialization is now conceived at the level of some specific subcognitive processing.

Interhemispherical dynamic – A complex exchange of information between the two hemispheres thought to allow for the full deployment of computational and cognitive processing. Interhemispherical dynamic is somewhat viewed as opposed to a static conception of hemispheric specialization. It stresses a dynamic, complementary sharing of labor, and a cooperative functioning relying on neural networks spread over the two hemispheres.

Lateralized stimulation – It has been used as a means of inducing the initial stimulation to one hemisphere only. It has been used in split-brain individuals as well as normal individuals (along with tachistoscopic presentations; see below) to study and compare the ability of each hemisphere individually. This method relies on the characteristics of most sensory and sensorial systems that project the stimulation to the contralateral hemisphere. It is the case for the visual

system (divided visual field presentations) as well as for the tactile system; given the presence of a large bilateral component, the auditory stimulation has a tendency to be more represented to the contralateral hemisphere only in the presence of a bilateral competition (dichotic listening). Finally, the olfactory central projection is uncrossed.

Split-brain individuals – Those who have suffered a surgical section of a part or all of the corpus callosum (callosotomy) dictated by therapeutic reasons. Indeed, in some rare cases of intractable and pharmacoresistant epilepsy, the section of the corpus callosum diminishes the frequency and intensity of epileptic seizures, probably because it interferes with the epileptic activity of malfunctioning bilaterally distributed neural networks. Initially, total callosotomy has become more and more partial. Individuals with callosotomy have provided a unique opportunity to study the functions of the two hemispheres in isolation.

Tachistoscopic presentation – Projection of a visual stimulus for a short time. This type of presentation is used to prevent the subject from using an eye saccade in order to centrally capture a lateralized visual stimulation. Once done using a mechanical shutter, tachistoscopic presentations are now done using computer screens having a few limitations due to the frequency of screen refreshment and the possible occurrence of remanence.

Historical Context

Although the cerebral hemispheres are relatively comparable in terms of size, weight, and surface area, centuries of studies on the effects of unilateral brain damage have shown major functional differences between them. In this regard, it was the study of language impairments following a lateralized lesion that provided the classic evidence that the left hemisphere is the primary locus of language. As Hughlings Jackson put it as early as 1864, the left and right hemispheres are to be conceived of as functionally complementary since the human brain cannot be duplicating functions in both hemispheres. In this regard, Hughlings Jackson later proposed that the right

hemisphere specialized in other functions such as the perception of visual objects. This conception of the two complementary hemispheres was more or less ignored until the 1930s, when the use of psychological tests in large patient groups revealed the specialized roles of the two hemispheres; more recently, the use of functional neuroimaging, such as functional magnetic resonance imaging (fMRI), has produced further data.

However, one of the most significant contributions to our understanding of the complementary functional contributions of each cerebral hemisphere came from the observation of individuals whose corpus callosum had been rendered nonfunctional. The two hemispheres are connected through the brain's largest bundle of fibers, the corpus callosum (CC). Containing more than 300 million axons, the CC forms a massive neural pathway between the two cerebral hemispheres, allowing excitatory or inhibitory transfers to occur between them.

Quite early in the history of the study of hemispheric specialization, the systematic analysis of the impact of a disruption in the flow of information between the two hemispheres allowed unique insights into the functional characteristics of each hemisphere. Over the years, three sources have provided such unique evidence: (1) individuals with agenesis of the CC, (2) individuals with a more or less complete lesion of the CC, and (3) individuals who must undergo a surgical separation of the two hemispheres, known as callosotomy.

Callosal agenesis. Agenesis of the CC stems from an *in utero* dysfunction in the growth of the central nervous system. The agenesis can be partial or complete depending on the stage at which the defect occurs. The first case of agenesis of the CC was described following an autopsy by Reil in 1812. The condition has been described as "a natural model of the split brain." There are definite signs of callosal disconnection in callosal agenesis, such as a lack of interhemispheric transfer of motor skills or sensory impairments when midline functions are involved. However, at the same time, individuals with agenesis of the CC frequently show other signs of brain insult or dysfunction. Moreover, since it is present at birth, individuals with callosal agenesis appear to develop a number of compensatory pathways or mechanisms.

Lesion of the corpus callosum. Dejerine was probably the first researcher to report the specific impact of a lesion to the splenium of the CC, combined with a left occipital lesion, on written language abilities (pure alexia without agraphia). In 1907, Liepmann and Maas reported a case of left apraxia accompanied by left-hand agraphia following a callosal lesion. Cases of callosal lesion are still reported today, and now neuroimaging can verify the lesion. For example, Habib, Ceccaldi, and Poncet reported the case of a young woman with a nearly complete callosal lesion. Apart from the usual aphasic and apraxic signs, the authors reported the presence of some strange inner

conflicts that raise questions about the integrity and uniqueness of the self in those patients.

Callosotomy. The surgical separation of the two hemispheres was introduced in 1939 by Van Wagenen and Herren as a drastic solution to help individuals with otherwise untreatable epileptic seizures. The first behavioral analyses of these patients by Akelaitis did not take advantage of the surgical separation of the two hemispheres to study their specialization. Two contemporary neurosurgeons, Phillip Vogel and Joseph Boghen, invited Roger Sperry and Michael Gazzaniga to examine some of their callosotomized young patients. The explosion of knowledge that resulted from this interdisciplinary approach was massive, as innovative methods of stimulus presentation (e.g., lateralized visual field presentation) made it possible to test each hemisphere separately. Roger Sperry received a Nobel prize in 1981 for his unique series of neuropsychological investigations of callosotomized patients that opened up a new era in the study of mental unity and the lateralization of cognitive functions. Rarely has a single paradigm in neuropsychology and the cognitive neurosciences represented such a leap forward in the evolution of the concept of hemispheric specialization and cooperation. After a brief presentation of the different behavioral approaches used to selectively examine each hemisphere, this article summarizes the most important discoveries about hemispheric specialization and cooperation in key cognitive domains.

Methodology

Studies that describe the respective cognitive potential of each hemisphere make full use of the fact that nearly all sensory and motor pathways are crossed. Thus, each cerebral hemisphere receives information primarily from the opposite half of the body and the corresponding sensory hemifield. Special stimulus presentation techniques have been introduced to confine sensory inputs and motor responses to one hemisphere in split-brain participants. The resulting restriction of stimuli to one hemisphere has allowed researchers to describe some of the specialized functions of the two hemispheres.

Lateralized Visual Field Presentation

The study of hemispheric specialization based on visually presented stimuli is based on the anatomical properties of the visual system, which is divided into left and right hemifields on either side of a small binocular zone. Thus, due to the partial chiasmatic reorganization of the nasal hemiretinas, the central visual pathways convey a complete visual hemifield to the lateral geniculate nucleus, which finally reaches the primary visual cortex

through the optic radiation. The restriction of visual presentation to one hemisphere is thus possible if one respects two conditions: the visual stimulus must be at a visual angle of at least 2.5° outside the fovea area (which projects to both the hemispheres), and the time of presentation must be less than the time necessary (estimated at between 80 and 220 ms) for an eye saccade that would allow the stimulus to be positioned in the central visual field and achieve bilateral visual representation. In early studies, this was managed using a mechanically driven tachistoscope. The participant would sit in front of a screen with a small black dot in the center and the tachistoscope (rapid shutter presentation) allowed the experimenter to precisely control the duration of presentation. In split-brain participants, this procedure was often used to compare the ability of each isolated hemisphere to process verbal and nonverbal stimuli. More recently, lateralized computer presentations have replaced the tachistoscope. Divided visual fields are also frequently used to test normal participants, although the fact that the two hemispheres are still connected imposes a fine-grained analysis of the respective combinations of visual field and response time for each hand in order to infer which hemisphere is best suited to process a given visual stimulus.

Auditory Dichotic Presentation

Unlike the visual pathways, the central auditory pathways are not anatomically lateralized. Indeed, each ear projects information to both the hemispheres following a complex multirelay and multicrossing brainstem pathway. However, probably because the contralateral projections are somewhat greater, there is evidence of a functional lateralization of the central auditory pathways when two different stimuli are presented simultaneously to both ears. This technique referred to as dichotic listening makes it possible to present auditory stimuli primarily to the contralateral hemisphere. As Kimura suggested, under dichotic presentation conditions, a modest group-based right-ear advantage emerges for verbal stimulation. Thus, in dichotic listening condition, a right-handed participant would report the syllables presented to the right ear first and more accurately because of its privileged functional connection with the left hemisphere. In this condition, dichotic listening for verbal stimuli results in a right-ear advantage, suggesting that the left hemisphere is superior at processing such stimuli. In split-brain participants, because the verbal response emanates from the left hemisphere, only the right-ear sound is reported.

Lateralized Tactile Stimulation

Tactile, or haptic, stimulation of one hand projects primarily to the contralateral cerebral hemisphere. The

usual testing arrangement combines lateralized visual or tactile stimuli and tactile responses. Such a set-up was used to investigate the contribution of each cerebral hemisphere in the categorization of tactile information, for example. Tactile information is kept within one hemisphere by presenting tactile stimuli out of sight. Under such conditions, for example, split-brain participants are incapable of comparing an object held by the left hand (right hemisphere) with a visual stimulus flashed in the right visual field (left hemisphere). Moreover, the participant is only able to name the object processed by the left hemisphere.

Lateralized Olfactory Stimulation

The central olfactory tracts first divide into medial and lateral stria, the latter of which end up in the prepyriform cortex and parts of the amygdala of the temporal lobe corresponding to the primary olfactory cortex. Unlike vision, hearing, and somesthesia, the olfactory system is essentially uncrossed: the left nostril projects to the left hemisphere, and the right nostril to the right hemisphere. Studies of normal subjects suggest that odor discrimination and intensity judgments show an advantage in the right nostril (right hemisphere), but odor naming shows a left nostril superiority. However, for split-brain subjects, odors identified through one nostril are not recognized through the other. These subjects fail to identify by verbal report the objects smelled through the right nostril, which are experienced within the right hemisphere.

The Contribution of Split-Brain Studies to the Comprehension of Functional Specialization

Complete severing of the CC drastically blocks the interhemispheric transmission of sensory, perceptual, motor, and other types of information. Yet, cursory observation of split-brain patients usually fails to demonstrate that surgical disconnection of the hemispheres has a significant impact on their behavior, cognition, affect, or sense of self. Nevertheless, under specific testing conditions, they can exhibit dramatic hemispheric asymmetries.

Motor Control

According to the split-brain literature, each hemisphere can control bilateral proximal muscles (muscles closest to the center of the body), but only exerts control over contralateral distal muscles (muscles farthest away from the center of the body). For instance, a disconnected hemisphere can control both arms (proximal muscles), but only the opposite hand (distal muscles). Nonetheless, the disconnected left hemisphere often shows an advantage

for motor planning of proximal movements (e.g., appropriately reaching for an object). While split-brain patients usually experience difficulty with bimanual asynchronous, simultaneous movements, they can often use both hands in a seemingly coordinated fashion when performing a task that requires the integration of both. They can also use both hands to execute simultaneous conflicting spatial programs, like drawing two different stimuli concurrently with both hands, whereas normal individuals are impaired in such tasks. However, in rare instances of diagnostic apraxia (alien-hand syndrome), the patient's hands may perform conflicting actions following callosotomy, such as opening a door with one hand while the other hand tries to close it.

Perception, Attention, and Visuospatial Processes

Somatosensory processes are largely lateralized. Thus, in split-brain patients, tactile information processed by one hand is not available to the ipsilateral hemisphere. As a result, split-brain individuals are unable to compare items held in each hand, even though they are aware that both hands are holding something. Likewise, visual information presented to one hemisphere is not available to the other disconnected hemisphere for perceptual analysis. Moreover, tactile information presented to one hemisphere cannot be cross-integrated with visual information presented to the opposite hemisphere. On the other hand, noxious somatosensory information (e.g., pain) is projected to both hemispheres, thus allowing bilateral perception of unilateral adverse stimulation. With regard to basic perceptual processes, the functions of both hemispheres appear to be duplicated in split-brain patients and may proceed independently. Some attentional processes also seem to function independently. For instance, split-brain studies have shown that each hemisphere is able to maintain an independent focus of attention in a visual search task. Accordingly, each hemisphere is able to concurrently and independently direct its attention to its own visual field. Therefore, when scanning a bilateral stimulus array, split-brain patients frequently outperform neurologically normal individuals. Likewise, they usually perform better in a test of visual retention when the information is distributed across both visual half-fields.

Split-brain studies often evince a right-hemisphere advantage for many aspects of visuospatial processing (even in right-handed individuals). For instance, drawings produced by the right hand of split-brain patients (left hemisphere) often lack spatial coherence, whereas those produced by the left hand (right hemisphere) show appropriate spatial organization. At the perceptual level, facial recognition of upright faces is more efficient when processed by the right hemisphere. The right hemisphere

also demonstrates an advantage for perceptual grouping processes, which involves the ability to assemble complex visual features into a combined representation of objects and surfaces. Although both hemispheres are able to perceive illusory contours (perception of a visual contour in the absence of lightness or color in a stimulus), only the right hemisphere performs well at amodal completion (perceiving a partly occluded stimulus as a complete whole). Sophisticated visual matching abilities, such as deciding whether two visual images are identical or mirror reverse, are also more efficient when executed by the right hemisphere. Moreover, the right hemisphere of split-brain patients is typically better than the left at performing higher-order cognitive tasks, such as the block design subtest of the Wechsler intelligence scale.

Language

The assessment of behavioral asymmetries for linguistic or verbal processing in split-brain patients has greatly contributed to our understanding of the hemispheric specialization of language. A common observation from such studies is that the left hemisphere plays a dominant role in linguistic or verbal processing for the majority of right- and left-handers. For instance, split-brain patients can easily tell the name of an object presented in the right hand or the right visual field (left hemisphere). However, they are typically unable name an object when it is presented in the left hand or the left visual field (right hemisphere), even though they seem to have full knowledge of what it is. Such results indicate that the left hemisphere is specialized for speech production. Moreover, the left hemisphere possesses a lexicon (meaning associated with words) and a complete grammar (rule-based system) and is fully capable of comprehending all aspects of language. Thus, in split-brain patients, only the left hemisphere is typically able to make judgments requiring phonological decoding (e.g., indicating whether two differently spelled words rhyme with each other) or converting graphemes (fundamental unit of written language) to phonemes (fundamental unit in the sound system of language). Nevertheless, split-brain studies have shown that the right hemisphere does have some linguistic abilities. For instance, it has the capacity to read whole words, primarily if they are concrete, picturable, and frequent, and may even have limited access to grammar.

Learning and Memory

It is not uncommon for split-brain patients to present memory problems. For example, there have been reports of short-term memory deficits following surgical sectioning of the CC, which seem to be related to the joint

suppression of the anterior commissure. Some studies also suggest that commissurotomy has detrimental consequences on free recall abilities (remembering without any clues to help retrieval), although recognition processes for previously learned material remain unaffected. Split-brain research also suggests that each hemisphere tends to demonstrate some material-specific abilities. For instance, the left hemisphere is better at encoding verbal material (e.g., words), while the right hemisphere is more proficient at remembering nonverbal information (e.g., faces). Hemispheric processing differences have been noted as well; the isolated right hemisphere performs better than the left at discriminating previously learned items from new items, such as words, faces, and abstract visual forms. Even so, both hemispheres are able to use procedural memory (implicit long-term memory of motor, perceptual, and cognitive skills), although the ensuing learning is limited to each isolated hemisphere.

Emotion and Sense of Self

When confronted with negative events, split-brain patients do not show the typical reactions associated with negative emotions (e.g., sadness). Even though they express a definite dissatisfaction, their reactions appear somehow diminished or distant. Yet, their personality characteristics have been described as relatively more positive than negative and they remain verbally expressive. Likewise, both isolated hemispheres are able to generate spontaneous facial expressions, although the left is dominant for voluntary facial expressions.

Following callosotomy, each hemisphere is able to operate independently without a contribution from or awareness of the other. Given that this surgical procedure apparently produces a division of conscious experience, it has raised questions about the possibility that each hemisphere may possess its own mind and sense of self. There is no clear evidence supporting such duality. Split-brain patients usually appear to have an unaffected sense of self. It has been suggested that this apparent unity may be attributed to the left hemisphere's ability to formulate hypotheses and generate explanations about the environment and itself, which has led Gazzaniga and colleagues to label the left hemisphere as the 'interpreter.' Since the right hemisphere is unable to do so, at least using articulated language, the interpreter (left hemisphere) would provide a sense of unified self. On the other hand, some split-brain data suggest that both hemispheres possess the ability to self-recognize, although only the right can recognize familiar others. Other evidence suggests that the left hemisphere requires less information than the right for self-recognition.

Other Aspects of Cognition

Split-brain studies have also contributed to the exploration of hemispheric specialization for other aspects of cognition. For instance, a few studies have shown that the left hemisphere is usually more efficient at performing mathematical operations (e.g., calculations) than the right hemisphere, even though both are able to compare numerical representations. There are also evidences that the isolated right hemisphere is superior at making temporal judgments, such as making fine temporal discrimination, which contrast with divided visual field studies of neurologically normal adults suggesting a left-hemisphere advantage. On the other hand, split-brain studies have also helped us understand the contribution of subcortical structures and different portions of the CC. For instance, subcortical structures are able to transfer some information to both isolated hemispheres, such as contextual information and a few aspects of spatial localization.

Theories of Callosal Dynamics

Three main classes of models are widely considered to explain why lateralized presentation results in hemispheric performance. The first two, the direct-access model and the callosal-relay model, are anatomically motivated and assume that the information transfer through the corpus callosum results in measurable losses of time and stimulus quality. A third class of models of laterality effects, first proposed by Kinsbourne in 1975, involves a dynamic shift of hemispheric control.

Direct-Access and Callosal-Relay Models

The direct-access model assumes that information will be processed by the hemisphere that first receives it, regardless of the difference in ability that may exist between the hemispheres. The hemisphere that receives the sensory information first will process it, for better or for worse. Laterality differences here are due to relative differences in the perceptual–cognitive competencies of the two hemispheres. The direct-access model predicts an advantage in performance for information that reaches the appropriately specialized hemisphere first, since processing by that hemisphere presumably would be better than processing by the other hemisphere. This model is often suggested by split-brain and lesion studies showing different performance styles in the two hemispheres for certain cognitive tasks.

The callosal-relay model, on the other hand, assumes that information is always processed by the more specialized hemisphere. If sensory information reaches the other hemisphere first, it will have to

shuttle across the CC to the specialized hemisphere prior to processing. In this case, the transfer results in some loss of clarity of information and an advantage would be found for stimuli that reach the specialized hemisphere directly.

A direct-access task usually shows small and comparable behavioral laterality effects in split and normal brains since no callosal transfer is involved. A callosal-relay task, on the contrary, will show a massive laterality effect in the split brain but a relatively small, even if significant, laterality effect in the normal brain.

The Interhemispheric Dynamic: A Modularity View

Kinsbourne suggests that hemispheric activation depends on psychological set effects and thus on a host of task parameters. In this view, dual-task priming can increase hemispheric activation, but overloading can eventually shift control to the other hemisphere. Dynamic-shift models utilize both the direct-access assumption of bilateral competence and the callosal-relay emphasis on cross-callosal transfer.

Banich and colleagues proposed the most elaborate account of interhemispheric interaction in decision making. They suggested that the processing required for decision making may be divided between the two cerebral hemispheres. If one postulates that each hemisphere is an independent processor, dividing and coordinating processing across the hemispheres may be advantageous in certain situations. These theoretical considerations were influenced in large part by experiments using a letter-matching paradigm, which allows one to compare performance when a match decision initially involves one hemisphere and when a match decision necessitates the division of processing across the two hemispheres, because of the level of complexity (simple vs. difficult). The results highlight a shift in efficiency from within- to across-hemisphere processing. For less complex tasks, processing is more efficient when information is directed to a single hemisphere (i.e., a within-hemisphere advantage). By contrast, when computational complexity is relatively high, the within-hemisphere advantage is diminished, and across-hemisphere processing is more beneficial. Interhemispheric processing was found to aid performance for the more complex task but not for the less complex one. These studies suggest that interhemispheric interaction (IHI) is a flexible mechanism, whose role in the performance of a task changes dynamically depending on what the task demands. Whether and how much IHI aids task performance depends on the relative balance between two factors, the division of processing between the cerebral hemispheres and coordination of processing, which is carried out by the CC. When the

computational complexity is relatively low, the benefits associated with the greater computational power afforded by dividing processing between the hemispheres are not large enough to outweigh the costs associated with integrating information across the hemispheres. Thus, processing is more efficient when all the information is directed to a single hemisphere, and IHI may be deleterious to task performance. By contrast, when the computational complexity is relatively high, the benefits associated with greater computational power begin to outweigh the costs of integrating processing between the hemispheres. Studies like those by Banich and her colleagues demonstrated that IHI increases the brain's information-processing capability during complex tasks by allowing the distribution of computations between the two hemispheres.

Glossary

Hormone (from Greek ὄρμη, meaning impetus) – A chemical released by cells that affects cells in other parts of the body. Endocrine hormones are released into the bloodstream. They typically bind to receptor proteins, resulting in the activation of a signal transduction mechanism and cell-type-specific responses.

Hypothalamus (from Greek ὑποθαλαμος, meaning under the thalamus) – A portion of the brain situated beneath the thalamus in the ventral diencephalon, which coordinates numerous endocrine processes, autonomic nervous system activities, and behavioral functions. The hypothalamus, sensitive to numerous forms of information, subserves many homeostatic processes, in part by synthesizing and secreting neuropeptides, including hypothalamic-releasing hormones that stimulate or inhibit the secretion of pituitary hormones.

Nucleus accumbens – Also known as the nucleus accumbens septi (from Latin, ‘nucleus leaning against the septum’), it is a collection of predominantly gamma-aminobutyric acid (GABA)ergic spiny neurons within the forebrain thought to play important roles in reward and motivation processes. The nucleus accumbens is composed of at least two structures – the nucleus accumbens core and the nucleus accumbens shell – with different morphology and function. The nucleus accumbens and the olfactory tubercle collectively form the ventral striatum, which is a part of the basal ganglia.

Peptide (from Greek πεπτίδια, meaning small digestibles) – An amino-acid-sequence polymer of ~50 residue length or shorter, in which the link between one amino acid residue and the next is an amide bond.

Vagus nerve – Also called the pneumogastric nerve or cranial nerve X, the vagus nerve is the 10th of the 12 paired cranial nerves and is the only nerve that originates in the medulla oblongata and projects, through the jugular foramen, to the neck, chest, and abdomen, where it contributes to the innervation of the viscera. Besides output to the various organs, the vagus nerve conveys sensory information about the state of the body’s organs to the central nervous system.

Indeed, 80–90% of the nerve fibers in the vagus nerve are afferent (sensory) nerves communicating the state of the viscera to the brain.

Peripheral Signals

Gut hormones play a major role in the regulation of food intake by signaling short- and long-term energy needs to the brainstem and mediobasal hypothalamus. Appetite-regulating neuropeptide systems in the brainstem and hypothalamus are activated or inhibited according to peripheral signals (Table 1), several of which are discussed below. Peripheral signals from the gastrointestinal tract, pancreas, liver, and adipose tissue allow for homeostatic control of appetite and energy expenditure.

Gastrointestinal Tract

Ghrelin

Ghrelin is a 28-amino-acid peptide hormone released from programmed death receptor 1 (P/D1) cells of the stomach fundus and, to a lesser degree, epsilon cells of the pancreas. Ghrelin is posttranslationally acylated at serine residue three by ghrelin O-acetyltransferase, a modification needed for its potent agonist activity at the G-protein-coupled growth-hormone-secretagog receptor (GHS-R). Central or peripheral injection of acylated, but not *des*-acyl, ghrelin rapidly initiates food intake and growth hormone release in animals, and chronic administration leads to weight gain and fat accumulation. Ghrelin administration in humans increases feelings of hunger. Ghrelin levels rise with fasting or weight loss, and fall following refeeding, leading to its proposed role as a meal initiator.

The orexigenic effects of ghrelin are mediated in part by activation of neuropeptide Y (NPY)- and agouti-related protein (AgRP)-expressing neurons in the arcuate nucleus (Arc) of the hypothalamus. GHS-R mRNA is expressed in many arcuate NPY/AgRP neurons, and ghrelin injection increases Fos expression in NPY/AgRP neurons. Intercerebroventricular injection of ghrelin increases NPY

Table 1 Major sites of synthesis and actions of selected appetite-regulating energy homeostatic molecules

<i>Site of Synthesis</i>	<i>Effect on Feeding</i>
<i>Gastrointestinal tract</i>	
Ghrelin	↑
Peptide YY	↓
Cholecystokinin	↓
Glucagon-like peptide-1	↓
Oxyntomodulin	↓
Enterostatin	↓
Bombesin-related peptides (gastrin-releasing peptide, neuromedins B and C)	↓
<i>Pancreas</i>	
Insulin	↓
Pancreatic polypeptide	↓
Amylin	↓
Glucagon	↓
<i>Adipose Tissue</i>	
Leptin	↓
<i>Hypothalamus</i>	
Neuropeptide Y	↑
Orexins	↑
Melanin concentrating hormone	↑
Agouti-related protein	↑
Galanin	↑
α-Melanocyte-stimulating hormone (from POMC)	↓
Corticotropin-releasing factor	↓
Urocortins 1, 2, and 3	↓
Cocaine and amphetamine-related transcript	↓
Thyrotrophin-releasing hormone	↓

expression in the hypothalamus and the orexigenic effects of ghrelin are absent in NPY/AgRP double null mutant mice and blocked by administration of a Y1 receptor antagonist. Ghrelin acts as an opponent to the anorectic adipocyte hormone leptin, disinhibiting NPY neurons and inhibiting pro-opiomelanocortin (POMC) neurons. The orexigenic response to ghrelin also involves specific inhibition of fatty acid biosynthesis resulting from AMP-activated protein kinase (AMPK) activation, which leads to decreased hypothalamic levels of malonyl-CoA and increased carnitine palmitoyltransferase 1 (CPT1) activity. An intact cannabinoid type 1 receptor-signaling pathway also is necessary for the stimulatory effects of ghrelin on AMPK activity and food intake.

In addition to activating neurons in the Arc of the hypothalamus, ghrelin has been shown to act on GHS-Rs in brainstem vagal afferent fibers. It was previously thought that ghrelin stimulated feeding by entering the brain through the blood-brain barrier, but recent studies emphasize that the orexigenic effects of ghrelin require the vagus nerve. Vagus nerve deafferentation abolishes the feeding effects of ghrelin. Binding, immunohistochemistry, and Fos expression studies also implicate vagal afferent fibers in the ability of ghrelin to induce growth hormone secretion and activate hypothalamic NPY neurons.

The hindbrain has also been shown to be involved in the effects of ghrelin. GHS-Rs are expressed in neurons in the

nucleus of the solitary tract (NTS) of the caudal brainstem. Correspondingly, local administration of ghrelin into the fourth ventricle or directly into the dorsal vagal complex increases food intake. Reciprocal connections are present between the NTS and hypothalamus, including an ascending noradrenergic pathway from the hindbrain to the hypothalamus. Thus, a component of ghrelin's orexigenic action following hindbrain administration may be mediated indirectly through activation of forebrain hypothalamic neurons. On the other hand, fourth ventricle injection of ghrelin increases Fos expression in the NTS, but not arcuate or paraventricular nucleus (PVN), suggesting that orexigenic effects of hindbrain ghrelin administration do not require hypothalamic activation.

In addition to increasing appetite, ghrelin also decreases fat expenditure and promotes fat storage. Conversely, ghrelin/GHS-R double null mutant mice exhibit decreased body weight, increased energy expenditure, and increased motor activity. Similarly, active immunization against the conserved N-terminal ghrelin residues slowed fat accrual in rats through a metabolic mechanism, with similar retardation of body weight gain reported in pigs.

Peptide YY

Peptide YY (PYY) is a 36-amino-acid gut hormone released by L cells of the ileum/colon in proportion to

ingested calories. PYY is functionally related to NPY and binds to the Y family of receptors, Y1R–Y6R. Most circulating PYY is the truncated form, PYY_{3–36}, a cleavage product yielded by dipeptidyl peptidase IV. PYY is a putative satiety signal released following a meal, decreasing food intake. Levels of PYY are reduced following a fast. Peripheral injection of PYY_{3–36} reduces food intake in rodents and humans, but anorectic effects of PYY are highly sensitive to mild stressors such as a new environment. PYY is hypothesized to enter the brain through the area postrema and NTS. Peripheral administration of PYY increases Fos immunoreactivity in the NTS and area postrema, and anorectic effects of PYY are diminished following transection of brainstem–hypothalamus connections. Anorectic effects are suppressed by a Y2R antagonist, suggesting that PYY_{3–36} acts through the Y2R receptor.

Cholecystokinin

Cholecystokinin (CCK) and related bioactive fragments such as the C-terminal sulfated octapeptide CCK-8 are released from I cells in the mucosal epithelium of the small intestine following a meal. CCK peptides can bind two G-protein-coupled receptors with nanomolar affinity (CCK1 and CCK2). CCK1 is abundant in peripheral organs, including the pancreas, gall bladder, pyloris, intestine, and vagus nerve, as well as in a few discrete brain regions, whereas CCK2 is the predominant CNS subtype, with limited distribution in the stomach and vagus nerve in some species. CCK secretion causes the release of digestive enzymes from the pancreas and bile from the gall bladder and inhibits gastric emptying. CCK is released postprandially, suppressing hunger and reducing food intake in part through CCK1 receptors on the vagus nerve. Accordingly, mice that lack CCK1 receptors are insensitive to the anorectic actions of CCK8. CCK1 antagonists increase food intake, and Otsuka Long-Evans Tokushima Fatty rats, which lack functional CCK1 receptors, are obese secondary to hyperphagia. CCK2 receptors do not appear to be essential for maintenance of normal body weight, though they help stimulate gastric acid secretion.

CCK1 systems synergistically and reciprocally interact with the adipocyte leptin hormone to curtail food intake. For example, CCK1 receptor agonists increase permeability of the blood–brain barrier to leptin, and leptin administration enhances the sensitivity of gastric and duodenal vagal afferents to CCK, thereby facilitating meal termination.

Glucagon-like peptide-1

Glucagon-like peptide-1 (GLP-1) is derived from the precursor protein preproglucagon and is secreted by L cells in the small intestine following food intake. The most common form of GLP-1 *in vivo* is GLP-1_{7–36}amide,

which can act both peripherally and centrally. Peripheral GLP-1 is an incretin, acting on GLP-1 receptors (Glp1r) in the beta cells of the pancreas to stimulate insulin secretion and decrease glucagon secretion. Central GLP-1 is localized in the NTS and area postrema and acts as a neuropeptide to control food intake and whole body glucose in hyperglycemic conditions. It decreases food intake and feelings of hunger, and also has effects on autonomic function. The GLP-1 competitive antagonist exendin-4_{9–39}, a truncated form of the GLP-1 agonist exendin-4, increases food intake when administered acutely and increases body weight when administered chronically.

Oxyntomodulin

Oxyntomodulin is a 37-amino-acid peptide product of a preproglucagon precursor molecule that is released after a meal by oxyntic cells in the oxyntic mucosa of the colon. It appears to act through GLP-1 receptors and, like GLP-1, reduces food intake. The anorectic effects of oxyntomodulin are abolished in GLP-1 receptor knockout mice and are blocked following administration of exendin-4_{9–39} administration to the Arc. Chronic administration of oxyntomodulin leads to weight loss and may increase energy expenditure.

Enterostatin

Enterostatin (the amino-acid sequence APGPR) is a pentapeptide derived from the precursor protein procalipase, produced by the exocrine pancreas, and expressed in the gastric mucosa of the gastrointestinal tract. Procalipase is also expressed centrally, in the PVN, amygdala, and cortex, and APGPR mRNA is expressed in the Arc. APGPR reduces insulin secretion and stimulates adrenal corticosteroid secretion. It leads to a feeling of fullness and reduces consumption of fat, specifically. Central injection of APGPR potently decreases intake of a high-fat diet, but has no effect on intake of a high-carbohydrate, low-fat diet. The effects of APGPR on fat intake are mediated by the melanocortin system, with studies showing the involvement of melanocortin receptor 4 (MC4R). The serotonin system is also involved. Injection of APGPR to the amygdala activates neurons in serotonergic brain regions that innervate the PVN. Administration of a serotonin 5HT1B receptor antagonist blocks the anorectic effects of injection of APGPR to the amygdala.

Enterostatin also reduces serum cholesterol levels, an effect that is blocked by administration of a CCK1R antagonist, suggesting involvement of the CCK system.

Gastrin-releasing peptide/neuromedin/bombesin family

Bombesin (BN) is an amphibian tetradecapeptide that shares a common C-terminal heptapeptide sequence with the mammalian peptides, gastrin-releasing peptide

(GRP_{1–27}) and neuromedin C (GRP_{18–27}). The C-terminal heptapeptide sequence of neuromedin B (NMB), which occurs in 30- and 32-residue precursors and in a 10-amino-acid residue mature form, differs by two amino acids from BN (i.e., Thr¹⁰ and Phe¹³ vs. Val¹⁰ and Leu¹³, respectively).

Central or systemic administration of BN, GRP, and NMB all decrease feeding in rodents, with the BN family peptides showing greater anorectic potency when administered into the cerebral ventricles than peripherally. The biological actions of BN are mediated through two pharmacologically distinct, cloned G-protein-coupled receptors, BB₁, also known as the NMB-preferring receptor, and BB₂, also known as the GRP-preferring receptor. During feeding, GRP immunoreactivity increases in the hypothalamus and central amygdala as well as in the antrum of the stomach. GRP has therefore been hypothesized to act as a negative feedback satiety signal in mammals through its neuronal and humoral effects. Consistent with this possibility, mice that lack BB₂ receptors (GRP-preferring receptors) eat more food than wild-type mice and show impaired glucose tolerance, with impaired early insulin and GLP-1 responses. These functions correspond to the high expression of BB₂ receptors in human pancreas, stomach, adrenal cortex, and brain. Altered function of GRP and/or BB₂ receptors also has been implicated in anorexia nervosa, bulimia, and mood disorders.

Consistent with the observed pharmacology, NMB anorexia, in contrast to GRP anorexia, occurs independent of BB₂ stimulation and is thought to be BB₁ mediated. Two association studies suggest a role of NMB genes in human eating disorders and obesity.

In addition to the BB₁ and BB₂ receptor subtypes, an orphan BN receptor subtype 3 (BB₃), identified in guinea pig uterus, is widely distributed in feeding-regulatory centers, including hypothalamic nuclei. The endogenous natural ligand for BB₃ remains unclear, because the receptor shows little affinity for BN, GRP, or NMB. Animal models indicate that the BB₃ subtype may have roles in energy balance and glucose homeostasis, but a Japanese association study suggests that BB₃ receptor gene mutations are unlikely to be a major cause of obesity in humans.

Pancreas

Insulin

Insulin is a 51-amino-acid peptide hormone synthesized in the pancreas and released from pancreatic β -cells following a meal. It signals cells to take up glucose from the blood, storing it as glycogen. Insulin reduces food intake and is an adiposity signal, increasing with increases in body fat stores. Insulin resistance can occur with excessive weight gain. If the pancreas fails to compensate for insulin

resistance by raising basal insulin levels as well as raising insulin levels postprandially, then hyperglycemia can occur. This relationship contributes to the association of type 2 diabetes with obesity. Insulin receptors in the hypothalamus inhibit neuropeptide systems that increase food intake, leading to a decrease in food intake when insulin is detected.

Pancreatic polypeptide

Pancreatic polypeptide is synthesized in and released from the endocrine pancreas after a meal and reduces appetite. Like PYY and NPY, pancreatic polypeptide binds to the Y family of receptors, preferentially to Y4 and Y5. Peripheral injection of pancreatic polypeptide reduces food intake, and chronic administration decreases body weight in obese mice. Mice that overexpress pancreatic polypeptide show reduced food intake and body weight, as well as reduced gastric emptying.

Amylin

Amylin, also known as islet amyloid polypeptide, is a 37-amino-acid peptide that is released from pancreatic β -cells along with insulin following a meal. It is thought to be involved in glucose homeostasis and also reduces food intake when administered at high levels peripherally.

Glucagon

Glucagon is a hormone released by alpha cells in the endocrine portion of the pancreas when blood glucose levels are low. It binds to G-protein-coupled glucagon receptors on hepatocytes, causing the liver to convert glycogen to glucose and release glucose into the bloodstream. Glucagon acts as an opponent to insulin, which signals cells to take up glucose in times of satiation, to maintain blood glucose homeostasis.

Adipose Tissue

Leptin

Leptin is an important protein hormone produced by adipose tissue. It binds to six receptor types, LepRa–LepRf, but LepRb is the only receptor that contains active intracellular signaling domains. Leptin levels in the blood are proportional to body fat content. An increase in body fat leads to an increase in leptin, which leads to a decrease in food intake and increase in energy expenditure. As with insulin receptors, LepRb receptors are abundant in the hypothalamus and inhibit neuropeptide systems that induce food intake, leading to decreased food intake when leptin is detected. Inadequate leptin signaling, whether due to leptin deficiency (e.g., *ob/ob* mice) or mutated leptin receptors (e.g., *db/db* mice, obese [*fa/fa*] Zucker rats), causes obesity and hyperphagia in both rodents and humans. Leptin resistance develops with obesity and is common in obese humans. Leptin levels

decrease during weight loss, leading to increased food intake.

Brainstem

The brainstem receives peripheral information about the current state of energy balance from reviewed peripheral endocrine feedback signals as well as direct neural innervations. Brainstem circuitry integrates these neural and hormonal indicators from the gut and elsewhere, communicates with other brain regions such as the hypothalamus, and regulates food intake according to energy needs. Brainstem motor systems involving the nucleus tractus solitarius (NTS) are involved in the control of feeding and respond to gut hormones through cranial nerves. The dorsal vagal complex is also of particular importance in the integration of neural signals.

Brainstem Motor Systems and Peripheral Signaling

Brainstem motor systems control eating behavior and food digestion. The trigeminal, facial, and hypoglossal cranial nuclei in the brainstem are responsible for the chewing and swallowing motor behaviors involved in eating. The dorsal motor nucleus of the vagus (DMX) contains motoneurons that project to the gut, liver, and pancreas to control gastric motility and secretion. Neurons in the DMX are organized topographically, with descending fiber projections organized in distinct columns that control different parts of the gut. Positive feed-forward information signaling the presence of food in the mouth or stomach is relayed from the gut to cortex, amygdala, and hypothalamus, and then transmitted to the brainstem. The brainstem integrates information and sends efferent signals to initiate chewing and gastric motility when appropriate.

Negative feedback from the gut is processed by intermediate, subpostrema, and caudal NTS in the brainstem. Tracing studies have shown topographically organized projections from the gut to NTS. The NTS receives mechanical and chemical satiety signals through the mechanosensitive and chemosensitive vagal fibers in the stomach. Mechanosensitive fibers respond to stomach distension and changes in gastric load following a meal, but do not detect nutrient content. Distension of the duodenum can also reduce feeding through satiety signals, but depends upon nutrient content rather than only mechanical stretch. Ingestion of food rich in amino acids, glucose, or lipids induces Fos activity in the NTS. Nutrient ingestion leads to the release of CCK from the duodenum, which signals to the brainstem through vagal afferent fibers. Vagal afferents terminate in the medial nucleus of the NTS, which is part of the dorsal vagal

complex in the medulla oblongata. The dorsal vagal complex is bidirectionally connected to the hypothalamus, making the brainstem an important link between peripheral hormones and hypothalamic neuropeptides. In addition to vagal input to the NTS, cervical ganglion and cervical spinal afferents play an important role in transducing peripheral feedback through direct neural mechanisms.

Chronically maintained decerebrate rats, whose caudal brainstem is dissociated from the forebrain, are able to regulate meal size and show similar energetic response to food deprivation as control rats, with both groups showing reduced energy expenditure and respiratory quotient. Decerebrate and control rats also respond to insulin administration with increased intraoral intake, and both groups respond to administration of the competitive glucose analog 2-deoxy-D-glucose (2DG) with sympathoadrenal hyperglycemia. Thus, the caudal brainstem is sufficient to maintain some aspects of the control of food intake and energy expenditure.

Hypothalamic Control of Food Intake

Along with the brainstem, the hypothalamus is a crucial brain region for the regulation of food intake and energy homeostasis, integrating signals from the hindbrain, periphery, and limbic regions. In the dual-center model of appetite control, the ventromedial hypothalamic nucleus (VMH) was hypothesized to be the satiety center of the brain, whereas the lateral hypothalamic nucleus (LH) was represented as the hunger center. While these regions are still recognized to have important roles in energy homeostasis, a more complex appetite-regulating network has been identified in the hypothalamus that involves not only the VMH and LH, but also the major roles of the Arc and the PVN. The hypothalamic control of food intake is achieved through the transmission of orexigenic or anorexigenic neuropeptides from neurons localized in these and other hypothalamic nuclei, as reviewed in this section.

Orexigenic Neuropeptides

Neuropeptide Y

Neuropeptide Y (NPY) is found in high concentrations in the hypothalamus and is the major orexigenic peptide in the brain. It is a 36-amino-acid peptide with six receptor types, Y1–Y6. Only the Y1 and Y5 subtypes have been shown to be involved in the orexigenic effects of NPY. Hypothalamic NPY is synthesized in large part by neurons in the Arc, which project to PVN, dorsomedial nucleus (DMN), and the median preoptic area. Neurons expressing NPY also express AgRP, another potent orexigenic neuropeptide.

Injection of NPY into the ventricles or hypothalamus increases food intake, increases meal duration, reduces latency to eat, increases the motivation to obtain food, and delays satiety. Neurons in the Arc, PVN, and hindbrain detect available energy through interactions with peripheral hormones and central peptides, and activate the NPY system if not enough energy is available to fulfill the body's metabolic needs. Thus, overnight food deprivation increases NPY expression in the Arc and PVN, and NPY immunoreactivity in hindbrain and hypothalamus increases with chronic food deprivation. NPY levels quickly return to normal following refeeding. The NPY system is activated by ghrelin, which is released in association with feelings of hunger and increases appetite. Orexigenic effects of ghrelin are suppressed when NPY or AgRP is blocked.

NPY neurons in the Arc contain leptin, insulin, and glucocorticoid receptors, allowing them to detect changes in hormone levels that occur with food deprivation, energy repletion, and changes in adiposity. Leptin and insulin form a negative feedback loop with NPY to regulate energy homeostasis. In times of negative energy balance (food deprivation and active depletion of body fat), leptin levels decrease, thus leading to increased NPY gene expression and increased food intake. In times of positive energy balance (excess energy intake and gains in adiposity), leptin levels increase, thus leading to reduced NPY levels and decreased food intake. Hyperphagia is often seen in diabetic states because the low levels of insulin (or insulin action) are unable to inhibit NPY neurons. Accordingly, treatment of diabetes with insulin can normalize NPY activity in the hypothalamus and decrease food intake.

Orexins

Orexins, also known as hypocretins, are orexigenic neuropeptides involved in the regulation of the sleep-wake cycle and feeding. Two hypocretins, orexin A, a 28-amino-acid peptide, and orexin B, a 33-amino-acid peptide, are synthesized in LH. The orexins bind to two orexin receptor subtypes, OX1-R in VMH and Arc and OX2-R in the PVN and hindbrain. Injection of orexin A and B into the ventricles or hypothalamus can increase food intake, but less potently than NPY. Orexins also increase drinking, food seeking, and spontaneous activity.

The orexin system is bidirectionally connected to the NPY system. NPY expression is increased with intraventricular injection of orexins, and NPY Y1 and Y5 receptor antagonists reduce the orexigenic effects of orexin injection. GABA is also involved in the modulation of orexin activation. GABA neurons co-express orexin, and orexin neurons are activated by a GABA agonist.

Orexin neurons are glucosensitive and respond to changes in blood glucose levels rapidly, making them an early hypothalamic factor for triggering food ingestion.

Glucosensitivity makes orexins highly sensitive to changes in food intake. A reduction in food intake leads to increased orexin concentrations in the LH, increased orexin gene expression, and increased expression of orexin receptors. As with NPY, orexins are also sensitive to changes in leptin levels. Leptin inhibits orexin gene expression, so an increase in leptin due to satiety or increased adiposity suppresses orexin activity in the hypothalamus, leading to decreased food intake.

Melanin-concentrating hormone

Melanin-concentrating hormone (MCH) is a 19-amino-acid peptide that is synthesized in the LH and binds to two receptor types, MCH-R1 and MCH-R2. MCH neurons are directly connected to orexin neurons and contain OX1-R receptors, as well as cannabinoid CB1 receptors.

Central injection of MCH increases food intake, and overexpression of MCH leads to obesity and insulin resistance. MCH is less potent than NPY, but as potent as orexins. Chronic MCH administration increases food intake and leads to weight gain when animals are fed a high-fat diet. Increased food intake is caused by action at the MCH-R1 receptor, which is widely distributed in the brain.

MCH neurons are not glucosensitive, but they are affected by food restriction. Fasting for 24 h leads to increased expression of MCH. As with NPY and orexins, MCH is inhibited by leptin. Central injection of leptin leads to decreased MCH expression, decreasing orexigenic signaling. MCH also interacts with other hypothalamic neuropeptides. For example, injection of MCH increases NPY expression and stimulates the release of NPY.

Agouti-related protein

Agouti-related protein (AgRP) is a neuropeptide released by NPY/AgRP neurons in the Arc of the hypothalamus. It plays a significant role in energy balance, in part through its inverse agonist action at anorectic melanocortin receptors 3 and 4. AgRP binds to MC3-R and MC4-R, antagonizing anorectic melanocortins such as α -melanocyte-stimulating hormone (α -MSH) that bind to MC3-R and MC4-R. Central administration of AgRP increases food intake potently and with long-lasting effects. Obese mice have increased levels of hypothalamic AgRP, and mice overexpressing AgRP are obese and hyperphagic. Like NPY, AgRP is downregulated by leptin and insulin, with increased leptin and insulin levels leading to decreased AgRP levels. Conversely, administration of the appetite-stimulating hormone ghrelin upregulates AgRP expression and induces Fos expression in NPY/AgRP neurons.

Galanin

Galanin is 29-amino-acid peptide formed by the cleavage of a prepropeptide encoded by the GAL gene. It binds to three receptor types, GALR1-3. Galanin plays a role in the regulation of several neuroendocrine functions in the hypothalamus, anterior pituitary, and peripheral organs. It acts as an orexigenic neuropeptide in the regulation of food intake. Neurons expressing galanin are found throughout the hypothalamus, including the paraventricular nucleus and Arc. Administration of galanin to the PVN increases food intake without increasing feeding-related behaviors such as drinking and grooming. Orexigenic effects of galanin are not as strong or long lasting as the effects of NPY however. The effects of chronic administration of galanin depend on the conditions of the administration. An early study showed that chronic administration did not lead to obesity, but chronic administration to mice lacking endogenous galanin did lead to increased food intake and obesity. Galanin appears to be related to fatty acid metabolism, as female rats fed a high-fat, but not high-carbohydrate or high-protein, diet have highly elevated levels of galanin in the PVN. In addition, injection of galanin to the PVN increases body fat accrual in rats on a high-fat diet, suggesting that galanin may directly influence fat oxidation or fat lipogenesis.

Anorectic Neuropeptides

Anorectic neuropeptides found in the hypothalamus include the melanocortin α -melanocyte-stimulating hormone (α -MSH), corticotropin-releasing factor (CRF), urocortins 1, 2, and 3, thyrotropin-releasing hormone (TRH) and cocaine- and amphetamine-regulated transcript (CART). Below we summarize findings concerning the important melanocortin control of food intake.

Melanocortins

Melanocortins are anorexigenic peptides cleaved from the POMC precursor polypeptide that can bind to MC1-MC4 receptors. The most abundant melanocortin found in the hypothalamus is α -MSH. POMC-expressing neurons in the Arc comprise a more distinct population of neurons than those that express NPY/AgRP and also co-express CART. Similar to NPY/AgRP neurons, POMC neurons appear to be nodal points of peripheral feedback to the CNS, but in this case subserving an anorectic role, and show major ascending projections to the PVN and LH.

Activation of the POMC system leads to anorexia. Synthetic MC3 and MC4 receptor agonists suppress food intake, whereas antagonists for those receptors increase intake. AgRP is a natural antagonist for melanocortin receptors and thereby increases food intake. POMC/CART neurons contain leptin and insulin receptors and are thus sensitive to changes in leptin and insulin

levels. Unlike NPY, POMC expression is increased with increases in leptin levels that come as a result of overfeeding and weight gain. Injection of leptin into the Arc also increases POMC expression. Increased POMC expression results in reduced food intake. Leptin or insulin deficiency decreases POMC expression, leading to promotion of food intake. Anorexia induced by increased leptin levels can be reversed by administration of a melanocortin receptor antagonist.

Other appetite regulatory peptide systems interact with melanocortin systems. For example, MCH inhibits the release of α -MSH. Some evidence suggests that PYY₃₋₃₆ reduces food intake by inhibiting melanocortin neurons, but PYY₃₋₃₆ reduces intake in the absence of melanocortin signaling, suggesting that while melanocortins may play a role in PYY action, they are not necessary for it.

As shown in **Figure 1**, POMC neurons receive inhibitory GABAergic collateral input from appetite-stimulatory NPY/AgRP neurons such that stimulation of NPY/AgRP neurons facilitates food intake both through direct effects of the orexigenic pathway and by inhibiting the anorexigenic pathway. A reciprocal inhibition of NPY/AgRP neurons by POMC neurons has not been identified, an absent regulatory mechanism that some have speculated contributes to the less strict control over positive energy balance.

Role of Reward Systems in Control of Food Intake

While food intake is regulated homeostatically by the interaction of peripheral hormones with hypothalamic neuropeptides, it is also modulated in partly nonhomeostatic fashion by corticolimbic reward pathways. Hunger and satiety signals from the periphery and hypothalamus are integrated with motivationally relevant reward and pleasure signals from the ventral tegmental area (VTA), nucleus accumbens (NAcc), and ventral pallidum (VP), among other brain regions, as briefly summarized below.

Dopamine

It is widely accepted that dopamine plays a significant role in reward and motivation. Dopamine neurons in the VTA project to the NAcc and cortex, creating a mesocorticolimbic dopamine circuit. Dopamine is released with the consumption of pleasurable food and other rewards. When animals seek and receive food rewards, dopamine neurons are activated and fire more in relation to preferred food than nonpreferred food. Food reward is enhanced with the activation of dopamine neurons.

However, the exact nature of dopamine's role in reward is controversial. It has been hypothesized that dopamine may mediate the pleasure in a reward, or liking;

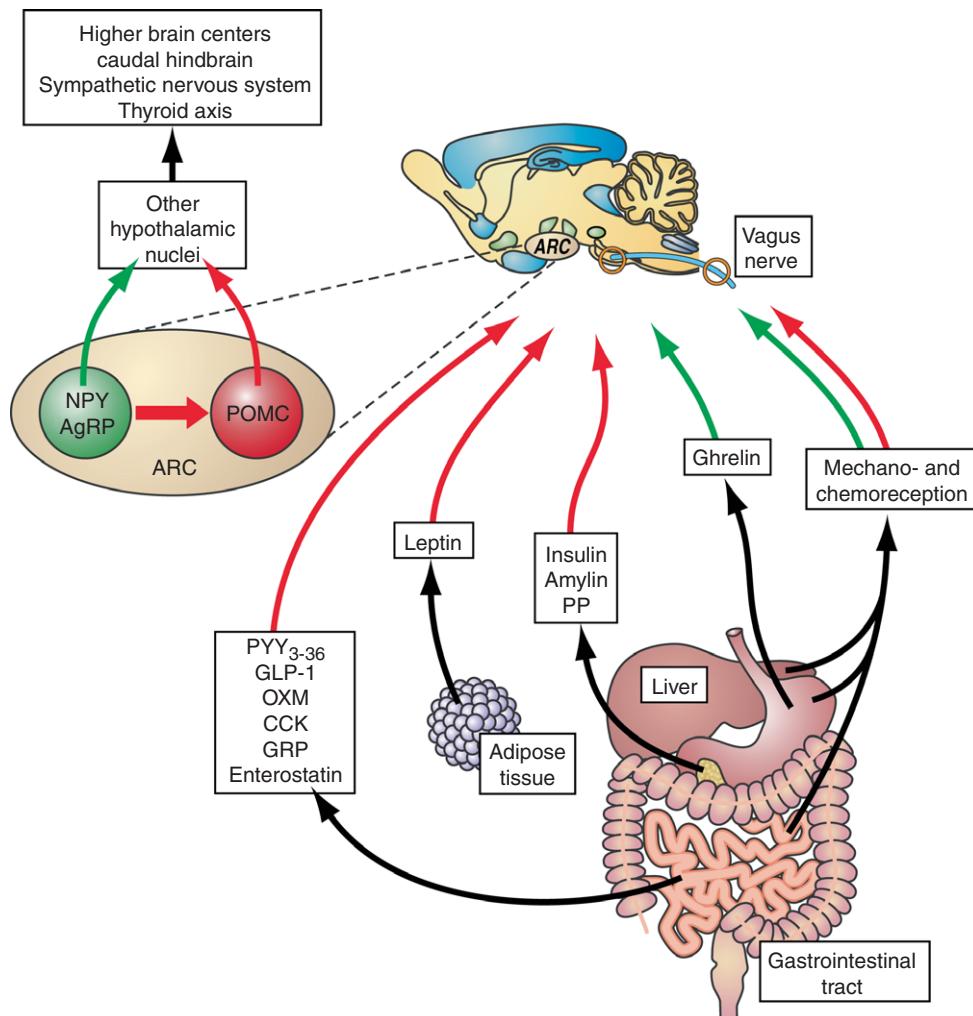

Figure 1 Role of peripheral signals in the regulation of food intake. Following a meal, PYY₃₋₃₆, glucagon-like peptide-1 (GLP-1), oxyntomodulin (OXM), cholecystokinin (CCK), gastrin-releasing peptide (GRP), and enterostatin are putatively released from the gastrointestinal tract, while insulin, amylin, and pancreatic polypeptide (PP) are released from the pancreas, signaling to the brain to inhibit food intake. The anorectic signal leptin is released from adipose tissue in proportion to body fat. During a fast, ghrelin is released from the stomach to stimulate food intake. Feeding-relevant signals encoded by mechanoreceptors (e.g., stretch/pressure) and chemoreceptors (e.g., pH and osmolarity) in the stomach and liver are relayed by the vagus nerve and splanchnic nerve fibers that project to the caudal hindbrain. The arcuate nucleus of the hypothalamus (Arc) helps integrate blood-borne peripheral signals, and NPY/AgRP and POMC neurons in the Arc signal to other hypothalamic nuclei and brain regions. Green arrows indicate stimulatory effects and red arrows indicate inhibitory effects on appetite. Adapted with permission from Murphy KG and Bloom SR (2006) Gut hormones and the regulation of energy homeostasis. *Nature* 444: 854–859.

it may regulate learning of predictions of future reward; or it may mediate the drive or desire to obtain a reward, or wanting. Taste reactivity studies monitoring the reaction of rats to different foods are able to identify when a rat likes or dislikes a food. Such studies have shown that the animal's liking of a food is not affected by the loss of striatal dopamine neurons or by the blockade of dopamine transmission. Electrophysiology studies in monkeys have shown that dopamine neurons do not fire in response to juice reward after the reward prediction is learned. Thus, dopamine is not a pleasure neurotransmitter and does not mediate the hedonic value of foods.

Instead, recent evidence has implicated dopamine as a motivational neurotransmitter, mediating the wanting of a reward. It is thought that activation of dopamine neurons enhances the desire for a reward through incentive salience, a process by which salience is attributed to a stimulus, making it wanted. Motivational value is assigned to the stimulus, causing the animal to seek it. Incentive salience is related to the sensory representation of the stimulus (i.e., how the food tastes, smells, and looks), what has been learned about the stimulus, and the current energy needs. Dopaminergic incentive salience interacts with peripheral and hypothalamic energy regulatory

signals. For example, after food deprivation, the incentive salience of food increases, making the subject want it more. The concept of incentive salience can explain how dopaminergic mesolimbic systems participate in motivation without encoding the hedonic value of a stimulus.

Opioids

Brain opioid systems also regulate food intake by mediating the rewarding properties of food. Opioids have been shown to be involved in the pleasure or liking of a food, as well as wanting of a food. Opioid transmission in a highly interconnected network of forebrain regions increases the hedonic value of foods, enhancing food reward. In particular, hedonic hot spots of μ -opioid receptors in the NAcc shell and VP have been identified as critical for liking reactions. Taste reactivity studies have shown that μ -opioid stimulation of a cubic millimeter in rostromedial NAcc shell and in posterior VP increase liking facial reactions to foods. In addition, injections of opioids into the NAcc and VP hot spots, as well as the other areas in NAcc, increase food intake, potentially consistent with an increase in wanting. In this case, there was no wanting hot spot in the NAcc, but instead a diffuse opioid network throughout NAcc that increased food intake. Thus, NAcc and VP are involved in both hedonic and motivational aspects of food reward. The NAcc and VP are highly interconnected and work together to enhance the hedonic value of food. The two regions modulate Fos expression in each other and μ -opioid stimulation in both regions simultaneously is necessary for enhancement of liking reactions to food. However, the NAcc appears to dominate the actual consumption of food, with opioid

injection into the NAcc alone increasing food intake. Thus, the opioid system in the ventral striatum is a key component of reward-related control of food intake.

Endocannabinoids

Endogenous cannabinoids (ECs) are thought to interact with energy regulatory systems in the periphery and hypothalamus, as well as in reward systems in limbic regions. The endocannabinoids anandamide (AEA) and 2-arachidonoyl glycerol (2-AG) have been shown to interact with leptin, the peripheral adiposity signal that decreases food intake. Leptin deficient mice (*ob/ob*) and leptin receptor signaling-deficient rats (*Zucker fa/fa*) have increased levels of 2-AG in the hypothalamus, while intraperitoneal administration of leptin decreases EC levels in the hypothalamus. ECs have been also shown to affect regulation of food intake. CB1 receptor antagonists decrease food intake as well as abdominal adiposity. LH-stimulated food intake is enhanced by the CB1 agonist tetrahydrocannabinol (THC), and blocked by CB1 antagonists.

EC transmission also appears to mediate the hedonic value of food. Microinjection of AEA into the medial shell of the NAcc increases liking reactions to sucrose taste. CB1 receptor density is decreased in rats fed a palatable diet, which may indicate increased EC activity with intake of pleasurable food. Further interactions with limbic reward systems were shown in studies that demonstrated increases in AEA and 2-AG levels in limbic regions after food deprivation and an increase in food intake after injection of 2-AG into the NAcc shell. Because of their role in both hypothalamic and limbic

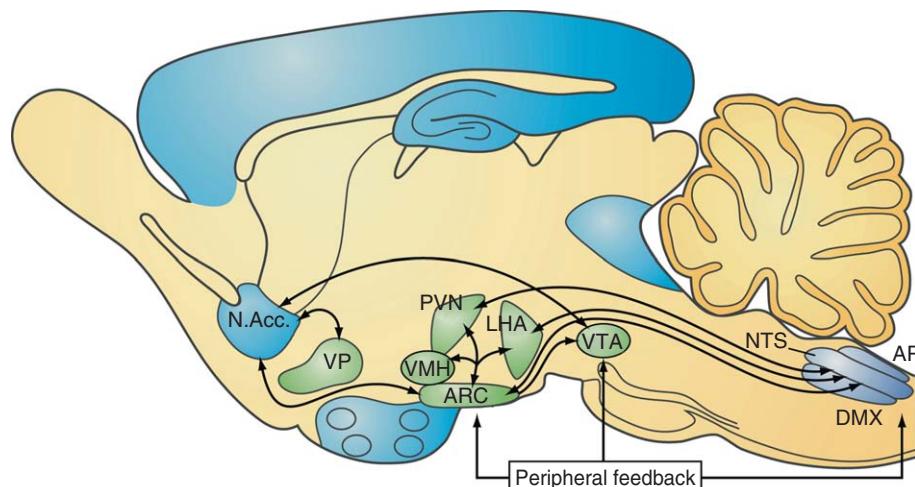

Figure 2 Neural circuitry that regulates food intake and energy homeostasis. Peripheral feedback signals converge on the arcuate nucleus of the hypothalamus (ARC), the ventral tegmental area (VTA), and the nucleus of the solitary tract (NTS). Reciprocal connections among hypothalamic nuclei, reward pathways, and the caudal brainstem allow for coordinated control of food intake and energy homeostasis. feeding-regulatory systems, ECs have been proposed to integrate energy homeostatic- and reward-based aspects of food intake control.

Summary

Figure 1 summarizes the manner in which peripheral gut-, pancreas-, and adipose tissue-derived endocrine hormones and visceral neural feedback signal the brain to stimulate (green arrows) or inhibit (red arrows) appetite in the service of energy homeostasis. **Figure 2** emphasizes that much of this peripheral feedback directly converges on the medio-basal hypothalamus, including the Arc of the hypothalamus and its ascending projections to other hypothalamic nuclei; the caudal brainstem, through vagal and splanchnic afferents and endocrine transmission; and brain reward pathways, such as the mesolimbic dopamine system. These feedback integration sites in the CNS intercommunicate to achieve a coordinated control of food intake with both energy and nonenergy homeostatic components.

Glossary

Acute-phase proteins – The serum proteins (e.g., haptoglobin, α 1-antitrypsin, α 1 and α 2 macroglobulin, and C-reactive protein) released from the liver that increase during acute inflammation. Negative acute-phase proteins (e.g., albumin), in contrast, decrease during inflammation.

Adrenocorticotrophic hormone (ACTH) – The polypeptide hormone secreted by the anterior pituitary; stimulates cells of the adrenal cortex to secrete cortisol.

Anhedonia – The loss of interest or pleasure in activities that would ordinarily be perceived as rewarding.

Antigen – Any foreign material that is specifically bound by a specific antibody or specific lymphocytes.

Apoptosis – Programmed cell death in which the chromatin becomes condensed and the DNA is degraded. No inflammation is typically observed, unlike passive death processes where leakage of organelles and intracellular proteases induce inflammatory reactions.

Autocrine – The action of a hormone on the same cell that synthesized it.

Chemokines – A family of 8- to 10-kDa cytokines that stimulate leukocyte movement and directed movement.

Corticotropin-releasing hormone (CRH) – Hypothalamic hormone that stimulates ACTH secretion by the anterior pituitary and acts as a neurotransmitter in the brain.

Cytokines – Immune system proteins that are biological response modifiers. They coordinate antibody and T-cell immune system interactions and amplify immune reactivity. Proinflammatory cytokines trigger inflammation. Cytokines include monokines (e.g., interleukin-1 (IL-1) and tumor necrosis factor alpha (TNF α)) synthesized by macrophages, and lymphokines (e.g., interleukins, gamma interferon, and lymphotoxin) produced by activated T-lymphocytes and natural killer (NK) cells.

Glucocorticoid – One of a group of hormones (e.g., cortisol) of the adrenal cortex that are important in protein and carbohydrate metabolism, secreted especially in times of stress.

IL-6 – A cytokine, formerly known as B-cell differentiation factor, produced by vascular endothelial cells, phagocytes, fibroblasts, activated T-lymphocytes, and neoplasms. IL-6 is secreted in response to IL-1 or

TNF. It mainly acts on B cells and hepatocytes. Its main function is to cause B lymphocytes to differentiate into cells that synthesize antibodies. IL-6 also induces hepatocytes to form acute-phase proteins including fibrinogen.

Interferon-gamma (IFN- γ) – A cytokine synthesized mainly by activated T-helper cells; it activates killer T-cells, NK cells, and macrophages.

Interleukin (IL)-1 – Produced by monocytes and macrophages, it stimulates acute-phase protein synthesis and promotes T-cell proliferation; it is also an endogenous fever-producing substance. IL-1 is comprised of two principal polypeptides: IL-1 α and IL-1 β .

Interleukins – A group of cytokines synthesized by lymphocytes, monocytes, and other cells, which promote growth of T- and B-cells and other hematopoietic stem cells, and have a variety of other biological functions.

Leukocyte – White blood cell. The principal types include the granulocytes (neutrophils, eosinophils, and basophils), lymphocytes (T- and B-cells), and monocytes (macrophages).

Lymphocytes – Small cells with virtually no cytoplasm, and bearing antigen-specific receptors, which are found in blood, in all tissue, and in lymphoid organs, such as lymph nodes, spleen, and Peyer's patches. Lymphocytes are divided into two principal groups: T-and B-lymphocytes. In addition, NK cells, which are large granular lymphocytes, comprise a small percentage of the lymphocyte population. Lymphocytes are distinguished by the expression of distinctive surface molecules that have precise roles in immune reaction.

Microglia – A type of glial cell present within the central nervous system that serves in a defensive capacity, constantly seeking damaged neurons, plaques, and infectious agents.

Motivation – A central state that organizes perception and action.

Myeloid cells – An immature bone marrow cell that is a precursor of the polymorphonuclear (multi-nucleated) leukocytes. Typical polymorphonuclear cells include neutrophils, eosinophils, and basophils, which are all present in the peripheral blood.

Natural killer (NK) cells – The cells that attack and destroy tumor cells and certain virus-infected cells. These cells induce lysis through the action of antibody.

Immunologic memory is not involved, in that previous contact with the antigen is not necessary.

Paracrine – The local effects of a hormone acting on cells in its immediate vicinity.

Prostaglandins – Biologically active lipids, with hormonal actions, derived from arachidonic acid by actions of the enzyme, cyclooxygenase. These are found in virtually all Mammalian tissues. Prostaglandins have numerous actions including decreasing blood pressure, stimulating muscle contraction, regulating inflammation and blood clotting, and modulating immune responses.

Pyrogen – A substance that induces fever. It may be endogenously produced, such as by IL-1, or may result from exogenous infection (e.g., bacterial or viral insults).

Transforming growth factor-beta (TGF- β) – A cytokine that induces the proliferation of many cell types, including epidermal and epithelial cells. It also facilitates the growth of selected transformed cells.

Tumor necrosis factor- α (TNF- α) – A monokine produced by macrophages. It participates in inflammation, wound healing, and tissue remodeling, and has potent antitumor properties and is associated with cachexia. More recently, this cytokine has been shown to be active in the central nervous system.

instance, recently identified interleukins, including IL-18 and IL-23, may contribute to neurodegenerative process that occur in multiple sclerosis, Alzheimer's disease (AD), and stroke. Conversely, other trophic cytokines, such as granulocyte colony-stimulating factor (G-CSF) and TGF- β , impart neuroprotective effects in models of stroke, traumatic head injury, and Parkinson's disease (PD).

Interleukin-1 β

The actions of cytokines, such as IL-1 β , involve an interaction between its type I receptor and the IL-1 β receptor accessory protein, which are not only found on immune cells, but also on neurons and glial cells within the brain. The actions of IL-1 β are regulated by activation of anti-inflammatory cytokines. In addition, an endogenous antagonistic cytokine, namely the IL-1 β receptor antagonist (IL-1ra), competes with IL-1 for binding sites, essentially terminating the effects of IL-1 β . In addition, there exists a second IL-1 receptor (type II) that acts as a decoy receptor, as it does not transduce a signal following binding with the cytokine. In effect, there are multiple checks and balances that determine whether and to what extent IL-1 receptor activation will occur. Once the type I IL-1 receptor is stimulated, a cascade of events ensues culminating in the phosphorylation and degradation of the endogenous inhibitory factor kappa B (I κ B). This results in nuclear factor kappa B (NF κ B) being translocated to the nucleus, where it promotes the expression of genes important in neuronal homeostasis and inflammatory processes. Similarly, IL-18 is a member of the IL-1 β cytokine superfamily and like IL-1 β , signals mainly through NF κ B-dependent processes. Specifically, IL-18 triggers intracellular cascades that ultimately induce the production of IFN- γ and other inflammatory factors through promotion of NF κ B-dependent gene transcription, often coupled with mitogen-activated protein kinase (MAPK) signaling.

Interleukin-6

A second essential cytokine, IL-6, is also secreted from macrophages and from T-lymphocytes following antigenic challenge. The receptors for this cytokine are present on numerous peripheral nonimmune cells (e.g., fibroblasts, adipocytes, hepatocytes, and endothelial cells) as well as on brain microglia, astrocytes, and neurons. Binding of IL-6 to its receptor results in a relatively low-affinity structure that requires recruitment of glycoprotein-130 (gp130) to create a functional receptor complex, thereby promoting a signaling cascade involving the stimulation of various protein kinases. Signaling through the IL-6 receptor-gp 130 complex primarily involves activation of the Janus kinase (JAK) signal and signal transducer and activators of transcription (STAT)

Cytokines as Signaling Molecules

In response to foreign particles (antigens), different immune cells (T- and B-lymphocytes, macrophages, as well as endothelial cells) involved in defense of the organism are activated. These cells communicate with one another and mobilize innate and adaptive immunological responses through signaling molecules that are referred to as cytokines. Several cytokines have been identified that include the interleukins (ILs), tumor necrosis factors (TNFs), interferons (IFNs), chemokines, and growth- and cell-stimulating factors. These cytokines have largely been classified on the basis of their molecular structure, and their physiological actions, including the production of fever (pyrogenicity) or inflammation (i.e., swelling resulting from leukocyte infiltration, redness due to local vasodilatation, heat, and pain). Of the various cytokines whose behavioral actions have been assessed, greatest attention has been devoted to the pro-inflammatory cytokines (IL-1 β , TNF- α , and IL-6) that are released from monocytes and macrophages, and the anti-inflammatory cytokines, IL-4 and IL-10, released from T-cells. Of course, numerous other cytokines have been found to influence brain pathology and have been implicated in acute and chronic neurodegeneration. For

pathway. Essentially, activation of the IL-6 receptor complex triggers conformational changes in the cytoplasmic domain of the receptor, resulting in JAK aggregation and subsequent phosphorylation of various STATs. Thereafter, nuclear translocation of STAT homo- or heterodimers provokes the transcription of a number of immune and central nervous system (CNS) regulatory proteins.

Other cytokines, including those with anti-inflammatory properties, particularly IL-4 and IL-10, also influence CNS processes by stimulating the JAK–STAT pathway. Although IL-6 can have proinflammatory actions, such as the provocation of acute phase proteins, this cytokine also shares anti-inflammatory functions with IL-10, including the inhibition of macrophages and TNF- α . In fact, IL-6 and IL-10 share many common effects that likely stem from similar signaling mechanisms that primarily involve activation of elements of the JAK–STAT pathway, particularly STAT3. Unlike STAT1 (induced by IFN- γ), which promotes inflammatory and proapoptotic responses, STAT3 counteracts inflammation and promotes cell survival. STAT3 phosphorylation may result in neuroprotective effects, either through the production of trophic or anti-apoptotic factors or by buffering the impact of extracellular excitotoxic/oxidative species.

Tumor Necrosis Factor- α

Like IL-1 β and IL-6, TNF- α is produced by macrophages, and excites receptors present peripherally (e.g., blood cells, fibroblasts, and insulin-sensitive adipocytes) and on brain neurons and glial cells. The actions of TNF- α are mediated by two receptor subtypes, termed p55 and p75. It seems that p55 contributes to apoptosis and cellular necrosis, and p75 is involved in cellular nutritive functions. TNF- α possesses a unique apoptotic signaling mechanism involving a death domain region intracellularly attached to its p55 receptor. Upon activation, this death domain triggers the recruitment of caspases 1 and 8, which engender cytotoxic consequences. The intracellular actions of p55 are, to some degree, counterbalanced by p75 receptor activation that promotes stimulation of the transcription factor, NF κ B, which may have inhibitory effects on apoptosis. In addition, there are endogenous antagonists for TNF- α , including α -melanocyte stimulating hormone (α -MSH), which contribute to the regulation of this cytokine.

Interferon

In addition to the aforementioned cytokines, IFNs are also considered within the proinflammatory category. In general, IFNs are divided into type I IFNs (including the IFN- α and IFN- β isoforms) and the structurally

unrelated type II form, IFN- γ , which possesses several functional actions similar to those of the type I IFNs. All IFNs act as signaling molecules of the immune system and control infection by blocking viral replication and promoting immune responses against infected cells. Importantly, through stimulation of STAT1 signaling, IFN- γ primes the antigen-presenting cells (e.g., macrophages and microglia) and renders them receptive to later antigenic challenges. Once bound to their respective receptor chains, the presence of an accessory protein is necessary for functional outcomes. The primary signaling pathway for the IFNs is the JAK–STAT pathway, resulting in phosphorylation by intracellular protein kinases. Moreover, the type I IFNs stimulate phosphatidylinositol 3-kinase (PI3K) and MAPK pathways, which might contribute to the ability of these IFNs to interfere with viral replication and promote the apoptosis of tumor and other cells.

Cytokines Influence CNS Processes

Cytokines may influence a variety of cell types, and affect physiological processes, such as cellular proliferation, immune and inflammatory responses, and behavioral states. Ordinarily, low levels of cytokines are present, primarily acting locally (i.e., in an autocrine fashion) or upon cells in close proximity to where they are produced (i.e., functioning in a paracrine manner), and rarely act on cells located some distance away, particularly as spillover into the circulation is rapidly diluted. Under certain conditions, such as severe immunological challenge (e.g., leading to septic shock), marked increases of circulating proinflammatory cytokines levels are provoked, causing the liberation of acute-phase proteins and, as will be seen shortly, promoting utilization of steroid hormones and increased central neurotransmitter activity.

Cytokines comprise relatively large molecules that ordinarily do not readily gain access to the brain. Nevertheless, there are several ways by which peripheral cytokines can influence brain functioning. For instance, cytokines may stimulate fibers projecting from the periphery to the CNS. For instance, IL-1 β and TNF- α stimulate visceral branches of the vagus nerve, thereby provoking altered neuroendocrine and neurochemical functioning and promoting behavioral changes. In addition, despite their large size, cytokines may gain entry to the brain at sites where the blood–brain barrier (BBB) is less effective, specifically at circumventricular organs (median eminence, subfornical organ, area postrema, and organum vasculosum of the lamina terminalis). Saturable transport mechanisms exist that can move IL-1 β and TNF- α into the brain, albeit in low concentrations. Interestingly, certain immunologic challenges or stressful events may undermine the BBB, thus permitting

greater cytokine entry to the CNS. In this regard, it was proposed that the release of corticotropin-releasing hormone (CRH) promotes brain mast cell activation, which in turn increases the release of IL-6, IL-8, and vascular endothelial growth factor. Likewise, proinflammatory cytokines themselves have such an action, as do chemokines (chemo-attractant cytokines). These chemokine actions may promote the formation of vasogenic brain edema that may be evident in neuropathological conditions, such as brain trauma, ischemia, CNS infection, presence of brain tumors, and recurrent flares in multiple sclerosis patients.

It is particularly significant that cytokines and their receptors are endogenously expressed in the brain, being synthesized by microglia, astrocytes, and perhaps by neurons as well. Thus, having gained access to the brain, cytokines may stimulate receptors on cells lining the BBB, particularly around the meninges as well as the vascular areas of the brain, and ultimately, through volume diffusion, receptors may be stimulated at hypothalamic, amygdaloid, and brainstem sites. Besides, cytokines may promote activation of secondary mediators (e.g., prostaglandins) that contribute to fever and possibly other actions elicited by inflammatory factors. In addition to their peripheral activation following infectious challenges, cytokine-producing leukocytes are also mobilized and may enter the brain as a result of such events. Under these conditions, peripheral immune cells can interact with local glia (e.g., through the release of cytokines), thereby affecting neuronal functioning and possibly survival. In addition, direct cell-to-cell interactions between leukocytes and microglia can influence the production of oxidative species important for neuropathology.

Production of both pro- and anti-inflammatory cytokine levels is provoked by traumatic insults and by psychological and physical stressors. It seems that microglia, which serve as specialized immune cells within the brain, are responsible for the synthesis of the majority of these cytokines following head injury, stroke, and neurotoxin treatments. It is less certain what function these cytokines play within the brain (e.g., are they neuroprotective, neurodestructive, or merely bystanders?). It is likely, however, that the actions of the cytokines may be determined by their concentrations (possibly being protective at relatively low concentrations, and destructive at high concentrations). Moreover, as indicated earlier, there is ample reason to believe that they may be involved in the provocation of a variety of pathological states of a psychological nature (e.g., depression) as well as those that involve degenerative processes (PD, AD, multiple sclerosis, as well as cardiovascular disease such as atherosclerosis). In addition, they may contribute to the comorbidities that have been observed between psychological and neurodegenerative disorders and heart disease.

Neurochemical Effects of Cytokines and the Implications for Depressive Illness

Activation of the immune system, as alluded to earlier, may affect multiple hormonal and neurotransmitter systems, and it has been suggested that the immune system acts like a sensory organ to inform the brain about the presence of antigenic challenges. Moreover, cytokines play a particularly essential role in this regard, acting as a messenger between the immune system and the brain (i.e., serving as an immunotransmitter), although this does not preclude involvement of other factors (e.g., cyclooxygenase-2 (COX-2)-derived products or even classical biogenic amines).

Neuroendocrine and Brain Neurotransmitter Changes Elicited by IL-1 β , IL-6, and TNF- α

Studies in rodents have shown that proinflammatory cytokines increase hypothalamic–pituitary–adrenal (HPA) functioning, and influence a range of monoaminergic and peptidergic neurotransmitter changes at hypothalamic and extrahypothalamic sites. Specifically, proinflammatory cytokines increase the release of CRH from paraventricular nucleus (PVN) terminals within the hypothalamus, leading to increased release of pituitary adrenocorticotrophic hormone (ACTH), thereby promoting elevated circulating levels of corticosterone in laboratory rodents and cortisol in human beings. Studies conducted in postmortem tissue as well as *in vivo* have shown that these cytokines increase the utilization of 5-hydroxytryptamine (5-HT) and norepinephrine (NE) within the hypothalamus, and increase NE and/or 5-HT utilization in the medial prefrontal cortex (PFC), hippocampus and the central amygdala, regions that are implicated in cognitive, affective and emotional (anxiety) processes.

These effects of cytokines are not unlike those provoked by physical and psychological stressors, and cytokine manipulations can moderate the impact of traditional stressors. For instance, inhibition of endogenously produced IL-1 β action by an exogenously administered IL-1 receptor antagonist (IL-1ra) attenuated the monoamine changes otherwise elicited by an immobilization stressor in rats. Likewise, several of the behavioral and neuroendocrine effects of a chronic mild stressor were precluded among IL-1 β type I receptor knock-out mice. Interestingly, mice lacking the IL-1 β receptor did not exhibit the reduction of hippocampal neurogenesis that was evident in wild-type mice that had been exposed to a stressor.

Inasmuch as these effects, as well as several behavioral actions of cytokines, are similar to those provoked by psychological and physical stressors, it was suggested

that activation of the inflammatory immune system might be translated much the same as other stressors. This should not be misinterpreted as suggesting that cytokine and stressor actions on biological systems are identical. Aside from the fact that diverse stressors engage different neuronal pathways, different appraisal and coping processes might be engaged to deal with cytokines versus psychosocial stressors. Most certainly, the presence of bacterial or viral infections does not promote cognitive information processing in the same way as psychosocial stressors, although it is possible that cytokine activation may affect appraisal of concurrent psychological stressors.

Neuroendocrine and Brain Neurotransmitter Changes Elicited by IFN- α

Although the extensive use of IFN- α in clinical practice for the treatment of viral diseases (e.g., hepatitis C) and cancer (e.g., metastatic melanoma) is known to be associated with a number of behavioral and psychiatric side effects, the central neurochemical and behavioral actions of this cytokine have not been assessed as extensively as those of other proinflammatory cytokines. It was reported that in rodents, *in vitro*, IFN- α stimulated CRH release from amygdala and hypothalamic neurons, and elicited several *in vivo* brain neurochemical and hormonal changes, although these effects were modest relative to those provoked by IL-1 β . Nevertheless, IFN- α treatment increased hypothalamic and hippocampal NE utilization, reduced DA concentrations within the amygdala, and stimulated activity of the amino acid transmitters, γ -aminobutyric acid (GABA) and glutamate, within limbic and hypothalamic regions.

Many of the effects of IFN- α stem from its central action; IFN- α administered directly into the brain of rodents provoked fever, anorexia, and analgesia, as well as changes of hypothalamic neuronal firing. This treatment also reduced 5-HT concentrations in the PFC, increased hippocampal dopaminergic activity, and increased expression of the serotonin transporter (5-HTT) at the messenger RNA (mRNA) level, which ought to promote reduced serotonin (5-hydroxytryptamine, 5-HT) availability. Moreover, this treatment provoked increased 5-HT_{2C} receptor mRNA editing, resulting in receptor downregulation. It is of particular relevance that 5-HT_{2C} receptor functioning has been associated with anxiety and depressive symptoms, and it was reported that depression/suicide was accompanied by altered 5-HT_{2C} editing.

The effects of chronic IFN- α treatments have not been assessed extensively, despite the fact that this cytokine is administered chronically in the treatment of several human conditions. Nevertheless, the available data using rodents indicate that when IFN- α was administered repeatedly, several 5-HT changes were induced

(e.g., diminished 5-HT levels and turnover in PFC, increased 5-HT turnover within the amygdala, and increased low-affinity 5-HT_{1A} receptor sites). In addition, the effects of acute IFN- α on plasma corticosterone levels diminished with repeated treatment, although cytokine mRNA changes that occurred in brain persisted. Not unlike some of the effects seen in rodents, acute IFN- α administration to healthy volunteers and to patients being treated for hepatitis C increased plasma levels of ACTH, cortisol, and IL-6, but as treatment continued, the increased cortisol and ACTH response was attenuated.

The impact of cytokines on brain monoamine functioning may come about in different ways. For instance, CRH activation evoked by cytokine administration may come to affect forebrain 5-HT functioning, by stimulating receptors present on the dorsal raphe. Alternatively, IFN- α stimulates indoleamine-2,3-dioxygenase (IDO), which is responsible for the catabolism of tryptophan to kynurene. Thus, the IFN- α -provoked increase of IDO will have the effect of reducing tryptophan availability, and hence diminish 5-HT availability. Indeed, it has been shown that depression provoked by IFN- α was accompanied by elevated levels of kynurene and reduced tryptophan. Beyond these actions of IDO, the elevated levels of kynurene are formed into the oxidative metabolites, 3-hydroxy-kynurene, and quinolinic acid (which are elevated in depression) that may have neurotoxic actions. The resulting diminution of neurons might thus favor the emergence of major depressive disorders. In this regard, parenthetically, it seems that these kynurene metabolites synergistically induce free-radical generation, and might also contribute to neurodegenerative diseases such as Huntington's, Parkinson's, and the acquired immune deficiency syndrome (AIDS) dementia.

Sensitization of Processes Related to Cytokine and Stressor-Provoked Neurochemical Changes

In most studies concerning the impact of cytokines (as well as stressors) on neurochemical and behavioral changes, these analyses were conducted at relatively brief intervals following the initial treatment. Yet, there is compelling evidence indicating that stressful experiences may result in the sensitization of neuronal processes, thus augmented behavioral and neurochemical changes (monoamine functioning and corticoid variations) are elicited upon later challenges with either similar or dissimilar stressors (including cytokines). It has likewise been shown that cytokine challenges (particularly IL-1 and TNF- α) result in the sensitization of neurochemical processes, and that some of these effects (e.g., the corticosterone variations) become progressively greater with the passage of time, at least over the 28 days following the initial treatment.

There are several nonmutually exclusive ways by which such a sensitization may come about, including altered receptor sensitivity, metabolic changes, or the induction of neurotrophic factors such as basic fibroblast growth factor (bFGF). Likewise, it is possible that the initial challenge may set in motion a cascade of phenotypic changes that culminate in altered circulating hormone levels. For example, arginine vasopressin (AVP) is ordinarily co-expressed in a modest number of CRH neurons of the PVN of the hypothalamus that terminate within the external zone of the median eminence. With the passage of time following a stressor or cytokine challenge, the co-expression of AVP and CRH increases. Upon later stressor or cytokine treatments, AVP and CRH are co-released and synergistically stimulate ACTH release from the anterior pituitary, leading to adrenal cortisol release. As alluded to above, several processes may be at work in promoting sensitization effects, and the processes governing hormonal changes may be distinct from those associated with neurochemical changes. Irrespective of the process by which a sensitization occurs, the fact is that cytokines may have proactive effects long after the initial effects of the treatment have subsided. Thus, it is possible that stressors and inflammatory immune challenges may increase vulnerability to pathology at lengthy intervals following the initial insult.

Of course, there are other related processes that exist that could influence the way in which a challenge comes to affect disease states. For example, inflammatory factors may become sensitized with their repeated activation, and during the course of a neurodegenerative disease activation of inflammatory processes may exacerbate the pathology. In effect, a disease itself may prime the brain for the damaging effects of inflammatory factors.

Cytokine-Induced Behavioral Changes

Sickness Behaviors in Animal Studies

Activation of the innate immune system, either through the administration of a bacterial endotoxin such as lipopolysaccharide (LPS), or by IL-1 β or TNF- α , provokes behavioral symptoms in rats and mice (e.g., soporific effects, ptosis, anorexia, fever, fatigue, reduced motor activity, and curled body posture) that have been referred to as ‘sickness behaviors.’ In addition, these treatments disrupt relatively complex behaviors, such as operant responding for food reward and disturb exploration and social interaction. Many of these symptoms can be elicited by administering cytokines directly into the brain and hence it is likely that the sickness is centrally mediated. It has been suggested that sickness, following immune challenge, represents an adaptive response to a pathogen, in the sense that it serves to diminish energy expenditure. Yet, the view has also been expressed that

the sickness associated with immune activation may reflect depressive-like behavior given that some of these symptoms are attenuated by antidepressant treatments.

Motivational Changes and Anhedonia

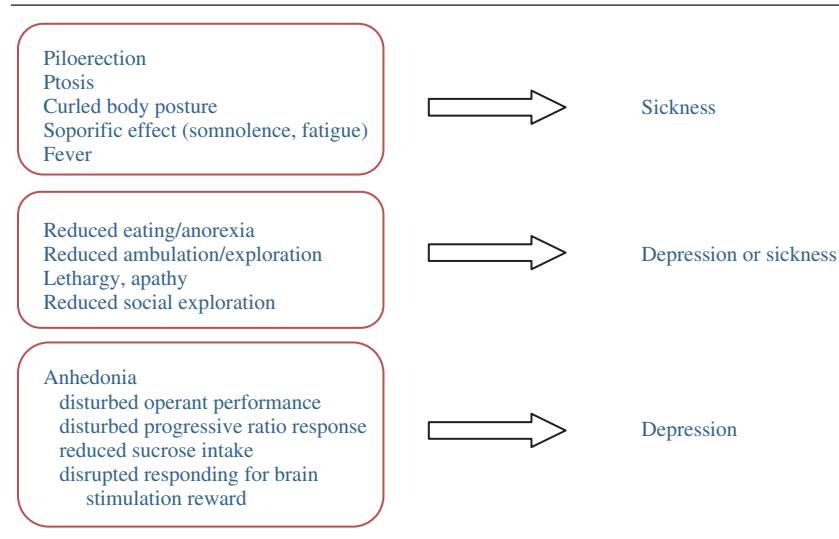

The findings using animal models of depression, coupled with the effects of antidepressants on sickness behaviors and other behavioral disturbances associated with cytokine challenges, are consistent with a role for inflammatory factors in mediating a depressive-like state. Indeed, besides sickness behaviors, cytokines and bacterial endotoxins may elicit anhedonia in mice and rats, a key symptom of depression. For example, LPS disrupted responding for rewarding brain stimulation, and diminished the motivation to work for a food reward. Specifically, using a progressive ratio (PR) schedule (i.e., progressively increasing the number of operant responses that are required for a fixed amount of reward) for a highly preferred treat, namely sucrose reinforcement, it was found that injection of IL-1 β to rats reduced both PR performance, just as free-chow consumption was diminished. Significantly, chronic antidepressant (fluoxetine) treatment attenuated the performance deficit elicited by the cytokine without altering the diminished free chow consumption provoked by the cytokine. Evidently, the cytokine promotes anhedonia independent of the anorexic actions that are induced.

As shown in **Table 1**, of the behavioral effects elicited by cytokines, on the surface, some of these reflect malaise or sickness elicited by the treatments, others reflect depressive symptoms, and still others might reflect sickness and depression. It should be underscored that even some of the symptoms that might be taken to reflect sickness, can be attenuated by repeated treatment with an antidepressant; thus, even these sickness symptoms could involve processes associated with depression.

Behavioral Effects and Correlates of Inflammatory Factors in Humans

Inflammatory Correlates of Depression

Studies in humans have been consistent with the view that inflammatory factors are involved in major depressive disorders. Specifically, it has frequently been reported that depressive symptoms were accompanied by indices of an acute-phase response, such as elevated complement protein levels (C3 and C4) and positive acute-phase proteins, haptoglobin, α 1-antitrypsin, α 1 and α 2 macroglobulin, and C-reactive protein (CRP), whereas negative acute-phase proteins were reduced. It has also been noted that, among depressed patients, activated T-cells (CD25 $^{+}$ and HLA-DR $^{+}$), secretion of neopterin, prostaglandin E2, and thromboxane were elevated. These markers were also

Table 1 Sickness and/or depressive symptoms elicited by cytokines

accompanied by several changes related to circulating or mitogen-stimulated cytokines, particularly among patients presenting with melancholic depression. These included elevations of IL-2 and its soluble receptors (sIL-2R), IL-1 β , IL-1ra, IL-6, sIL-6R, and IFN- γ , and the circadian variations of IL-6 were disturbed. Consistent with the view that cytokines and depression were related, it was reported that the elevated levels of IL-1 β , IL-6, TNF- α , and IFN- γ normalized with antidepressant; however, it was also reported that many of these effects were not apparent with successful pharmacotherapy. Still, the possibility cannot be dismissed that cytokine normalization might occur with more protracted treatment, or alternatively, that cytokine normalization might occur in a subset of individuals, and that the absence of such a normalization might be a marker for illness recurrence. It is also possible that cytokine variations and the normalization of cytokine levels might vary with particular symptoms of depression (or particular subtypes of the illness, e.g., typical vs. atypical depression). For example, it is possible that proinflammatory cytokines, such as IL-1 contribute to the fatigue and increased sleep ordinarily associated with atypical depression.

Reports that cytokine levels are associated with depression do not, of course, indicate that cytokines provoked the depressive state. To be sure, it is equally possible that depressive mood (or the stress associated with depression) altered circulating cytokine levels. It is likewise possible that any number of factors secondary to (or related to) depression provoked the cytokine variations. For instance, factors that promoted depression (e.g., antecedent conditions, such as recent stressful experiences, stressors encountered early in life, and altered

coping with stressors) could have influenced cytokine levels. In addition, institutionalization (and the social and environmental change related to this) of depressed patients may itself have contributed to cytokine variations, as would an increase of drug use (including nicotine, alcohol, as well as illicit drugs). Indeed, it was reported that when age and body mass index were statistically controlled, the differences in circulating cytokine levels between controls and depressed patients were absent. Furthermore, it is possible that certain neurovegetative features of typical major depression (reduced eating and weight loss, reduced sleep) promote altered cytokine levels, as might gender, smoking habits, recent infection or prior medication, as well as altered circadian cycles. Finally, the cytokine variations might stem from any of the many pathologies that have been shown to be comorbid with depression.

Cytokines Promote Depressive States

There is ample reason to believe that the depressive state brought on by immunotherapy with IFN- α in hepatitis-C and cancer patients reflects a genuine major depressive episode rather than being secondary to malaise associated with the treatment. In this regard, the development of depression following IFN- α therapy was aligned with many of the features associated with depression that occur in the absence of cytokine immunotherapy (e.g., stress-related depression). For example, major depressive symptoms in response to IFN- α were most prominent among patients who presented with sub-syndromal levels of depression prior to immunotherapy, those who showed symptoms such as sadness, pessimistic thoughts, and sleep disturbances, as well as individuals with poor social

support. Furthermore, paralleling the mood changes brought on following depletion of tryptophan, depressive symptoms elicited by IFN- α were most prominent among women and those with a history of depression, among individuals with low tryptophan levels prior to treatment, or those with relatively high baseline levels of sIL-2r, IL-6, and IL-10.

Finally, it is significant that selective serotonin reuptake inhibitors or serotonin-specific reuptake inhibitors (SSRIs) influenced the expression of several cytokines and generated marked anti-inflammatory effects. Moreover, it was shown that the depression brought about by IFN- α therapy could be attenuated by SSRIs (e.g., sertraline, paroxetine, and citalopram). In this regard, paroxetine primarily affected the mood-related symptoms, with only minor effects on fatigue and anorexia. Furthermore, it was shown that SSRIs influenced the expression of several cytokines and generated marked anti-inflammatory effects. Together, these findings indicate that the relationship between cytokines and depression is not simply one of a correlational nature, but possibly through effects on 5-HT functioning, cytokines may provoke the emergence of depressive symptoms.

Although 5-HT activity possibly contributes to the effects of inflammatory factors on depressive symptoms, other neurochemical factors may also play a prominent role in this regard. Specifically, like the SSRIs, the phosphodiesterase IV inhibitor (e.g., rolipram), which acts as an antidepressant, likewise diminished cytokine production in response to LPS in rodents. Further, administration of 5-HT itself reduced the expression of TNF- α and IFN- γ , and this outcome could be attenuated by CRH treatment. Thus, it is likely that 5-HT and CRH-related neuronal activity might reciprocally affect one another, thereby influencing depressive mood.

It would be expected that if inflammatory factors contribute to depressive symptoms, then anti-inflammatory compounds might themselves possess antidepressant properties, or enhance the effects of conventional antidepressants. In fact, COX-2 antagonists, normally used as nonsteroidal anti-inflammatory drugs (NSAIDs), attenuated the depressive-like behavioral and neurochemical alterations associated with both LPS and IFN- α treatment in animal models of depression, and also diminished glucocorticoid responses to social stressors. Moreover, it has been shown that a COX-2 inhibitor enhanced the effectiveness of antidepressant medication in treating depression in humans; however, the usefulness of combining NSAIDs with antidepressant medication is limited by the increased risk of gastrointestinal disturbances that may ensue.

Effects beyond Major Depressive Disorder

In addition to mood changes, IFN- α may engender disturbed vigilance, alertness, and may promote some

memory problems. In addition, IFN- α immunotherapy was accompanied by disrupted neurocognitive functioning (retarded cognitive processing and impaired executive functioning, concentration and memory, as well as irritability and anxiety), and at high doses, a confusional state characterized by disorientation as well as psychotic-like features was apparent. These features (e.g., disturbances of immediate recall) may become more pronounced with treatment continuation. The nonspecificity of symptoms begs the question as to whether or not the effects observed are a genuine manifestation of neurochemical changes that underlie depression, or whether the constellation of symptoms is more a reflection of general malaise or toxicity provoked by the treatment.

Comorbidity with Other Illnesses

Comorbidity between depression and neurological conditions is common, with two or more pathological states often influencing one another's course. Indeed, the presence of depression may augment the neurological decline in PD patients and hampered functional recovery in stroke patients. In some instances, the development of comorbid depression might result from the psychological distress or major life changes and psychosocial factors associated with the neurological condition. However, in other instances, the depressive symptoms might emerge as part of underlying processes that are in common with the neurological disturbances. For instance, stressor-provoked elevations of corticosterone may instigate hippocampal neuronal damage, and may contribute to both depression and chronic neurodegenerative diseases. Likewise, cytokines and associated inflammatory factors (e.g., COX-2 and inducible nitric oxide synthase (iNOS)) have been implicated in both depression and PD and might thus contribute to the comorbidity.

Interestingly, besides affecting mood, antidepressants such as rolipram and bupropion have anti-inflammatory properties, largely by increasing the release of the anti-inflammatory cytokine, IL-10, while reducing levels of the proinflammatory cytokines, TNF- α and IFN- γ . In addition, antidepressants, such as imipramine, were reported to have neuroprotective consequences against the impact of high doses of inflammatory agents. Similarly, anti-inflammatory drugs that inhibit COX-2 production have also been shown to be protective in animal models of neurodegeneration relevant to PD and AD, just as they enhanced the effects of SSRIs in reducing depressive symptoms. Evidently, multiple links may exist between activation of the inflammatory system and the development of depressive and neurodegenerative pathology.

In the case of acute neurological conditions, such as traumatic head injury and stroke, depression is often present, and the depressive symptoms are more resistant to treatment relative to that evident in the absence of comorbidity. It seems that stressor and stroke-induced elevations of IL-1 β , TNF- α , and IL-18 influence some of the same enzymatic pathways, including IDO, resulting in 5-HT depletion. Conversely, stressors that increase IL-1 β or TNF- α have been reported to increase infarct size caused by later middle cerebral artery occlusion. Finally, in addition to CNS pathologies, it was observed that depression was associated with increased likelihood of cardiovascular disease, and conversely myocardial events were predictive of subsequent depression.

Glossary

Phenomenology – It is the subjective mental experiences of observers during cognition or perception. These experiences are assumed reportable, although the nature of the experiences may be influenced by the requirement to report them, and the veracity and reliability of reporting is often of concern.

Semantic knowledge – It is the long-term knowledge about the properties of objects and canonical features of events. This form of memory is typically spared by damage to medial temporal lobe and midline diencephalic brain regions that support the memory for specific events and experiences.

for episodic memory designs, which often test for the remembrance of arbitrary associations or contextual associations, for example, the ability to remember that the word ‘cabbage’ was previously part of an animacy rating task as opposed to a subjective pleasantness rating task (**Figure 1**). This type of mini-event is not associated with a routine experience and therefore observers are limited in their ability to reconstruct the event from semantic knowledge stores. Regardless of these differences, episodic and autobiographical memory are generally considered highly overlapping memory capacities, and the term episodic memory will be taken here to refer collectively to both.

Conceptualizations of Episodic and Autobiographical Memory

The ability to recover information about unique prior experiences in order to guide current choices is a cornerstone of human adaptive behavior. When memories are temporally remote, personally significant, and encompass extended events (e.g., one’s high school graduation), this skill is referred to as autobiographical memory. In contrast, when the remembered events are highly controlled laboratory experiences with verifiable characteristics (e.g., retrieval of newly learned word associations), the skill is typically referred to as episodic memory. The distinction between autobiographical and episodic memory is largely quantitative and not qualitative. In general, autobiographical memories contain considerably more emotional content and visual imagery than episodic remembrances, although it is sometimes unclear the degree to which autobiographical reports rest, not on specific remembrances, but on the observer’s knowledge of the typical characteristics of the targeted experiences. For example, when asked to describe one’s high school graduation, one can rely on the features common to all high school graduations when attempting to report the event. To control for this, autobiographical designs typically score reports for their specificity and degree of idiosyncratic content, in hopes of attributing the report to a genuine remembrance. This reconstruction problem is typically less of a concern

Contrasts with Other Forms of Memory

The distinction between episodic memory and other kinds of memory has been conceptualized along many dimensions, such as phenomenology, content, persistence, behavioral control, and, most recently, neural substrate. Phenomenology was perhaps the earliest characteristic used to parse putative types of memory, dating back to the Ancient Greeks, and it contributes to modern conceptualizations as well. For example, one fundamental modern distinction is between declarative memory (making declarations about the past, or ‘knowing that’) and procedural memory (carrying out actions based on past learning, or ‘knowing how’). The latter encompasses a broad range of skills and abilities that rely upon processes observers are often unable to describe or characterize, such as motor skills like riding a bike and tying one’s shoes. In contrast, knowledge that is accessible to conscious awareness falls under the category of declarative memory. Within declarative memory, an important distinction arises between episodic and semantic memory. One’s general knowledge of the world, such as knowing that lions have manes or that breakfast occurs in the morning, constitutes one’s semantic memory. In contrast, it is also possible to report the details of a particular episode in which say a lion was viewed, or a specific breakfast was consumed. Critically, accessing semantic memory does not require retrieval of the original time or place of learning, as opposed to episodic retrieval. As a particular type of episode recurs across the lifespan, it is

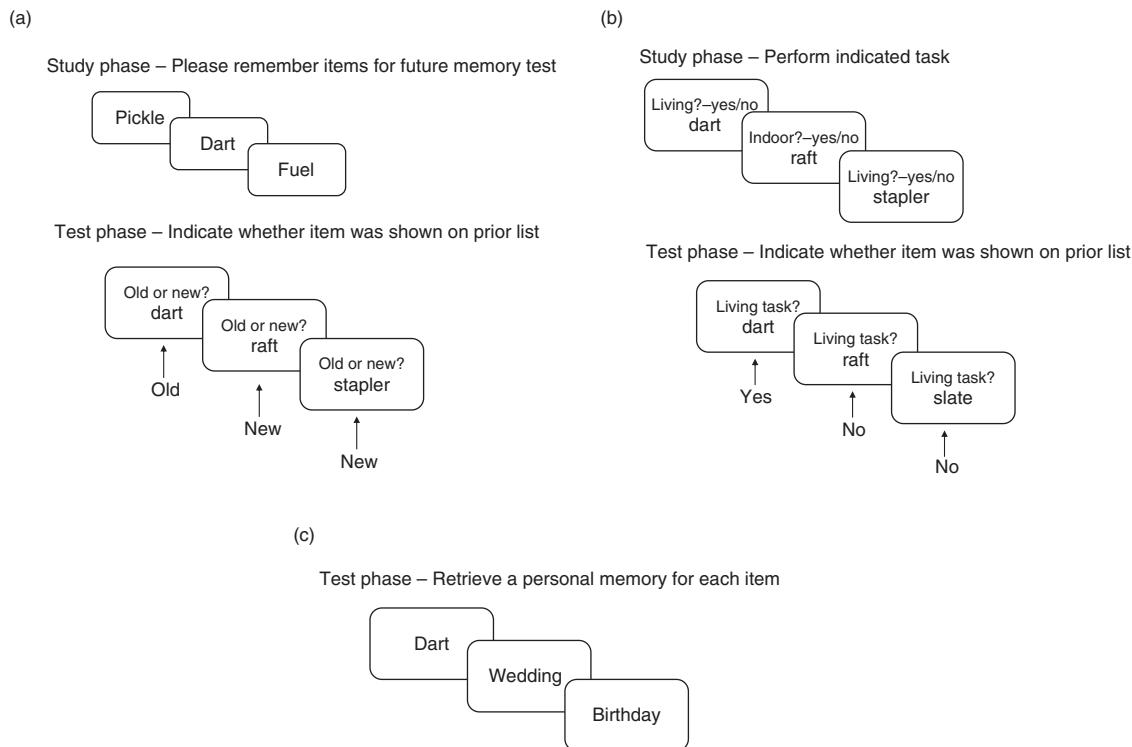

Figure 1 Examples of experimental episodic- and autobiographical-memory tasks. (a) Item recognition. Participants are asked to remember presented words for an unspecified number of memory tasks. During testing they are prompted with studied or novel items and asked to indicate whether items originated from the study list. (b) Context/source task. Participants encounter words during two different encoding tasks. During testing they are required to identify items from the study phase and further to distinguish between items originating from each context task. generally assumed that its canonical features are incorporated into the semantic knowledge store.

Episodic and semantic memory reflect examples of long-term memory, since retention lasts more than several seconds and survives intervening experiences. In contrast, the concept of working memory describes a collection of temporary memory processes in which information is maintained and manipulated in an active or labile state for a short period of time. It is an essential part of current conscious awareness, with important connections to attention and mental ability. Working-memory tasks usually require one to maintain and transform information, keep track of changes, divide attention, and make comparative judgments. Originally thought to function independently of episodic representations, recent conceptualizations of working memory have introduced an episodic buffer which enables the integration of information from perceptual and linguistic operations and long-term memory. The component is episodic because it is assumed to bind different features of an event into a unitary episodic representation; however, it differs from episodic memory in that the episodic buffer is a temporary store.

As is clear from the above, the clarity of the theoretical boundaries between episodic memory and other kinds of memory vary. In most instances, experimental tests of memory cannot be assumed to be ‘process pure’ in that they likely recruit several partially or fully independent memory processes. Nonetheless, through behavioral experimental dissociations, animal lesion studies, the examination of special populations, and, most recently, functional imaging of the brain, psychologists and neuroscientists have amassed evidence for an episodic memory system that is at least partially dissociable from other forms of memory.

Neuroanatomical Frameworks of Episodic Memory

The Amnesic Syndrome

The strongest evidence for a unique episodic memory capacity arose from neuropsychological research examining the patterns of spared versus disrupted memory capacities following neurological insult. In the late 1950s, seminal case-study research examining

a 27-year-old patient undergoing experimental surgical treatment for intractable epilepsy demonstrated that bilateral damage to the hippocampus and surrounding cortical structures resulted in a global amnesia syndrome characterized by severely impaired memory for events occurring up to 3 years before the surgery (retrograde amnesia) and a virtually complete inability to remember new experiences following the surgery (anterograde amnesia) (Figure 2). The severity of the syndrome is easy to underestimate and such patients often demonstrate complete forgetting of to-be-remembered material when distracted for mere seconds with a secondary task. Despite this profound memory impairment for episodes, other intellectual domains appear spared and this has been used as a defining characteristic of the amnesia syndrome, namely, an abnormally low standardized memory score in relation to a preserved estimate of general intelligence. Subsequent animal research and lesions of opportunity in human subjects have also implicated other medial brain structures outside of the medial temporal lobes (MTLs) as critical, including the thalamus, mamillary bodies, fornix, basal forebrain, and retrosplenial areas. Damage to any of these regions can result in a profound global amnesia with preserved intellectual functioning in other domains, such as reasoning, the expression of general semantic knowledge about the world, and the learning of new motor skills.

Perception and Short-Term Visual Memory

Although global amnesia is defined as gross episodic memory impairment in concert with preserved intellectual functioning in other domains, closer examination of patients with damage to MTL regions suggests that not all nonepisodic functions may be fully preserved. Both animal and human neuropsychological studies indicate that the ability to discriminate perceptually similar visual exemplars over short periods may be compromised by damage to MTL regions. During these paradigms, subjects are typically shown a visual sample, required to wait for a brief unfilled delay (e.g., 4–8 s), and then asked to identify the target probe among visually similar lures. Such tasks were thought to fall fully within the realm of working-memory maintenance, that is, the form of memory supporting the maintenance of items in the mind during brief unfilled delays, such as when one holds a phone number in mind before dialing. Previous extensive work with amnesic patients suggested that visual and verbal short-term working memory was spared; however, these designs typically did not use highly visually confusable stimuli. Nonetheless, damage to the MTLs does yield impairment on such tasks, although the cause of the impairment remains controversial. From one viewpoint the compromised short-term working memory suggests a link between working memory and the MTL regions. In contrast, the deficit may reflect the fact that control subjects may occasionally rely upon episodic memory to overcome occasional lapses or disruptions of working-

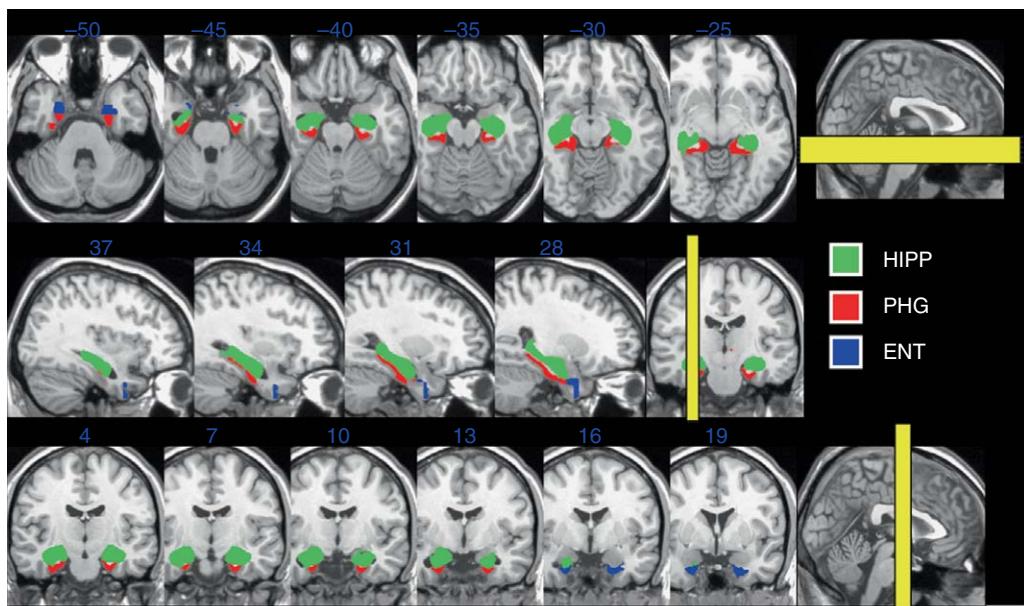

Figure 2 Schematic rendering of regions of the medial temporal lobes (MTLs) critical for episodic memory. Green regions approximate the hippocampus. Red regions encompass the parahippocampal gyrus, the anterior extent of which is often referred to as perirhinal cortex. Blue regions illustrate the entorhinal area. The filled yellow area on the three cardinal views indicates the range from which the partially overlaid slices originated.

memory maintenance. This latter account fits with the observation that even brief attentional distraction in global amnesic subjects is sufficient to cause complete forgetting, which in turn suggests that hippocampally supported retrieval processes are important for bridging even brief delays when attention has been captured or otherwise diverted.

Transitive Inference and Flexible Reasoning

Episodic memory is a vital contributor to flexible, adaptive behavior. For example, determining the correct course of action can be facilitated by remembering that alternative courses of action previously led to undesirable outcomes in similar situations. Here episodic memory does not directly inform the most adaptive behavioral choice, but it can be used to inform reasoning about the relative merit of options. The simplest tests capturing this type of flexibility are known as transitive inference problems. During such problems, observers are selectively reinforced for responses to pairs of stimuli. For example, the bolded items in the following set would lead to reinforcement when selected (**A–B; B–C; C–D; D–E**). Critically, the redundancy of the pairs means that the reinforcement status of B, C, and D items is entirely contextually dependent; thus, the acquisition of the appropriate response requires configural-level knowledge. Furthermore, these designs allow testing with critical probes (e.g., B–D) that have never been reinforced, but which should lead to a preference (B) if a hierarchical episodic representation has been encoded ($A > B > C > D$) or if observers can inductively construct such a representation given the individual learning of the pairs. Animal, neuropsychological, and functional imaging research implicates the hippocampus as important during both the acquisition and critical probe periods of transitive inference problems. However, despite this convergence of evidence, the level of conscious awareness required to solve such problems remains in dispute. Although episodic memory is often considered to pertain to conscious recollection of prior events (or reasoning based on conscious recollection), and is known to require the hippocampus, this does not logically require that all hippocampal-dependent tasks be accompanied by conscious recollection. This argument is bolstered by findings in repeated visual search and visual-inspection paradigms, where hippocampally dependent improvements in detecting target stimuli enmeshed in visual arrays may occur outside of observer awareness that the arrays have been repeated.

Developmental Trends and Dependencies

At both ends of the developmental spectrum, episodic memory is less efficient when compared with that of young adults. In the case of early development, the

study of episodic memory has been challenging since instruction and verbal report measures are inappropriate. However, mimicry paradigms that can be accomplished by pre-verbal children suggest that episodic remembering occurs in children as early as 2 years of age. Although such research has demonstrated that episodic-memory functioning occurs earlier than once thought, it nonetheless remains the case that a major portion of early childhood experience, up until approximately age 3 or 4 years is later either wholly inaccessible to most adults, or when available is quite fragmentary and impoverished. This phenomenon, termed infantile or childhood amnesia, suggests that the co-development of semantic knowledge and other representational systems may be critical for adult levels of episodic memory capabilities. Although widely debated, one current hypothesis is that prior to age 3 or 4 years, children often do not actively construct larger more distinctive representations of ongoing experiences and for the same reason also do not adopt reconstructive strategies during attempted retrieval. The ability to precisely encode the relationships between event elements and to situate events into larger experiences likely relies upon the pre-frontal cortex (PFC) function and is conceptually linked to the idea of an episodic buffer within working memory. This hypothesis receives further support from functional brain imaging research demonstrating PFC recruitment during both initial encoding and later retrieval in the kinds of memory tasks with which young children experience the most difficulty. For example, although children below the age of four are rapidly acquiring large amounts of semantic information, behavioral experiments demonstrate they are impaired in the ability to later remember where and under what circumstances this information was acquired, a phenomenon known as source amnesia. The demonstration, using functional imaging, that PFC regions are heavily involved in source memory tasks (Figure 3), and the known late developmental maturation of PFC cortex in humans, jointly suggest that in this region may underlie the emerging ability to distinctively encode and selectively recover extended events and experiences in childhood.

At the other end of the developmental continuum, impairments in episodic remembering are also prominent. Indeed, even during healthy aging, lapses in episodic memory are one of the most prominent complaints of older adults. As with early childhood, a portion of the impairment likely reflects impairments in organization or processing of information during the encoding of experiences. For example, although older adults experience relative decline in memory performance for even basic item-recognition tasks compared to young adult controls, a large portion of this decline is eliminated when participants are provided explicit strategies that encourage reflecting upon the semantic and unique characteristics of each stimulus during initial study. This has led to one

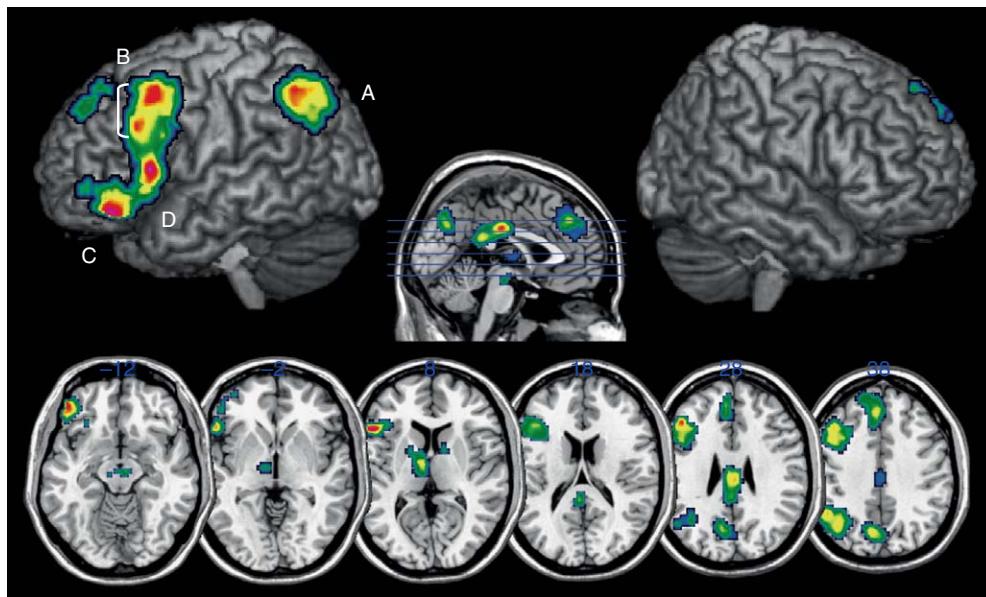

Figure 3 An example of the network implicated in context/source–memory retrieval relative to simple item recognition. Source–memory retrieval increasingly activates left lateral parietal (A), dorsolateral PFC (B), and ventrolateral PFC (C and D) regions along with midline areas.

major theoretical account of age-related memory decline that stresses the role of self-initiated distinctive processing in creating durable episodic memories. Although the root cause for the failure of older adults to spontaneously process materials and events in a distinctive manner remains debated, as with the relative episodic impairment in children, it has been linked to PFC. Consistent with a common PFC locus, older adults, as with children, demonstrate considerable difficulty in source–memory paradigms that require recovery of the contextual specifics of prior encounters and experiences. Despite the evidence for a gross role of PFC in the memory impairments observed at both ends of the developmental spectrum, the precise neurological causes for the failure to recruit PFC, while unknown, presumably arise from different root causes.

Functional Magnetic Resonance Imaging Data

Subsequent Memory and Episodic Encoding

Forming a new memory depends upon the neural mechanisms set in motion at the moment the event is experienced. An influential approach to the study of memory formation or encoding is the subsequent memory paradigm. Neural activity is recorded while participants study a sequence of items, after which memory for the items is tested. The neural responses elicited during prior study are retrospectively coded according to whether the items were later remembered or forgotten, with

differences between cortical responses for later remembered versus forgotten items taken as correlates of successful memory encoding. Data from electrophysiological event-related potentials (ERPs) and functional magnetic resonance imaging (fMRI) suggest that the neural mechanisms that mediate encoding depend upon several factors including the nature of the stimulus, the goals or tasks during encoding, and individual differences in the tendency to adopt particular processing strategies. For example, successful word encoding is associated with activation in the left ventrolateral PFC, MTL, and fusiform gyrus. In contrast, successful encoding of complex visual scenes has been associated with right inferior PFC and bilateral MTL. Aside from these simple stimulus differences, the specific PFC–MTL circuits that covary with successful encoding depend on the particular task and the subject's goals during learning. Subsequent memory designs in which the semantic features of study materials are processed have implicated bilateral PFC and left MTL regions, but when the same items are studied in a perceptual manner, only a subset of these regions is activated and predictive of later memory. Differences in the degree to which these regions are spontaneously activated also vary considerably across subjects and populations. For example, when the encoding tasks are largely unconstrained and participants are simply instructed to memorize meaningful materials, there are considerable individual differences later reported in terms of adopted strategies, with some participants reporting perceptual or imagery strategies, and others reporting adopting complex semantic judgments

and construction of sentences or stories, for example. Critically, these differences are reflected in the pattern of activity seen during encoding and in the later level of success during memory judgments; the left ventrolateral PFC, in particular, appears associated with adopting semantic analysis strategies during encoding. The degree to which these strategies facilitate later memory is dependent upon the form of the later memory task, and tasks that require the recovery of context associations, as opposed to the simple identification of familiar stimuli, appear to benefit considerably from recruitment of PFC during encoding.

Aside from individual differences in encoding strategy, recruitment of left ventrolateral PFC during encoding also varies across age cohorts with elderly participants often demonstrating reduced recruitment compared to younger controls. Requiring all subjects to render semantic level judgments for each to-be-encoded item, in part, eliminates these age-based differences. Thus, when considering both differences across individuals and across age populations, it appears to be critical to consider the degree to which the encoding environment controls the approach to the task, since this will necessarily constrain the types of information later available for retrieval. Nonetheless, recruitment of left ventrolateral PFC and MTL regions during the initial encoding of meaningful events is associated with increased episodic memory for those experiences during later retrieval.

Retrieval Success

Along with a role in memory formation, MTL structures are associated with successful retrieval. Neuroimaging research suggests that distinct subregions of the MTL support dissociable retrieval processes with the hippocampus proper involved in the contextual recollection of past event features and extra-hippocampal regions supporting judgments based on item familiarity. Hippocampal activation is consistently reported during successful source–memory judgments, when subjects correctly retrieve the prior context of a previously encountered item, relative to correctly identifying new unstudied items or correctly identifying items as studied but failing to retrieve context information. In contrast, the surrounding perirhinal and parahippocampal cortices of the MTL region appear to show a different pattern, with the former hypothesized to support familiarity-based recognition for individual objects, independent of whether contextual retrieval is possible or required. This characterization is largely based on reports demonstrating that although the region displays increased fMRI activation for correctly identified and studied materials relative to novel materials, the level of activation for studied materials does not further differ as a function of contextual retrieval outcomes. Anatomical projection

studies in animals complement these findings by demonstrating that the perirhinal cortex receives considerable information about the properties of items to be remembered whereas the parahippocampal gyrus receives inputs about the spatial context in which the items are encountered. This coarse ‘what’ versus ‘where’ distinction is itself undergoing refinement in the literature; however, it nonetheless suggests that different regions of the extra-hippocampal portions of the MTL process different information about events. These two regions then converge in the hippocampus, potentially supporting the ability to situate objects into larger episodes at retrieval. Human neuropsychological investigations further support this two-retrieval-process interpretation with reports linking damage of the hippocampus proper to marked declines in the behavioral estimates of contextual recollection with relatively preserved scores of item-familiarity discrimination. Despite the convergent evidence suggesting separable familiarity and recollection-retrieval processes in the MTLs, the utility of this dichotomous characterization of the MTL processes has been questioned and this remains a highly active area of investigation.

Although research continues to focus on the role of MTL in successful retrieval, an emerging body of literature has also begun to focus on the putative role of left lateral parietal cortex during successful episodic retrieval (**Figures 3(A) and 4(B)**). The earliest findings suggesting a role for this region were based on ERP research, and subsequent fMRI studies have documented increased left lateral parietal responses when subjects correctly detect previously encountered items compared to the correct identification of new items. Furthermore, the inferior extent of this lateral parietal activation often extends into the region of the angular gyrus, and demonstrates activation properties consistent with a role specifically in contextual recollection. For example, the activation tracks phenomenological reports of recollection, is present for the autobiographical recall of distant prior events, distinguishes successful from unsuccessful source–memory judgments, and tracks the amount of episodic detail that can be reported about a prior event. Nonetheless, the hypothesis that left lateral parietal cortex supports a core element of recollection faces opposition. This opposition primarily arises from the fact that damage to the left lateral parietal region is not linked with a global amnesia syndrome in the neuropsychological literature. This conspicuous absence may reflect the fact that the contralateral region is capable of assuming a mnemonic role following damage to the left hemisphere, and the possibility that language and comprehension dysfunction due to damage in proximal regions may mask a more subtle memory impairment in patients. Nonetheless, the historic failure to observe striking deficits such as those that occur following insult to the MTL and midline diencephalic regions, continues to

challenge the idea that lateral parietal cortex plays a direct or critical role in recollection.

Retrieval Strategies and Decision Operations

The products of an episodic retrieval attempt are usually not immediately available. For example, in autobiographical-memory tasks, participants often take 6–8 s to recover the first piece of relevant memory content. The dependence of these types of memories on volitional and sustained retrieval attempts, and the frequent correlation between tests of episodic retrieval and general intelligence, suggest that successful episodic retrieval often depends upon effective memory search and evaluation processes. Recent functional imaging research supports this assumption, demonstrating considerable PFC activation for memory judgments that require recollection of contextual information. Critically, this activation is robust even when participants ultimately fail at the task, which further suggests that PFC supports retrieval search and evaluation processes that are recruited even when sufficient memory evidence ultimately fails to be recovered. Currently, it is assumed that distinct ventrolateral (**Figures 3(C)** and **3(D)**), dorsolateral (**Figure 3(B)**), and rostralateral (**Figure 4(A)**) regions of the PFC contribute to different search or evaluative processes, although there is considerable variety in the functional characterizations ascribed to these regions. Furthermore, because these regions are also active during a host of tasks other than episodic retrieval, any successful functional characterization must accommodate a large range of decision-making and reasoning tasks. To this end, current characterizations of the role of left ventrolateral PFC during retrieval are perhaps the most successful. Recruitment of this region during context relative to item memory judgments has been interpreted as reflecting controlled semantic operations that facilitate the recollection of contextual information by foregrounding or selecting the semantic features of retrieval probes that are potentially central to an episodic representation of the event. Consistent with

well-documented cognitive models, this is thought to improve the match between active search cues and the original event, increasing the likelihood of recollection when appropriate. Buttressing this view, activation in this region has been reported in tasks in which subjects must retrieve contextual memories about prior object encounters that are linked to the semantic properties of the memory probes (e.g., remembering having made a pleasant/unpleasant or a living/nonliving judgment at encoding for each test probe – **Figure 1(b)**). In contrast, when the to-be-remembered information is perceptual in nature (e.g., whether the object had appeared in a large or small size during prior encoding), the left ventrolateral region is not recruited, presumably reflecting the reduced relevance of the semantic or conceptual features of the memory probes during memory search. Thus activation in the left ventrolateral region potentially signifies a proactive strategy enabling the maintenance of semantic information that serves as a cue to retrieval during memory search. This characterization fits well with research directly examining semantic processing, and with research on self-initiated semantic encoding strategies, with both research domains implicating the same left ventrolateral PFC region.

In contrast to the selection or foregrounding of semantic information during memory search, dorsolateral PFC activation during retrieval instead appears to reflect the monitoring or evaluation of the products of retrieval with respect to decision standards. Thus the region is thought to underlie the ability to evaluate the products of memory retrieval with respect to their task relevance. Direct comparisons between inclusion tasks (wherein subjects must respond ‘yes’ to studied words regardless of their specific prior context) and exclusion tasks (in which subjects are asked to respond ‘yes’ only to words that are familiar and from a specific source) reveal increased dorsolateral PFC activity, during the latter. Similarly, memory tasks that require a greater number of intermediate judgments about recovered episodic information elicit greater activation than simpler tasks with matched materials requiring fewer intermediate memory judgments. Thus, activation in dorsolateral PFC appears to index either the number of judgments rendered during retrieval attempt or the complexity of the decision standard adopted by the participants when evaluating memories. From either perspective, extended retrieval tasks that require successful recovery of convergent aspects of a prior event are predicted to be the most compromised following damage to dorsolateral PFC.

The least-understood PFC region that is routinely activated during episodic retrieval tasks is rostralateral PFC. Neuropsychologically, the most prominent behavioral impairment following damage to rostralateral PFC is one of flexible planning and multitasking, not memory retrieval. Despite this, the region is frequently implicated in the functional imaging of simple item-recognition

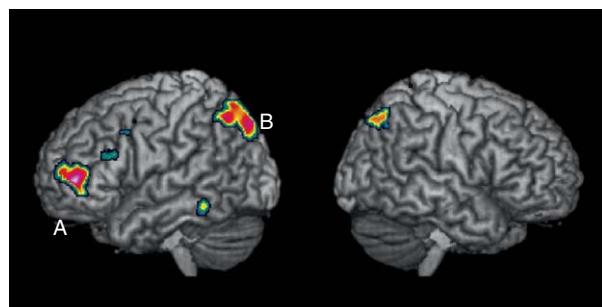

Figure 4 An example of regions implicated in simple item recognition for the contrast of correct responses to studied items (hits) vs. correct responses to new items (correct rejections). Left rostralateral PFC (A) is frequently implicated in this contrast.

memory, demonstrating greater activation for correctly recognized old items versus correctly rejected new items, typically lateralized to the left hemisphere (**Figure 4(A)**). However, this differential activation is sensitive to subjects' beliefs regarding the relative frequency of old and new items in the test list, with the differential response amplified when subjects believe old items to be relatively infrequent, even if objective frequency remains constant. Furthermore, the region has been shown to demonstrate complex temporal profiles of activation during retrieval. For example, in the right rostralateral PFC there is an increase in tonic or sustained activation across recognition trials under conditions of low discriminability during item recognition, whereas the region demonstrates an increased trial-based anticipatory response when subjects are forewarned of an upcoming context-memory demand compared to when they are forewarned of an upcoming simple recognition demand. Given the temporal complexity of the responses, combined with the dependence upon subjects' beliefs about the list structure, a consensus of the region's contribution to retrieval will likely require considerable future research. As with ventrolateral and dorsolateral PFC regions, a major challenge will be to ensure that retrieval characterizations accommodate the role of the region in nonepisodic tasks as well. For example, fMRI studies of analogical and complex reasoning also frequently implicate rostralateral PFC. At present, the only firm conclusion that can be drawn with respect to episodic memory is that activation in the region represents a complex combination of global beliefs regarding the structure or properties of the test list and the recovery of episodic information for individual items within the list.

Event Reconstruction and Forecasting

Cognitive and computational models of episodic memory have long assumed that efficient retrieval requires reconstructive processing, in which observers fill in aspects of a to-be-remembered event with semantic knowledge of its most likely components. For example, when attempting to retrieve a memory about a given breakfast, observers will often fill in details based on their semantic knowledge of the typical components of the meal, in addition to refining these components if additional constraints are also available. For example, if one is trying to remember a particular breakfast that occurred when one was in a hurry, then candidate meal items and event characteristics can be further constrained. This reconstructive process not only serves as a best guess of the likely event elements should retrieval ultimately fail, but a large body of cognitive behavioral research demonstrates that it also facilitates actual recovery of episodic information by improving the overlap between the retrieval cues actively held in working memory, and the actual event.

Based on this framework, pioneering memory researchers speculated that anticipating the future should recruit many of the same mechanisms engaged when reconstructing the past. In short, thinking about the likely constituents of a prior event should recruit much of the same processing as trying to predict the characteristics of an event that has not yet occurred.

Recent functional imaging work has supported this hypothesis by directly comparing the networks activated during autobiographical retrieval tasks to those in which subjects are instructed to imagine specific future scenarios (e.g., imagine yourself in a future beach holiday). The networks activated by these two tasks are virtually identical with both the tasks implicating left dorsal PFC, medial prefrontal and anterior cingulate areas, posterior cingulate and restrosplenial areas, and parahippocampal gyrus. Critically, this network is engaged above and beyond conditions that attempt to control for simple visual imagery. At present there are multiple ways of interpreting the high degree of similarity between the network activated during future simulation or forecasting, and that typically observed during autobiographical memory retrieval. Much of this overlap could be due to the voluntary or involuntary retrieval of episodic content when attempting to construct a future scenario. Although subjects are encouraged to create entirely new episodes this need not mean that every element is new, since the task merely requires the configuration of elements to be novel. Thus the overlap could largely result from the fact the both tasks encourage retrieval of episodic content. Somewhat similarly, both tasks have a constructive component whereupon initial descriptions are incrementally enhanced across an extended time period and this requirement would likely recruit working memory operations. Finally, both tasks may require mechanisms for overcoming episodic interference with the autobiographical task triggering multiple candidate events competing for selection and the future simulation tasks triggering episodic remembrances that potentially interfere with the goal of creating novel future scenarios. Current research is investigating these possibilities, and given the importance of accurate prediction and simulation in higher-order reasoning, this new line of research is quite important.

G

Gastrointestinal Peptides and the Control of Food Intake

Glossary

Enteric neurons – Neurons that have their cell bodies and processes confined to the wall of the gastrointestinal (GI) tract. These neurons and their processes form two plexuses or nerve nets. One plexus, the submucosal plexus is immediately beneath the GI mucosa, while the other, the myenteric plexus, lies between two layers of smooth muscle that make up the wall of the GI tract.

Enteroendocrine cells – Specialized endocrine cells scattered among the absorptive cells of the gastrointestinal mucosa. These cells often are characterized as open or closed. Open enteroendocrine cells make contact with the luminal surface of the intestinal mucosa, while closed cells lie beneath the luminal mucosal surface. All enteroendocrine cells secrete one or more biologically active peptides, many of which enter the circulation and act hormonally at target sites in the GI tract and/or brain. Collectively, the enteroendocrine cells are referred to as the diffuse gut endocrine system.

Nodose ganglion – A cluster of nerve cell bodies lying next to the carotid artery at the base of the skull. This ganglion contains the cell bodies of vagal afferent neurons, many of which carry sensory signals from the gastrointestinal tract to the brain.

Paracrine – It refers to a secreted substance producing its action by acting on other cells that are accessed by diffusion of the secreted substance through the interstitial fluid. This mode of action is in contrast with an endocrine mode, in which secreted substance arrives at its target of action via the blood circulation.

Vagal afferents – Vagal fibers that carry sensory information from the internal organs, including the heart, lungs, stomach, and intestines, to the brain. The cell bodies of the vagal afferents are located in the nodose ganglion. From the nodose, each neuron cell body extends one end of an axon to terminate in the hindbrain, while the other extends to form a sensory ending in an internal organ.

History and Background of Gastrointestinal (GI) Peptides

The gastrointestinal (GI) tract accumulates food during meals and subjects it to physical and chemical processes to release absorbable products. These digestive products are transported across the intestinal mucosa and carried away by the hepatic portal circulation or intestinal lymphatics. Prior to their absorption, mechanical and chemical stimuli from ingesta trigger a variety of reflex changes in GI blood flow, motility, and secretion, as well as changes in ongoing and subsequent food intake. Thus, the GI tract is a site from which the quantity and chemical composition of foods can be pre-absorptively monitored in the interest of controlling ongoing or subsequent food intake. The manner in which the GI tract communicates intake-control signals to the central nervous system (CNS) is only partially appreciated. Nevertheless, it is apparent that peptides secreted by the GI mucosa profoundly affect food intake and may be major contributors to its control.

The epithelial lining of the GI tract, the mucosa, contains a variety of unique cell types that secrete peptide hormones. Collectively, these hormone-secreting GI mucosal cells are known as the diffuse gut-endocrine system. Indeed, the field of endocrinology itself began with the discovery that the upper small intestinal mucosa secretes a substance, secretin, that acts on the exocrine pancreas to evoke water and bicarbonate secretion. Later, the word ‘hormone’ – which literally means ‘I act’ – was coined following Gregory’s discovery of gastrin – a hormone secreted by cells in the gastric mucosa (G-cells). In 1973, Gibbs, Young, and Smith published the first evidence that a GI hormone participates in the control of food intake. They reported that injection of cholecystokinin (CCK) – a peptide secreted by the small intestinal mucosa – reduces food intake in rats and monkeys. Across more than three decades following the first reports

of CCK's effect on food intake, a number of additional GI peptides have been proposed to contribute to control of food intake. In addition, several nonpeptides, including cannabinoids, large proteins (insulin and leptin), and lipoproteins (apolipoprotein IV), are produced by or associated with the GI tract, and control food intake. These substances are not discussed in this article. Rather, coverage of nonpeptide or non-GI-related controls of food intake can be found elsewhere in this encyclopedia.

Gastrointestinal peptides appear in the systemic circulation after passage through the liver, via the hepatic portal venous drainage of the GI tract. The liver degrades a significant proportion of some of these peptides, such that plasma concentrations of many GI peptides typically are in the picomolar range. Gastrointestinal peptides in the systemic circulation act as hormones, reaching target sites in the GI tract and brain via the arterial circulation. However, one must remember that during their secretion these peptides must diffuse locally and, therefore, may exert their effects by paracrine as well as endocrine mechanisms. The GI sources of peptides discussed in this article are illustrated in **Figure 1**. An image of an immunohistochemically stained enteroendocrine cell is shown in **Figure 2**.

Cholecystokinin (CCK)

Discovery of CCK

As the first GI hormone implicated in the control of food intake, CCK's effects on feeding have been studied longer and more intensively than other GI peptides. In fact, subsequent to the first reports that exogenous CCK reduced food intake in rats and monkeys, CCK has repeatedly been found to reduce intake in rats, monkeys, the human, and other animals. The discovery of CCK activity was published, in 1928, by Ivy and Oldberg. They reported that extracts from small intestinal mucosa of the swine evoked contraction of canine gall bladder. Accordingly, they named the putative active agent CCK. In 1943, Harper and Raper reported that intestinal mucosal extracts evoked protein secretion by the exocrine pancreas, and named the active agent pancreozymin. However, by the 1960s purification and characterization of mucosal extracts in the laboratory of Viktor Mutt revealed that pancreozymin and CCK were the same substance, and cholecystokinin became its official name.

In the GI tract, CCK is synthesized and secreted by the enteroendocrine I cells located primarily in the duodenal and jejunal portions of the small intestine. Plasma CCK concentrations rise following food intake, especially when foods are high in fat or protein content. In rats plasma

Sources of Gastrointestinal Peptides controlling food Intake

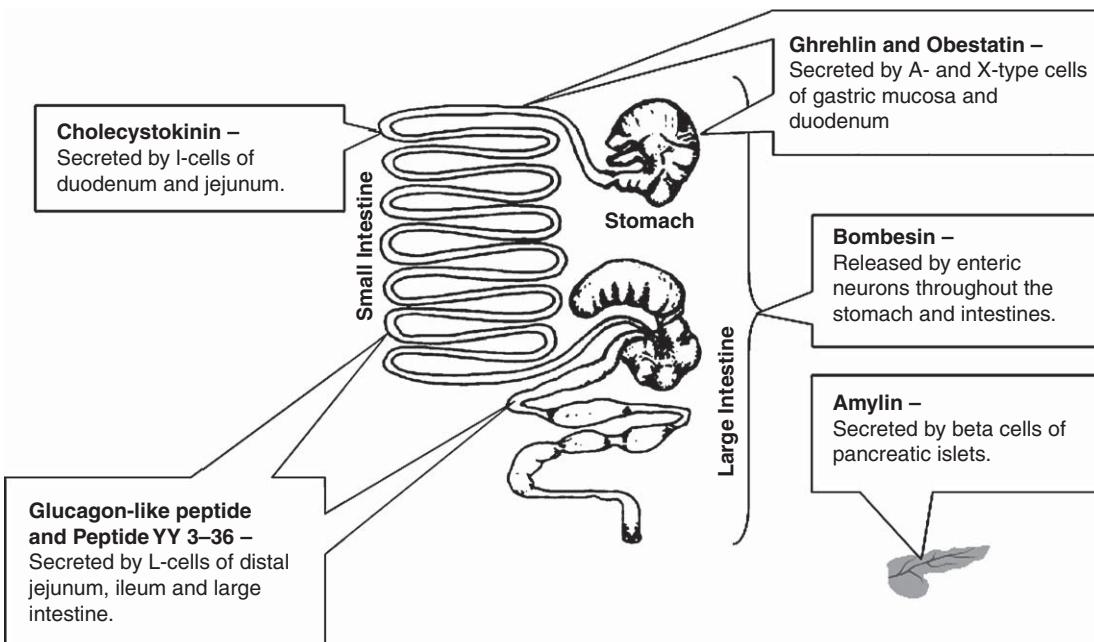

Figure 1 Sources of gastrointestinal peptides controlling food intake. Diagram of rat gastrointestinal tract is adapted with permission from Swenson MJ (1977) *Dukes' Physiology of Domestic Animals*. Figure 2 Fluorescence photomicrograph of rat small intestinal mucosa showing an enteroendocrine cell (L-cell) stained to reveal peptide secretory granules containing GLP-1 (green). Nutrients in the intestinal lumen stimulate these cells to secrete peptides into the submucosal space where they enter blood capillaries of the hepatic portal circulation. The secreted peptides also are likely to activate nerve fibers in the submucosa. The red linear structure in this image is a nerve fiber. Note its close proximity to the secretory process of the enteroendocrine cell. This proximity is consistent with local paracrine action of the secreted peptide to activate the fiber. Image is from C. Philes and R. Ritter, unpublished data.

CCK concentration is also elevated by direct intestinal infusion of long-chain fatty acids, protein, or peptones, but not by infusion of carbohydrate.

Forms of CCK

Cholecystokinin has been detected in the intestinal mucosa and in the circulation in a variety of molecular forms ranging from 8 to 58 amino acids, all of which are sulfated at tyrosine seven.

Because the principal identifying biological actions of endogenous CCK are mimicked by the sulfated carboxyl terminal eight-amino-acid sequence, most investigations of CCK effects on food intake have been conducted using the synthetic CCK octapeptide, sulfated CCK-8. However, Reeve and colleagues have demonstrated that the 58-amino-acid form of CCK, CCK-58, is the sole circulating form of endogenous CCK in the rat, and probably is also the principal form in other species as well. Moreover, several intriguing reports reveal that some biological actions of CCK-58 are distinct from those of shorter CCK forms, like CCK-8. Finally, because the circulating half-life of CCK-58

is significantly longer than that of CCK-8, it is likely to persist in the vicinity of its receptors for a longer period of time than do shorter CCK fragments. Whether there are quantitative or qualitative differences between CCK-58 and CCK-8 relative to control of food intake awaits further investigation.

CCK Receptors

Cholecystokinin acts via two G-protein-coupled receptors (GPCR) – the CCK-1 (formerly CCK-A) and CCK-2 (formerly CCK-B/Gastrin) receptor. Effects of CCK on food intake are mediated by CCK-1-receptor activation. Gastrin or unsulfated CCKs have activity at CCK-2 receptors, but not CCK-1 receptors. Hence, unsulfated CCK and gastrin do not significantly reduce food intake. Reductions of food intake following injection of exogenous CCK, or release of endogenous CCK after intestinal nutrient infusions, are attenuated or abolished by CCK-1 receptor antagonists in the human and the rat, while systemic administration of CCK-2-receptor antagonists are ineffectual. Therefore, it appears that reduction of food intake by both exogenous and endogenous CCK is mediated by CCK-1-receptor-dependent mechanisms.

Sites and Mechanism of CCK Action in Control of Food Intake

The vagus nerve and CCK's effects on feeding

Both *in situ* hybridization and electrophysiological studies indicate that between 30% and 40% of vagal afferents express CCK-1 receptors. Moreover, experiments using retrogradely labeled vagal afferents suggest that virtually all CCK-1-expressing vagal afferents innervate the upper GI tract. Finally, extracellular recording from vagal afferent fibers indicates that the activation of vagal afferents by intestinal stimuli is attenuated by CCK-1-receptor antagonists. These data are consistent with behavioral evidence for vagal afferent mediation of exogenous and endogenous CCK effects on food intake. Specifically, reduction of food intake by intraperitoneal injection of exogenous CCK is attenuated in rats that have undergone surgical vagal deafferentation of the GI tract or capsaicin-induced destruction of small unmyelinated vagal afferent neurons. In addition, both surgical vagal afferent denervation of the GI tract and capsaicin treatment attenuate reduction of food intake in response to intestinal nutrient infusions that stimulate CCK secretion. Thus, activation of abdominal, capsaicin-sensitive vagal afferents is necessary for the reduction of food intake by intraperitoneal CCK injections and by endogenously released CCK.

Recent reports suggest that most CCK-sensitive vagal afferents innervate the stomach and upper small intestine. In other words, it appears that the specific vagal afferent population that responds to CCK is targeted to the upper GI tract. Furthermore, intra-arterial infusion experiments

reveal that exogenous CCK infused near or directly into the celiac arterial supply to the stomach and upper small intestine reduces food intake at a dose below that required when CCK is infused into the systemic venous circulation. Finally, the infusion of a CCK-A-receptor antagonist directly into pancreaticoduodenal artery – supplying the upper small intestine – has been reported to increase meal size at doses that are ineffective when infused via the jugular vein. Taken together, these results suggest that the control of food intake by CCK is mediated specifically by the activation of peripheral vagal afferent fibers that innervate the upper GI tract.

Most of CCK's physiological actions are presumed to occur by an endocrine mechanism. That is, CCK secreted from the intestine enters the hepatic portal venous circulation and arrives at its target receptors via the arterial supply. However, some intestinal vagal afferents course through the lamina propria close to CCK-secreting I-cells, and several investigators have suggested that CCK might activate these afferents in a paracrine manner. Circumstantial evidence for a proposed paracrine mode of action comes from studies of the CCK-1 receptor state that mediates reductions of food intake. Specifically, the CCK-1 receptor exhibits both high- and low-affinity binding states. The high-affinity domain has a dissociation constant (K_d) for CCK in the picomolar range, while the low-affinity domain has a nanomolar K_d . Examinations of CCK responsiveness in cultured vagal afferents indicate that all vagal afferent responses to CCK are mediated by the low-affinity CCK-A-receptor state. Most experimental evidence indicates that plasma CCK concentrations sufficient to reduce food intake are in the range of those that would act on the low-affinity state, consistent with a paracrine mode of action. In addition, consistent with a paracrine mode of action is the fact that JMV-180 – a CCK analog that is an antagonist for the rat low-affinity CCK-1-receptor state, but an agonist for the high-affinity state – reverses reduction of food intake by exogenous CCK-8 in the rat. This result suggests that, at least in the rat, feeding effects of CCK are low-affinity-site effects. Nevertheless, if gastric as well as duodenal vagal afferents participate in CCK's effects on feeding, then endocrine CCK must play some role because, while gastric afferents are CCK sensitive, no CCK is secreted from the gastric mucosa. Hence, paracrine activation of gastric vagal afferents cannot occur.

CCK, the brain, and control of food intake

Using chronically decerebrated rats fed via cheek fistulas, Grill and colleagues demonstrated that the termination of consumption by CCK can occur in the absence of forebrain connections. While this result demonstrates dramatically that substrates for meal termination are present in the hindbrain, they do not obviate forebrain participation in affective, motivational, and metabolic

aspects of satiation. Nor do they rule out the participation of nonvagal sites of CCK action. Indeed, CCK has been shown to alter the activity of neurons in a variety of brain areas, some of which are associated with control of food intake. Likewise, CCK has been shown to modulate the activity of hindbrain neurons by acting, in part, on central terminals of vagal afferents. In addition, injection of CCK-8 into several forebrain and hindbrain sites is reported to produce small-to-moderate reductions of food intake. However, centrally applied CCK-receptor antagonists do not reverse the effects of systemically injected CCK, and do not attenuate reduction of food intake following intestinal infusions of fatty acid, which releases endogenous CCK. Therefore, it is unlikely that direct action on the brain by circulating CCK can account for CCK effects on food intake. However, CCK is synthesized by many neurons in the brain, and a role for central neuronal CCK in control of food intake should not be ruled out.

CCK and Body-Weight Control

Cholecystokinin is thought to reduce food intake by contributing to the process of satiation or meal termination. Consistent with this interpretation, rats injected with exogenous CCK reduce food intake primarily by reducing the size of individual meals (meal size), rather than decreasing the number of meals taken (meal frequency). Rats that are treated chronically with CCK exhibit reduced meal size, but tend to compensate for this reduction by increasing meal frequency. Hence, chronically infused CCK tends not to reduce long-term food intake or body weight. On the other hand, repeated administration of synthetic CCK-1-receptor agonists has been reported to reduce both food intake and body weight in rats and monkeys. Furthermore, rats that do not express CCK-1 receptors overeat and become obese. Finally, CCK-1-receptor-deficient rats do not gain excess weight if their food intake is yoked to that of normal control rats. Hence, obesity in this model appears to be entirely due to increased food intake. Unlike CCK-1-receptor-deficient rats, mice that do not express CCK-1 receptors do not overeat or become obese. However, examination of their meal patterns reveals that they exhibit increased meal size, which is compensated by decreased meal frequency. Thus, unlike rats, mice without CCK-1 receptors do have a satiation deficit, but effects of the deficit on body weight seem to be compensated by adjustments in meal frequency.

CCK and Treatment of Obesity

The prospects for CCK in the pathogenesis or treatment of obesity have risen and fallen over the decades since its effects were first recognized. The fact that several CCK-

1-receptor gene polymorphisms have been associated with excess body weight in the human suggests a link between CCK and obesity pathogenesis. In addition, plasma CCK concentrations appear to vary inversely with body mass index, suggesting that decreased CCK might play a role in sustaining increased body adiposity. On the other hand, while increased postmeal plasma CCK concentration has been reported in patients who have undergone vertical gastric banding for treatment of obesity, CCK is not generally elevated in patients who have undergone other bariatric procedures. Hence, for the most part, CCK has not been strongly implicated in loss of body weight following bariatric surgery. Trials of CCK agonists for control of food intake and body weight have, in general, been disappointing. However, several nutraceuticals that release endogenous CCK claim efficacy in the treatment of obesity, and have received limited support from controlled experiments in human volunteers.

Glucagon-Related Peptide 1

Preproglucagon Gene Products

Glucagon-related peptide 1 (GLP-1) is coded by the preproglucagon gene. The best-known product of this gene is the hormone glucagon itself, which is secreted by the pancreatic α -cells. During the 1970s, the use of antisera raised against pancreatic glucagon detected glucagon-like immunoreactivity in the GI tract. However, cloning of the preproglucagon gene in the 1980s revealed that it encoded not only glucagon, but also several other related peptides, which are generated in a tissue-specific manner by posttranslational processing. These include GLP-2 and oxyntomodulin. Of these preproglucagon-derived peptides, GLP-1 has been most extensively studied with regard to control of food intake. Systemic administration of GLP-1-receptor agonists reduces food intake in rodents, monkeys, and the human. Furthermore, in rodents, GLP-1 agonists reduce food intake when they are injected into the brain ventricles at doses that are ineffective when systemically administered. Although GLP-1-receptor knockout mice do not overeat or become obese, the fact that GLP-1 antagonist administration increases food intake supports a role for the endogenous peptide in control of food intake. Though not studied as extensively as GLP-1, oxyntomodulin is also reported to decrease food intake. At the moment, it is not entirely clear whether or not oxyntomodulin's effects are mediated by actions at the GLP-1 receptor.

Source and Disposition of Circulating GLP-1

Most GLP-1 is synthesized in the GI mucosa, where GLP-1 immunoreactivity is localized to enteroendocrine L-cells, distributed primarily in the mucosa of the distal

jejunum, ileum, and colon. In many L-cells, GLP-1 immunoreactivity is colocalized with another gut peptide, either gastric inhibitory polypeptide (GIP) or peptide YY (PYY; See below). GLP-1 secretion by L-cells is directly triggered by nutrients entering the distal small intestine and colon, but its secretion may also be triggered by endocrine/vagal reflex in response to nutrient stimulation of the proximal small intestine. GLP-1 secretion is most strongly stimulated by fat, but unlike CCK, carbohydrate also triggers GLP-1 release.

The principal biologically active forms of GLP-1 in the circulation are GLP- 1_{7-36} and GLP- 1_{7-37} amide. However, both of these GLP-1 forms are rapidly degraded by dipeptidyl peptidase IV (DPP-IV), which is present in the circulation and in the capillary endothelium adjacent to L-cells. Additional degradation of GLP-1 occurs as the peptide transits the hepatic portal circulation. Consequently, only a fraction of active GLP-1 reaches the systemic circulation, and circulating concentrations even of total GLP-1 immunoreactivity are in the low picomolar range. Because the enzyme dipeptidyl peptidase IV (DPP-IV) also rapidly inactivates exogenously administered GLP-1, many pharmacological studies of GLP-1 effects on food intake have used the GLP-1-receptor agonist, exendin 4, a DPP-IV-resistant peptide found in gila monster lizard venom.

Sites of GLP-1 Action in Controlling Food Intake

GLP-1, the brain, and control of food intake

In addition to being synthesized and secreted by intestinal L-cells, GLP-1 is synthesized and released by a small population of neurons located in the dorsal hindbrain. Interestingly, hindbrain GLP-1 neurons provide a dense projection throughout the forebrain, including areas of the hypothalamus that are involved in control of food intake and body weight. Moreover, these neurons are activated by the adipokine hormone, leptin, and by GI stimuli, such as gastric distension. Activation of hindbrain GLP-1 neurons also occurs during visceral illness, and the synaptic release of brain GLP-1 may play an important role in toxin-induced suppression of food intake and in conditioning of taste aversions. Brain GLP-1 receptors that are activated by neuronal GLP-1 might also be activated by circulating GLP-1. However, while this mode of action might account, at least in part, for actions of exogenously administered GLP-1 agonists, especially DPP-IV-resistant agonists, it seems unlikely that endogenous GLP-1 from L-cells would reach plasma concentrations sufficient to influence brain GLP-1 receptors.

The vagus nerve and GLP-1 control of feeding

The GLP-1-receptor mRNA is present in vagal afferent neurons. In addition, vagal afferent neurons in culture are

activated by GLP-1. Therefore, vagal afferent activation comprises a route by which endogenous GLP-1 could trigger reduction of food intake. Nevertheless, at this time there is only one published report suggesting that vagotomy attenuates reduction of food intake by exogenous GLP-1. This paucity of data demonstrating an exclusively peripheral site of action for GLP-1-induced reduction of food intake may be related to the short half-life of native GLP-1 in peritoneal fluid or plasma. In addition, DPP-IV-resistant GLP-1 agonists may remain in the circulation at concentrations high enough to activate central as well as vagal GLP-1 receptors, making it difficult to confirm the physiological site of GLP-1 action using pharmacological approaches.

GLP-1 Agonists and Body-Weight Control in the Human

In some, but not all, studies, chronic treatment of rodents with DDP-IV-resistant GLP-1 agonists has resulted in significant reduction of food intake and body weight. In addition, several GLP-1-receptor agonists have shown some promise for reducing food intake and body weight in the human. Exenatide, a DPP-IV-resistant GLP-1 receptor antagonist, is approved for use as an adjunct in treating diabetes mellitus. In combination with metformin or a sulfonylurea, exenatide treatment of type 2 diabetics is associated with reduced food intake and a small amount of body-weight loss. However, the drug must be injected twice a day in association with meals, and nausea is a significant side effect. Finally, exenatide is only 53% homologous with human GLP-1, and therefore its use results in the generation of antibodies against this peptide. In recent short trials, another DPP-IV-resistant GLP-1 analog, liraglutide, has been reported to produce moderate weight loss without inducing an immune response. These results and others raise the possibility that GLP-1 agonists might be useful in the treatment of nondiabetic obese individuals as well as for diabetics.

Peptide YY 3-36 (PYY 3-36)

Chemistry and Source of PYY 3-36

PYY3-36 is a member of the pancreatic polypeptide (PP)-fold family of peptides, so named because members of this family, including PYY, PP, and neuropeptide Y (NPY), have an N-terminal polyproline segment that enables it to fold back onto a C-terminal-adjacent α -helical portion of the peptide. PP-fold peptides act at a series of receptors, Y1–Y6. Notably, some members of this family, including PYY and NPY increase food intake when they bind to Y1 and Y5 receptors in the brain. On the other hand, PYY3-36 reduces food intake in rodents, the human, and nonhuman primates when it is administered systemically.

PYY3-36 is generated when an N-terminal Tyr-Pro dipeptide is cleaved from PYY1-36 by DPP-IV. This enzymatic conversion confers a relative preference for binding at Y2 receptors, and it is this preference that accounts for PYY3-36's ability to reduce food intake. As mentioned above, PYY is synthesized by enteroendocrine L-cells of the distal jejunum and large intestine. Many of these cells also produce GLP-1 and oxyntomodulin. High levels of DPP-IV are found in capillary endothelium near the base of the L-cells. Thus, it seems that the conversion of potentially orexigenic PYY to the satietogenic PYY3-36 is mediated by the same enzyme that actually destroys the satietogenic activity of GLP-1.

Sites of PYY 3-36 Action in Controlling Food Intake

Effects of intracerebral PYY 3-36 on food intake

While exogenous PYY3-36 reduces food intake following systemic administration, direct injection of the peptide into the brain has produced mixed results. Injection of the peptide into the hindbrain or the hypothalamic paraventricular nucleus (PVN) increases food intake, while injection into the arcuate nucleus (ARC) of the hypothalamus decreases food intake. This variability probably is related to the fact that, although PYY3-36 is a Y2-receptor agonist, at high concentrations it may also activate Y1 and Y5 receptors. In addition, differences in the density of Y1, Y2, and Y5 binding sites accessed by the injections may determine the sign of the behavioral response.

Vagal involvement in control of food intake by PYY 3-36

While Y2 receptors expressed in the hypothalamic ARC have been proposed as a site of PYY3-36-induced reduction of food intake, Y2 receptors are expressed by vagal afferent neurons. Furthermore, several reports indicate that vagotomy and capsaicin treatment abolish reduction of food intake by PYY3-36. Therefore, it seems that PYY3-36, like GLP-1, can reduce food intake by actions at more than a single neural substrate. Nevertheless, it is not yet clear from available data which substrates comprise physiological sites of action for circulating PYY3-36.

Possible Involvement by PYY 3-36 in Weight Gain and Weight Loss after Bariatric Surgery

As with CCK, a role for PYY3-36 in the control of body weight has not been conclusively determined. However, compared to wild-type controls, female mice that do not express the PYY gene become obese on standard rodent diet, and both males and females gain excess weight on high-fat diets. As mentioned above, the administration of

exogenous PYY3-36 reduces food intake in the human, and chronic administration reportedly results in loss of body weight. In this regard, it is intriguing that plasma concentrations of PYY3-36 are elevated in people who lose weight following gastric bypass surgery, suggesting a possible role for this peptide in reduced food intake and body weight following this bariatric procedure.

Bombesin-Related Peptides

Discovery of Bombesin and Distribution of Bombesin-Related Peptides

Bombesin (BBS) is a 14-amino-acid peptide first isolated from the skin of the frog, *Bombina bombina*, in 1970 by Erspamer. Injection of exogenous BBS in rat and other mammals reduces food intake, and in the rat it triggers a sequence of behaviors that accompany satiation. While BBS-like immunoreactivity is present in a variety of cells and organs, including the GI tract and the nervous system, BBS itself is not synthesized by mammals. However, several peptides that appear to be structural homologs of BBS have been characterized in mammals. Specifically, gastrin-releasing peptide (GRP), a 27-amino-acid peptide was identified in GI extracts in 1979 by McDonald. It has a 10-amino-acid carboxyl terminal sequence that differs from BBS by just one amino acid. Similarly, neuromedin B (NMB), which exists as a 32-amino-acid peptide as well as a C-terminal 10-amino-acid peptide, is also similar to BBS and related peptides from amphibian skins. Both GRP and NMB reduce food intake when systemically administered. However, neither is as potent as BBS, perhaps because GRP and NMB prefer different and distinct GPCRs, while amphibian BBS binds with high affinity both to GRP- and NMB-preferring receptors. GRP and NMB are found in neurons of the CNS and peripheral nervous system, including enteric neurons of the small and large intestines. Neither peptide appears to be synthesized in enteroendocrine cells, making it unlikely, but not impossible, that BBS-like peptides exert their effects via an endocrine pathway.

Receptors for BBS-Related Peptides

Three GPCRs for BBS-like peptides – BB1, BB2, and BB3 – have been cloned from various mammals, including the human, rat, and monkey. NMB binds with higher affinity to the BB1 receptor than does GRP, whereas GRP has a higher affinity than NMB for the BB2 receptor. The distribution of BB1 and BB2 closely parallel the distribution of NMB and GRP respectively. A third orphan receptor, BB3, appears to be a binding site for BBS-like peptides, but both GRP and NMB bind BB3 with low affinity. While synthetic ligands for BB3 have been synthesized, the endogenous ligand has not been identified.

Sites Where BBS-Related Peptides Act to Control Food Intake

Abdominal visceral BBS receptors

Experiments involving near-arterial infusion of BBS into the celiac or superior mesenteric vascular beds suggest that reduction of food intake by systemic BBS is mediated by receptors in the upper GI tract. Reduction of food intake by systemic BBS depends on both the vagal and spinal innervation of the GI tract, as abolition of BBS-induced reduction of food intake occurs only in rats with bilateral abdominal vagotomy plus transection of the thoracic spinal cord. Furthermore, it appears that some, but not all, of systemic BBS effects on food intake are mediated by small, unmyelinated, primary afferent neurons. Specifically, reductions of food intake by systemically administered BBS or NMB are abolished in capsaicin-treated rats, but reduction of intake by GRP injections is not attenuated. Thus, it appears that the two known mammalian BBS-like peptides act via distinct neural substrates.

Hypothalamic BBS receptors and control of food intake

As with GLP-1, BBS-like peptides reduce food intake when injected into the brain, as well as when they are injected systemically. BBS-like peptides and their receptors are expressed in many brain areas known to participate in control of food intake, including the paraventricular, arcuate, and ventromedial hypothalamic nuclei of the hypothalamus, the lateral parabrachial area in the pons, and the nucleus of the solitary tract in the dorsal medulla. Therefore, it is probable that BBS-like peptides participate in control of food intake at more than one central site. Finally, hypothalamic expression of at least one BBS-like peptide, GRP, has been shown to vary with conditions and treatments that alter food intake. Specifically, GRP expression in the PVN is decreased by food deprivation, and this decrease is reversed by administration of a melanocortin agonist that reduces food intake. Hence, central BBS-like peptides modulate feeding behavior in response to signals of systemic energy deficit and surfeit.

Hindbrain BBS receptors in control of food intake by central and peripheral BBS-related peptides

A role of brain BBS-like peptides in reduction of food intake by systemically administered BBS is uncertain. However, fourth ventricle administration of BBS-receptor agonists reduces food intake. Moreover, the nucleus of the solitary tract adjacent to the area postrema appears to be the most sensitive and selective brain site for BBS-induced reduction of food intake. In this regard, it is interesting that lesions involving the area postrema and nucleus of the solitary tract attenuate reduction of food

intake by both centrally and systemically administered BBS. In addition, hindbrain injection of a GRP antagonist has been shown to attenuate reduction of food intake by systemically administered GRP, indicating that hindbrain GRP receptors are involved in reduction of food intake by systemically injected peptide. Whether these results indicate a role of the hindbrain BBS-like peptide receptors in the communication of other visceral afferent signals to the brain has not been determined.

BBS Receptors and Obesity

Intracranial injection of BB1 and BB2 receptor antagonists results in increases of short-term food intake, but is not reported to increase body weight. Furthermore, rodents that do not express BB1 or BB2 do not become obese. On the other hand, mice in which BB3 had been knocked out are hyperphagic and obese. Because the endogenous ligand for BB3 does not appear to be either GRP or NMB, the contribution of endogenous BBS-like peptides to the pathogenesis of obesity remains an important unresolved issue.

Amylin

Source of Amylin

Amylin is a 37-amino-acid peptide that is co-secreted with insulin from the pancreatic beta cells. Therefore, unlike true enteroendocrine peptides, amylin is secreted primarily in response to postabsorptive stimulation of pancreatic beta cells by glucose. Injection of exogenous amylin reduces food intake in rats, mice, and humans. The effect of exogenous amylin on food intake is achieved by reducing meal size. However, high doses of amylin administered chronically also produce decreased meal frequency. Since endogenous amylin secretion is prandial in nature, it is not yet clear whether reduced meal frequency is a physiological effect of amylin. However, it does seem clear that under conditions of chronic amylin administration both laboratory rodents and the humans exhibit reduced food intake and decreased body-weight gain. Like CCK, GLP-1, and PYY 3-36, amylin inhibits gastric emptying. However, similar to CCK, the effects of amylin on satiation do not depend on inhibition of gastric emptying, since amylin inhibits ingestion when rats are consuming a diet that empties from the stomach via an open gastric cannula (sham feeding).

The Area Postrema and Amylin's Control of Food Intake

Amylin reduces food intake when injected directly into the brain. Furthermore, amylin receptors are expressed in multiple areas of the forebrain and hindbrain.

Nevertheless, reduction of food intake by either acute or chronic systemic administration of amylin is abolished by lesions of the area postrema and adjacent nucleus tractus solitarius (NTS). Moreover, while systemic amylin injection triggers neuronal activation in the parabrachial nucleus, bed nucleus of the stria terminalis, and central nucleus of the amygdala, this activation – along with reduction of food intake – is abolished in area postrema-lesioned rats, indicating that it is synaptically driven and not due to a direct forebrain effect of circulating amylin. Systemic administration of amylin is reported to decrease food-deprivation-induced neuronal activation in the lateral hypothalamus in a manner similar to refeeding. However, experiments designed to determine whether this effect is mediated via the area postrema, or is a direct action of amylin in the brain, have not been reported.

Amylin Agonists and Body-Weight Control in the Human

The amylin agonist, pramlintide, is being used as an adjunct in treating diabetes mellitus in the human, where it contributes to the plasma glucose-lowering effect of insulin through inhibition of glucagon secretion, gastric emptying, and food intake. In addition, pramlintide is reported to produce sustained small-to-moderate reductions of food intake and body weight in obese individuals who are injected the drug on a 2–3-times-daily basis over the course of a year. Therefore, this amylin agonist may turn out to be a useful adjunct for weight control especially in overweight individuals with type 2 diabetes.

Ghrelin

Ghrelin's Discovery and Sources

Ghrelin distribution and secretion from the GI tract

The name ghrelin derives from an Indo-European root word meaning ‘to grow.’ This peptide is the endogenous ligand for the growth hormone-stimulating receptor (GHSR), which was an orphan receptor prior to ghrelin’s isolation from gastric mucosa in 1999. At present, ghrelin is the only peptide secreted by the GI tract that is known to increase food intake. It is a 28-amino-acid peptide cleaved from the protein product of the preproghrelin (PPG) gene. The PPG gene also codes for another peptide, obestatin. Some investigators have reported that obestatin decreases food intake, while others have observed no effect of this peptide on food intake. Although small amounts of ghrelin may be produced in the brain and other organs, virtually all circulating ghrelin comes from the stomach (75%) and upper small intestine (25%), where it is synthesized and secreted by two anatomically distinct populations of mucosal endocrine cells.

So far as is known, ghrelin is unique in that its biological activity depends upon it being octanoylated (octanoylation refers to the formation of an ester or amide with octanoic acid) at the serine-3 amino acid residue.

Ghrelin and meal initiation

Within 2 years of its isolation, several research groups reported that ghrelin increased food intake when injected either systemically or into the brain. Moreover, while peptides such as CCK and GLP-1 reduce food intake primarily by reducing the size of individual meals, exogenous ghrelin increases food intake mainly by shortening the latency to eat. In other words, ghrelin is involved in triggering meal initiation, not in increasing meal size. Consistent with its effect on meal initiation, circulating ghrelin levels rise prior to the onset of meals and fall to lower levels immediately after a meal.

Ghrelin Receptors and the Control of Food Intake

Forebrain ghrelin receptors and food intake

The GHSR or ghrelin receptor is expressed in many areas of the nervous system that are involved in the control of food intake and metabolism. It is abundant in the hypothalamus, especially the ARC and PVN, but it also is expressed in other brain areas, including the ventral tegmental area, amygdala, and the nucleus of the solitary tract. Interestingly, ghrelin injection into any of these areas elicits increases food intake. These observations, and others, suggest that ghrelin may enhance the activity of multiple brain circuits that participate in the reflexive, appetitive, and motivational aspects of feeding behavior. On the other hand, lesion of the ARC or the destruction of NPY-receptor-expressing neurons in the basomedial hypothalamus abolishes increased food intake in response to central ghrelin injection, suggesting that hypothalamic circuitry is necessary for ghrelin-evoked increase in food intake.

Potential for hindbrain and vagal ghrelin receptors in the control of food intake

The ghrelin receptor is expressed in the NTS, and also by primary vagal afferent neurons that terminate there. Furthermore, hindbrain injection of ghrelin increases food intake suggesting that the peptide may interact with viscerosensory signals from the GI tract. In fact, ghrelin-receptor expression is colocalized with the CCK-1 receptor in vagal afferent neurons. Thus, a component of ghrelin action might involve modulating vagally transmitted satiation signals. In this regard, it is interesting that bilateral subdiaphragmatic vagotomy or destruction of the NTS catecholamine neurons has been reported to abolish increased food intake evoked by ghrelin. However, attenuation of ghrelin-evoked feeding in vagotomized rats or rats with selective and verified destruction

of NTS catecholamine neurons has not been replicated by several laboratories that are expert with these lesion preparations. Hence, participation of visceral afferent ghrelin receptors in ghrelin-evoked feeding remains uncertain.

Ghrelin and Control of Body-Weight Gain

Effects of pharmacological and genetic manipulations of ghrelin on food intake and body weight

Chronic central administration of ghrelin results in increased adiposity and reduced oxygen consumption in rodents, indicating that this peptide has effects on energy balance that go beyond its effects on food intake. In addition, mice with targeted deletion of the ghrelin receptor tend to be somewhat leaner than wild-type mice. In contrast to GHSR knockouts, the adiposity of PPG knockout mice does not differ from that of wild-type mice. However, mice that do not express the PPG gene are unable to maintain body temperature when food deprived in moderately cool environment. Therefore, it seems evident that understanding of ghrelin's functions is far from complete, and much remains to be revealed about its role in energy homeostasis.

Circulating ghrelin and response to bariatric surgery

Like other peptides with effects on food intake and adiposity, ghrelin and its receptor have attracted considerable interest as potential points of intervention in treatment of human eating disorders and obesity. Plasma ghrelin levels have been measured by many investigators prior to and following various bariatric surgical procedures for treatment of obesity. Not surprisingly, bariatric procedures in which substantial amounts of the gastric fundus are excised (sleeve gastrectomy) result in reduced plasma ghrelin concentrations. On the other hand, procedures in which weight loss results after gastric banding report mostly increases or no change in plasma ghrelin levels. While some reports suggest that reduction of plasma ghrelin concentration is correlated with weight loss after Roux-en-Y gastric bypass surgery, others find that ghrelin levels are not decreased even though patients experience massive postbypass weight loss. Thus, while altered circulating ghrelin may contribute to decreased appetite and weight loss following some procedures, it is likely that additional factors contribute to the weight-loss efficacy of bariatric procedures, and that decreases in plasma ghrelin are not essential to postsurgical weight loss.

Glossary

Conjugate eye movements – Eye movements of similar amplitude and direction for both eyes.

Disjunctive eye movements – Eye movements of different amplitude for the two eyes. Disjunctive components are typically quantified by measuring the vergence angle, defined as the difference between the right and left eye position.

Nystagmus – A sawtooth-like (zigzag) pattern where slow deviations in eye position are interleaved with oppositely directed fast phases (reflexive saccades) that keep eye position within the oculomotor range.

Optokinetic nystagmus (OKN) – A reflexive visuo-ocular response to motion of a large visual field that matches slow-phase eye velocity to the velocity of the visual surround.

Otolith organs – Inertial sensors that are located in the inner ear and consist of receptor hair cells with different polarization vectors distributed over the utricular (approximately in the horizontal plane) and the saccular (approximately in the sagittal plane) maculae.

Retina – The inner, posterior surface of the eye that houses the photoreceptors responsible for transducing visible light. The region of the fovea with the most densely packed photoreceptors is known as the fovea and provides high visual acuity.

Retinal slip – Difference between the velocity of the movement of a retinal image and the velocity of the eye movement that is picked up by motion detectors in the visual system.

Semicircular canals – Vestibular end organs that measure angular acceleration of the head. In each ear there are three semicircular canals: horizontal, anterior, and posterior. Each canal senses angular motion in its respective plane.

Vergence – The angular difference between right and left eye position. Vergence angle is zero when looking at optical infinity and reaches higher values the closer a target is to the eyes.

Vestibular apparatus – A set of balance receptors in the inner ear consisting of the otolith organs (utricle and saccule) that encode linear acceleration and the semicircular canals (horizontal, anterior, and posterior) that measure angular acceleration.

The vestibulo-ocular reflexes (VORs) are eye movements designed to keep the visual image stable on the retina when the head is in motion in order to facilitate perception. This is largely done by moving the eyes in an equal but opposite direction to the movement of the head. Keeping gaze (i.e., the line of sight) fixed onto objects of interest is a critical task in humans because only a small region of the retina, known as the fovea, has the most densely packed photoreceptors and thus provides high visual acuity. Due to this anatomical feature, light reflecting from important objects must remain on the fovea for one to perceive them accurately. For example, one is quite good at reading the words on this page even when one shakes one's head right and left. In contrast, the world would appear much more unstable without this reflex, as is the case when viewing the world after it has been filmed with a handheld camera. This shaky view is likely what patients with a damaged VOR see. They cannot read while walking or even sitting in bed unless they physically hold their heads perfectly stationary.

Detecting Head Motion with the Vestibular Apparatus

The VOR is activated when movement of the head is detected. This is accomplished by several structures in the inner ear, collectively known as the vestibular apparatus ([Figure 1\(a\)](#)). First, two sets of three nearly orthogonal canals, symmetrically positioned as mirror images of each other on each side of the head, detect head rotations in space ([Figure 1\(b\)](#)). These rotations can be described as movement about three perpendicular axes known as yaw (the longitudinal body axis), pitch (the intra-aural axis), and roll (the naso-occipital axis). Shaking the head is mainly a yaw rotation, whereas nodding the head is mainly a pitch rotation. Bringing the right ear down to the right shoulder constitutes a roll rotation.

Physiologically, head motion is detected because the semicircular canals are filled with fluid. When the head begins to rotate, the bony canals move with it. However, the viscous fluid, known as endolymph, is not physically attached to the body and so it lags behind. Thus, relative to the canals, the endolymph rotates in the opposite direction and consequently displaces a gelatinous

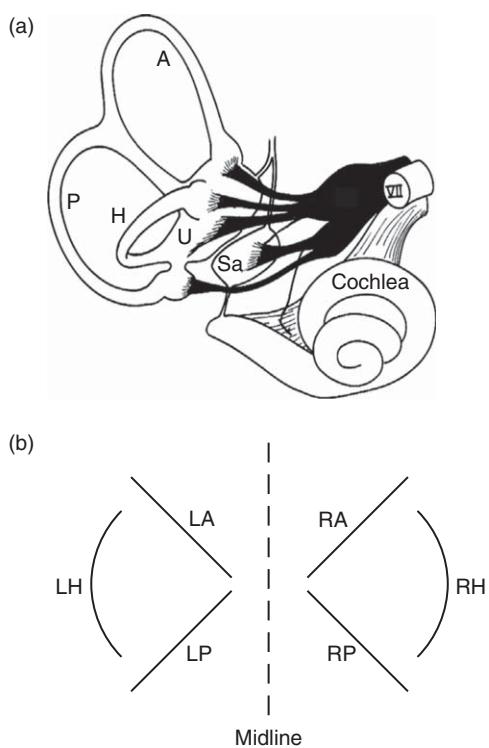

Figure 1 Vestibular apparatus. (a) Structures of the inner ear (side view). The vestibular system consists of three semicircular canals (A, anterior; P, posterior; H, horizontal) that detect rotational motion and two otolith organs (U, utricle; Sa, saccule) that detect translational motion and changes in the body's orientation relative to gravity. Signals from these end organs are transmitted to the vestibular nucleus via the vestibular nerve (cranial nerve VII). These structures are found next to the cochlea that transduces sound waves. (b) The three semicircular canals are bilateral structures (a). RA, right anterior; RP, right posterior; RH, right horizontal; LA, left anterior; LP, left posterior; LH, left horizontal. Pairs of canals (RA-LP; LA-RP; and RH-LH) detect head motion in the same plane. Working like a push-pull mechanism, one canal in the pair elicits excitation, whereas the other canal causes inhibition (depending on the direction of rotation). (a) Reprinted from [Hardy M \(1934\)](#) Observations on the innervation of the macula sacculi in man. *Anatomical Record* 59: 403–418, copyright 1934. With permission of John Wiley & Sons, Inc.

structure located in each canal known as the cupula. Hair cells embedded in the cupula are also displaced by this motion, and their displacement unleashes an electrochemical change (i.e., transduction) that is transmitted to the brain, indicating that the head is rotating. Displacement of the hair cells in one direction causes depolarization (and therefore excitation), whereas displacement in the opposite direction causes hyperpolarization (and therefore inhibition). The VOR associated with head rotations is referred to as the rotational VOR or rVOR.

Two additional structures, the utricle and the saccule, use similar mechanisms to signal that the head is translating or changing its position relative to gravity. Translational movements include standing up from a seated position (i.e., a vertical translation) or accelerating

in a car (i.e., a horizontal translation). Changes relative to gravity include lying down in bed from an upright position and tilting the head forward to look at one's feet. The utricle and saccule are collectively known as the otoliths because their hair cells are weighted with stone-like crystals. The VOR associated with translations of the head is referred to as the translational VOR or tVOR.

Neural Circuitry of the Rotational VOR

Because head movements are extremely fast, the rVOR must be activated very quickly if the image is to be adequately stabilized. Indeed, the associated eye movements follow the head motion by less than 10 ms, making the rVOR one of the fastest reflexes of the body. This is possible because of its relatively simple underlying neural circuitry. The pathway for the rVOR is known as the three-neuron arc because it involves only three sets of neurons between detecting the head motion and moving the eyes. [Figure 2\(a\)](#) (red pathway) describes the rVOR pathway for a rightward head movement that is initially detected by the right horizontal semicircular canal. First, a neuron transmits information from the right canal to the right vestibular nucleus, and subsequently, a second neuron sends this information to the contralateral abducens nucleus (a group of cells that controls the eye muscle that pulls the eye to the left). Finally, a third neuron connects the abducens nucleus to the lateral rectus muscle (the leftward pulling eye muscle), where excitation causes the eye muscle to contract and abduct the left eye, thereby rotating it to the left. In addition, such that both eyes move simultaneously, the left abducens nucleus sends its projection across the brain to the right oculomotor nucleus, which contracts the medial rectus muscle and causes the right eye to move to the left as well. This direct pathway provides the eye muscles with a phasic, velocity-related signal that moves the eyes in an equal and opposite direction to that of the head.

The increase of neural activity caused by fluid rotating in the right horizontal semicircular canal when the head moves to the right is balanced by a decrease of neural activity caused by fluid rotating in the left horizontal semicircular canal. Through the same three-neuron-arc pathway (but mirrored on the opposite sides of the brain), the medial rectus of the left eye and the lateral rectus of the right eye (both of which pull the eyes to the right) are relaxed, thus aiding in the rotation of the eyes to the left ([Figure 2\(a\)](#) – blue pathway).

If the head rotates so far to the right that the eyes reach their orbital limits and cannot rotate any further, then the eyes make a quick movement in the opposite direction and the rVOR begins anew. This occurs, for example, when one is spun in an office chair or rides a merry-go-round (with the eyes closed). The resulting pattern of eye

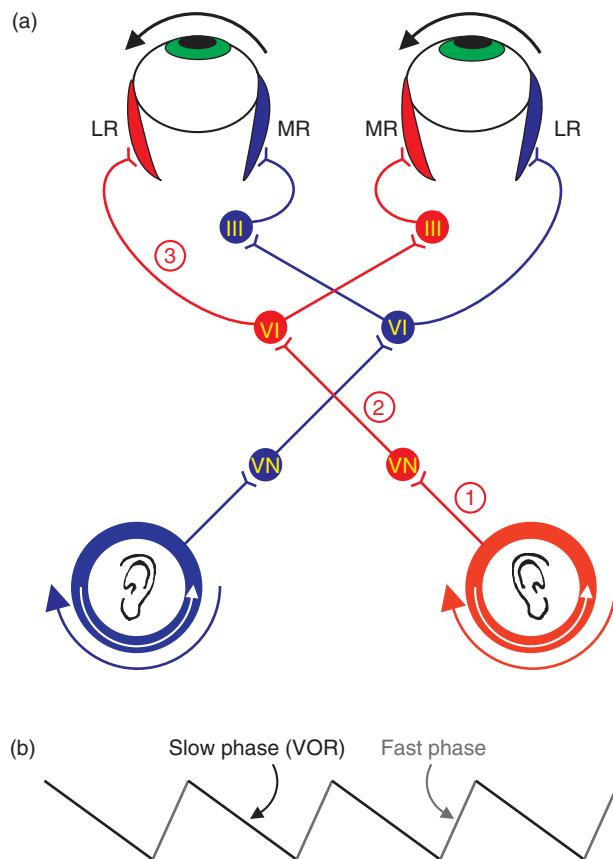

Figure 2 The rotational vestibulo-ocular reflex (rVOR). (a) Excitatory (red) and inhibitory (blue) neural pathways for the rVOR. Head/canal rotation to the right (red and blue arrows) causes endolymph fluid to rotate in the opposite direction (white arrows). This causes excitation signals to reach the right vestibular nucleus (VN) which is then transmitted to the left abducens nucleus (cranial nerve VI), which in turn innervates the lateral rectus muscle (LR) that abducts the left eye to the left. ①, ②, and ③ indicate the cells that comprise the rVOR's three-neuron arc. A signal from VI is also sent to the contralateral oculomotor nucleus (cranial nerve III), which innervates the right medial rectus muscle (MR) that adducts the right eye to the left. The inhibitory pathway is bilaterally symmetric to the excitatory pathway and ultimately causes relaxation of the MR muscle of the left eye and the LR muscle of the right eye. (b) Nystagmus, which alternates between slow-phase and fast-phase eye movements, is seen initially when the head undergoes continuous rotation. This movement pattern dies out over time when head experiences constant velocity rotation. Eye position is plotted as a function of time.

movements is known as nystagmus and is characterized by alternating slow VOR tracking movements and fast resetting eye movements (**Figure 2(b)**).

If the head stops rotating before the eyes reach their limits, then an indirect pathway exists to keep the eyes on target after the head movement is terminated. This indirect pathway is necessary because without it, elastic forces in the eyes and surrounding tissue would draw the eyes back to a more central position. The indirect pathway takes the phasic signal from the vestibular nucleus and sends it to the nucleus prepositus hypoglossi where it is transformed into a tonic, position-related signal (**Figure 3**). The tonic signal is then sent to the abducens nucleus so it too can be transmitted to the eye muscles as it is critical for keeping the image stable on the eye when the head movement is terminated.

The effectiveness of the rVOR is measured by its gain. The gain is simply a ratio of how much the eyes have moved as a function of how much the head has moved.

Thus, a perfect rVOR has a gain of 1 since the eyes move exactly as much as the head moves (but in the opposite direction). In reality, monkeys have been shown to have near-perfect gains of 0.9–1.0, whereas humans have less-than-ideal gains of 0.5–0.8, depending on the speed of the head movement. Likely, cognitive factors influence the gain of the rVOR in humans.

Limitations of the Rotational VOR

The rVOR gains, however, are only this good at certain frequencies of head rotation. In general, the rVOR performs best at relatively high frequencies (from 0.1 to 50 Hz) that are often associated with head movements. This is largely due to the dynamics associated with transducing the semicircular canal signals. At lower frequencies, the optokinetic nystagmus (OKN) takes

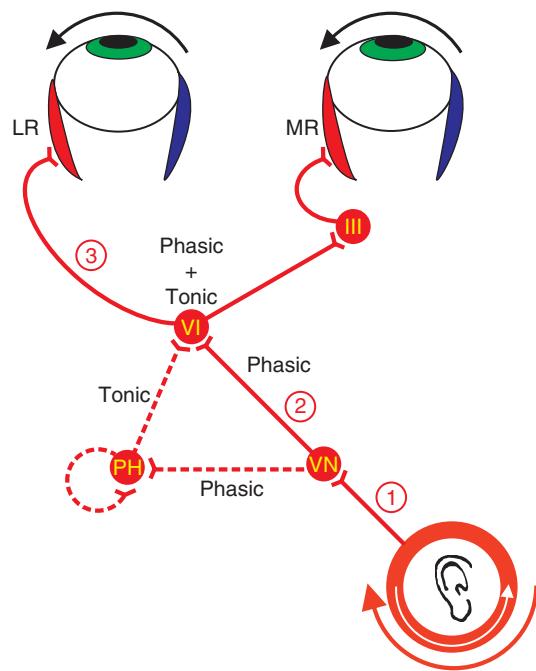

Figure 3 The indirect rVOR pathway (dashed red lines). Phasic signals indicating head velocity branch off from the direct rVOR pathway (solid red lines) at the level of the vestibular nucleus (VN). They are sent to the nucleus prepositus hypoglossi (PH) which performs the mathematical equivalent of integration, resulting in the output of a tonic, position-related command. This command is sent to the abducens and oculomotor nuclei such that the eye muscles receive signals to both move the eye and hold its final position.

over from the VOR. The OKN also maintains a stable image of the world on the retina, but rather than using the vestibular system as an input, it uses the motion of the visual image to initiate the eye movements. For example, the OKN is activated when a stationary observer watches a merry-go-round. As with the VOR, the OKN also produces a nystagmus-like pattern when the eyes reach their oculomotor limits and are quickly moved back in the opposite direction.

The rVOR also fails to respond to head motion during constant-velocity rotations. For example, on a spinning amusement park ride, we can easily detect the initial acceleration of the ride, but if the ride reaches a constant speed and our eyes are closed, we begin to lose the feeling of motion over time. This again is a result of how the semicircular canals detect motion. The endolymph begins to rotate during quick movements, which in turn displaces the hair cells that initiate transduction. However, once constant velocity is reached, the fluid begins to slow down until it no longer displaces the hair bundles and a motion signal is no longer sent to the brain.

Finally, if we are suddenly stopped (i.e., decelerated) from constant-velocity rotation in one direction (with the eyes still closed), we initially misperceive that we are

moving in the opposite direction (although we are really motionless). This is because, while the semicircular canals stop rotating when the body does, the fluid inside the canals circulates in the opposite direction because of its inertia, thus impinging on the cupula and causing a signal to be sent to the brain indicating head motion even though the head is no longer moving.

Interestingly, while rotating at constant velocity or after terminating a rotation, the hair cells physically stop signaling changes in head position after a few seconds. However, the associated nystagmus continues for many tens of seconds. This discrepancy is known as velocity storage because it implies that the signal indicating head motion is kept active somewhere in the brain and extended for reasons that are yet unclear.

The Translational VOR

The function of the tVOR is much like the rVOR in that it rotates the eyes in order to keep the visual image stable during translation. Signals to drive the tVOR arise primarily from the otolith organs. For example, the tVOR is necessary to fixate a telephone pole when one is traveling on a train or to gaze at a rock star while swaying to his or her music. However, there are several notable differences between the two. First, while the rVOR stabilizes the entire visual image, the tVOR only stabilizes one particular object of interest at a time. This is largely due to geometrical issues associated with translations as explained by motion parallax. This phenomenon occurs because (1) objects that are closer to the observer travel a greater distance across the retina than objects that are farther from the observer and (2) during translations, especially along the forward/backward axis, the distance an object travels across the retina depends on where the observer is looking. For (1), a train passenger who fixates on a nearby tree will have to generate a larger compensatory eye movement than if he or she were to fixate on a tree far off in the distance ([Figure 4\(a\)](#)). Since differently sized eye movements are required for objects at different distances, then only one object can be stabilized at any one time. For (2), to a space traveler navigating through space, stars near the line of site appear to move slower (i.e., move a small distance on the retina), while stars located more peripherally move faster (i.e., a greater distance on the retina) ([Figure 4\(b\)](#)). In addition, objects in this optic flow pattern (like the starfield screensaver on your computer) all appear to move in different directions depending on where one is looking, such that different eye movements are required for different gaze direction ([Figure 4\(c\)](#)). Thus again, the tVOR can only produce compensatory movements to one object, moving at one speed, in one direction, at a time.

Second, whereas the rVOR always rotates both eyes in the same direction, the tVOR often needs to move the two

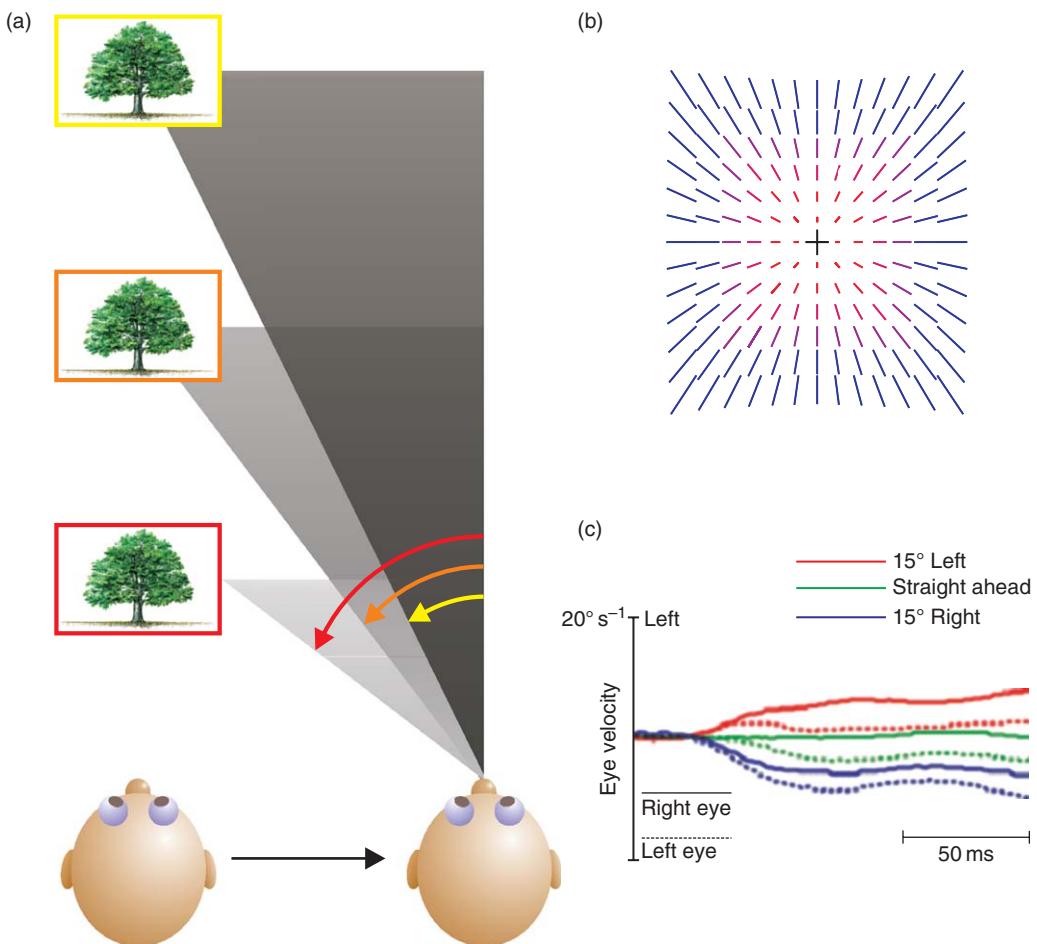

Figure 4 The translational VOR (tVOR). (a) The tVOR must deal with the consequences of motion parallax. Objects (e.g., trees) seen at different distances in depth move different distances on the retina when a person translates. Closer objects (red-boxed tree) move larger distances on the retina (red arrow), whereas farther objects (yellow-boxed tree) move smaller distances (yellow arrow). (b) Optic flow pattern observed during forward translation while looking straight ahead (black cross). Objects in the periphery move more across the retina (purple), while objects closer to the fixation point move less (pink). (c) The amplitude of the tVOR during forward motion depends on the target position and is different for the two eyes. Eye velocities of the right (solid line) and left (dotted) eyes are plotted as a function of time for targets to the left (red), straight ahead (green), and right (blue). eyes in opposite directions in order for the image of an object to be stabilized. For example, if one fixates on the eraser of a pencil and translates one's head toward it, the eyes must converge toward each other in order to keep the eraser on the retinas of both eyes. The eyes must then diverge, away from each other, as one translates the head back. Lastly, since the tVOR stabilizes only one object at a time on the retina, it is only present in animals, such as primates and humans, which have a fovea. In contrast, animals that do not have a fovea, including all lateral-eyed animals such as rabbits and horses, also do not exhibit a tVOR response. However, all these animals have rVOR responses.

The tVOR successfully stabilizes single images by scaling the incoming vestibular signal by the inverse of target distance and eye position. Because of these extra computations the response time of the tVOR is not as quick as that of the rVOR (the eyes lag the head by 15–30 ms). The tVOR has generally favorable gains for far targets but somewhat low gains (~ 0.5) for near targets. This may be due to the fact that both version (i.e., both eyes moving together) and vergence (i.e., eyes moving in opposite directions) movements must be elicited to follow such close targets and the fact that such eye movements are not typically made in everyday life (i.e., we rarely look at very near objects during navigation).

Tilt VOR

The tilt VOR is the least known of the VOR reflexes mainly due to its extremely low gain (0.1) in humans and primates, and thus its minimal impact on perception. As with the other VORs, the goal of the tilt VOR is to move the eyes in an equal and opposite direction to that of the head and thereby stabilize the visual image, but its range of operations is limited to low frequencies. The signals driving the tilt VOR arise from the otolith organs whenever the head moves relative to gravity. Therefore, the eyes will move up when the head is pitched down and the eyes will roll counterclockwise when the head moves clockwise (i.e., when the right ear moves toward the right shoulder). There is no tilt VOR for yaw rotations since with yaw rotations the head stays upright and does not move relative to gravity. The tilt VOR is much more important and robust in lateral-eyed animals without a well-defined fovea since they only have this one gravity-sensing mechanism to maintain their gaze in line with the horizon. In frontal-eyed animals with well-defined foveas and saccadic systems, the small contribution of the tilt VOR is likely sufficient to assist with the proper maintenance of eye position during eye-head coordination and with the alignment of the two eyes for binocular vision.

Plasticity

The VOR exhibits a remarkable ability to adapt. Because the VOR operates in an open-loop fashion (i.e., the vestibular system is independent of the resultant eye movements), its performance can only be useful if the brain continuously monitors the clarity of the incoming visual scene during head movements. This constant monitoring and the subsequent changes in the VOR that are produced as a result can be observed in everyday life. For example, whenever one dons a new pair of glasses, there is an initial period of discomfort since the VOR is not yet adapted to the new magnification. But over time, the VOR begins to produce larger eye movements with higher magnifications (i.e., an increase in the VOR gain), and smaller eye movements with lower magnifications (i.e., a decrease in the VOR gain). Spectacles that increase or decrease the visual image have been used to demonstrate such gain increases and decreases in the laboratory. As anyone who wears glasses can attest, the brain does not simply exhibit these changes in gain transiently. With enough experience, the brain can store and utilize different gain calibrations for different conditions (e.g., an eyeglass wearer has one gain when their glasses are on and another gain when their glasses are off).

Interestingly, reversing prisms, which change the visual image such that objects in the world located to

the right of an observer are perceived to be to the left, have been shown to actually reverse the VOR over a period of several days. After adaptation, a head movement to the right elicits an eye movement to the right and vice versa. This reversal response disappears almost immediately after the prisms are removed.

Finally, the gain of the VOR can also be adapted when head movements are paired with moving visual stimuli. If the head moves in one direction and the visual world moves in the opposite direction, then the gain of the VOR is increased, whereas if the head and visual world move in the same direction, then the gain of the VOR is decreased (toward a value of zero). Such VOR plasticity is frequency specific and hence the largest changes in gain will be observed around the frequency used for adaptation. In fact, opposite changes in gain (i.e., increasing vs. decreasing) can be made at high versus low frequencies.

Besides changes in gain, the VOR can also modify its direction. If the head is rotated horizontally while the visual world is moved vertically, subsequent horizontal head rotations in the dark elicit both horizontal and vertical eye movements. Aside from such extrinsic changes in the VOR, intrinsic factors such as those brought about by disease or trauma can also be adapted for (e.g., decreases in unilateral vestibular function due to antibiotic-related degeneration and unilateral Ménière's disease).

Neural Pathways for Plasticity

The specific mechanisms responsible for changes in the gain of the VOR are still being scrutinized, but are believed to occur with the help of the cerebellum. A dominant theory states that head movement signals derived from the vestibular organs are compared with visual images from the retina (known as retinal slip) that are a measure of the image's stability (**Figure 5** – yellow cross). Vestibular signals travel to the flocculus and paraflocculus of the cerebellum via mossy fibers which synapse onto the parallel fibers of granule cells. Visual signals reach the cerebellum via the inferior olive nuclei as climbing fibers. Once there, Purkinje cells compare the discrepancy between the visual and vestibular signals and make appropriate changes that are then sent to vestibular nucleus cells that drive the VOR.

Others have proposed that VOR adaptation occurs in the vestibular nucleus itself, while the output of the cerebellum simply provides an error signal for recalibration (**Figure 5** – black double-cross). A subset of vestibular nucleus cells, known as flocculus-target neurons, receives direct inhibition from the flocculus as well as inputs from the ipsilateral vestibular nerve. These cells change their firing pattern quickly and dramatically following changes in the VOR. Importantly, their firing-rate

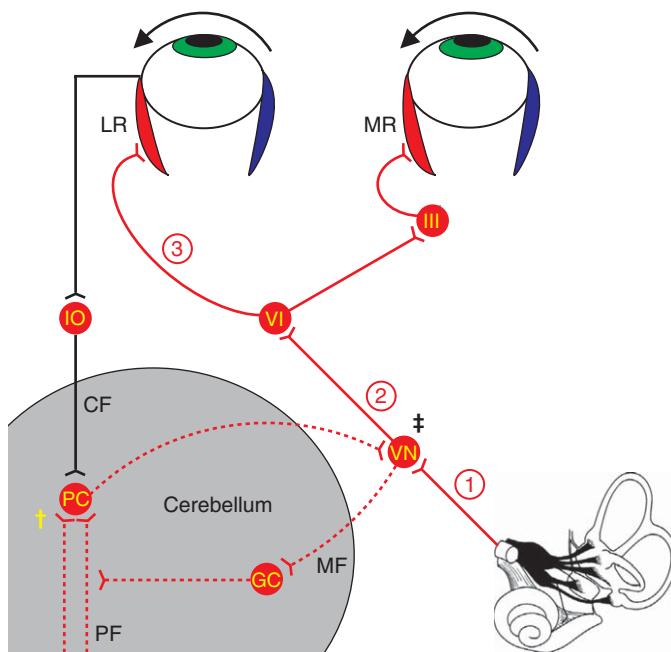

Figure 5 Two possible sites for VOR adaptation. Vestibular signals from the vestibular nucleus (VN) are taken to Purkinje cells (PC) of the cerebellum via mossy fibers (MF), granule cells (GC), and parallel fibers. Retinal slip signals are brought to the same Purkinje cells via the inferior olive (IO) and climbing fibers (CF). Once the two are compared, adjustments in gain can then be made (yellow cross) and the resultant signals are sent back to the VN. Alternatively, modifications may be made in the VN itself (black double-cross).

modifications are in the appropriate direction for the plasticity to take place. Currently, none of these theories can account for all the experimental findings. Likely, VOR plasticity occurs at multiple locations, both inside and outside the cerebellum. These different sites might account for the different gain changes observed at different head-oscillation frequencies, directions of motion, and timescales.

Hemispheric Specialization: Language, Space, and Sexual Differentiation

J B Hellige, Loyola Marymount University, Los Angeles, CA, USA

Glossary

Broca's aphasia – Also known as expressive aphasia or nonfluent aphasia, this type of aphasia constitutes language difficulties associated with damage to a specific region within the inferior frontal lobe of the left hemisphere (Broca's area). Broca's aphasia is characterized by labored speech consisting largely of content words and devoid of syntax and by difficulty using syntax and grammar to understand language.

Categorical spatial relations – Spatial relations that group locations into equivalence classes so as to delineate regions and boundaries or limits separating or connecting patches of space (e.g., object A is below object B; or, object C is touching object D).

Coordinate spatial relations – Spatial relations that occur within a 'metric' space and that allow perception and expression of space in a quantitative sense (e.g., object A and object B are about 1 m apart).

Hemispheric specialization – The fact that the left and right cortical hemispheres are functionally asymmetric, with each side having its own processing abilities and biases.

Sexual differentiation – The process of development of differences between males and females from an undifferentiated zygote; differences in behavior, neurophysiology, or brain-behavior relationships as a function of biological sex.

Split-brain patients – The individuals whose left and right cortical hemispheres have been surgically disconnected by severing the corpus callosum and other connecting fibers; usually performed as a treatment for severe epilepsy when less-invasive forms of treatment have failed.

Wernicke's aphasia – Also known as receptive or fluent aphasia, this type of aphasia constitutes language difficulties associated with damage to a specific region within the posterior part of the superior temporal gyrus of the left hemisphere (Wernicke's area). Wernicke's aphasia is characterized by difficulty in the understanding and comprehension of words; speech often sounds natural, with syntax and grammar being relatively normal, but is typically meaningless, often containing natural-sounding real words and nonwords in a context that does not make sense.

Introduction

The left and right cerebral hemispheres of the human brain are functionally asymmetric, with each side having its own abilities and biases. Functional left-right brain differences are ubiquitous across information-processing domains in humans and across contemporary animal species. This article illustrates characteristics of hemispheric asymmetry in humans by focusing on three well-studied topics: language, processing locations in space, and sexual differentiation. For each of these topics, hemispheric asymmetry in humans is emphasized, while also considering the relationship to asymmetries in other contemporary species that may shed light on the evolutionary origins of hemispheric specialization.

Language

The most well-established processing asymmetry in humans deals with various aspects of language. It has been observed for well over 2000 years that various problems in the generation and understanding of language are typically more severe after damage to the left side of the brain than after damage to the right side of the brain. For over 150 years, these aspects of hemispheric asymmetry have been studied in a formal, scientific manner. For example, in the latter half of the nineteenth century, a French neurologist named Paul Broca reported that certain characteristic difficulties in producing fluent speech were associated with damage to a region within the frontal lobe of the left hemisphere. Characteristics of what has come to be called 'Broca's aphasia' (also known as 'expressive aphasia' or 'nonfluent aphasia') include labored speech consisting largely of content words and devoid of syntax or grammar (sometimes referred to as 'telegraphic speech'). Comprehension may be relatively normal, although there is often great difficulty when syntax or grammar is essential for determining meaning. A few years later, a German neurologist named Karl Wernicke reported that receptive language problems were associated with damage to a region further back in the left hemisphere, within the temporal lobe. Characteristics of what has come to be called 'Wernicke's aphasia' (also known as 'receptive aphasia' or 'fluent aphasia') include

difficulty in the understanding and comprehension of language, both spoken and written. Although speech sounds natural and syntax and grammar are relatively normal, it is typically meaningless, often containing natural-sounding nonwords as well as real words in a context that does not make any sense. From the perspective of hemispheric asymmetry, it is important to understand that damage to corresponding regions of the right brain hemisphere is far less likely to produce these various forms of aphasia. Broca's and Wernicke's areas are connected through a neural pathway known as the 'arcuate fasciculus' so that those areas along with others constitute a left-hemisphere network that underlies much of our language ability.

In the years since the pioneering work of Broca and Wernicke, neurologists and cognitive neuroscientists have used a variety of techniques to refine and extend our understanding of hemispheric specialization for language. The study of language disorders after brain damage has continued to provide a rich source of information, especially as modern brain imaging techniques permit damage to be localized precisely within the living brain. Our understanding of hemispheric specialization was greatly enhanced in the latter part of the twentieth century by the study of the so-called split-brain patients, work for which neurobiologist Roger Sperry received the Nobel prize in 1981. In the normal brain, the left and right cerebral hemispheres are interconnected by a vast network of neurons, with the largest and most prominent fiber tract being the corpus callosum. As a last resort for the treatment of severe epilepsy, the corpus callosum (and sometimes smaller fiber tracts as well) is surgically severed, thereby disconnecting the left and right hemispheres or splitting the brain. Using a clever set of methods to present information, it is possible to test these split-brain patients to examine the competence of each cerebral hemisphere in the absence of its partner. The latter half of the twentieth century also saw the emergence of behavioral techniques to study hemispheric specialization in neurologically intact individuals, leading to an explosion of research on various aspects of functional asymmetry as well as on the ways in which the two hemispheres interact in the normal brain. This time period also saw the development and refinement of techniques that permit us to observe which brain areas are most activated as individuals perform tasks that are carefully chosen to involve specific language-related processes. These techniques include things such as measuring the electrical activity of the brain (e.g., event-related potentials or ERPs) and functional neuroimaging (e.g., positron emission tomography (PET); functional magnetic resonance imaging (fMRI); and magnetoencephalography (MEG)). Along with this, techniques have been developed to temporarily interfere with processing in specific brain areas (the Wada test; transcranial magnetic stimulation

(TMS)) so as to study the behavioral consequences of what might be thought of as temporary cortical lesions. One advantage of having so many techniques to study brain-behavior relationships is that, while each technique has shortcomings that sometimes make inferences difficult, together the techniques provide a powerful set of converging operations that paint the following picture of hemispheric specialization for language.

It is estimated that speaking is controlled by the left hemisphere in 95% of right-handed individuals and 65–70% of left-handed individuals, with the remaining left-handers being evenly divided between those for whom speaking is controlled by the right hemisphere and those for whom speaking is controlled bilaterally. In understanding speech, the left hemisphere is superior to the right in processing phonetic information, in processing syntax and grammar, and for processing many aspects of word meaning. These aspects of left-hemisphere superiority extend to the derivation of meaning from printed material and, perhaps, to other forms of communication such as American sign language. With respect to reading, an area of the left hemisphere in the vicinity of the angular gyrus seems particularly important for processing visual word form.

Though the left hemisphere is regarded as being specialized for language, the right hemisphere is not completely without ability in this regard and may even be superior to the left for certain language-related functions. For example, though the left hemisphere is superior for identifying words and phonemes, the right hemisphere is superior for identifying the prosody or rhythm of speech and for identifying the emotional tone conveyed by speech. The right hemisphere is also involved in processing narrative-level linguistic information of the sort that develops over several sentences and creates a context that is necessary for appreciating things such as the plot line of stories and the punch line of jokes. Although there is clear evidence of left-hemisphere superiority for generating propositional speech, the right hemisphere is capable of producing what is termed as 'formulaic' or 'automatic speech' (e.g., reciting a well-learned nursery rhyme, swearing, and so forth). Furthermore, if the left hemisphere is extensively damaged or removed at a sufficiently young age, the intact right hemisphere is capable of developing normal speech.

In language, as in other domains, many hemispheric asymmetries in humans appear to be complementary, with each side being superior for different and sometimes contradictory aspects of a task. In addition to those functions already noted, there are other, more subtle, instances of complementary specialization. For example, when a word is presented (e.g., bank), the left hemisphere quickly restricts activation to the dominant meaning (a monetary institution) or the meaning most consistent with the preceding words, whereas the right hemisphere maintains activation of multiple meanings or remotely associated

words (both a monetary institution and a river bank). Note that both processing biases are useful for understanding normal discourse. The left-hemisphere strategy would generally be more effective for quickly honing in on the intended meaning, whereas the right-hemisphere strategy would be more effective for reinterpreting subsequent words indicate that a different, usually subordinate meaning was intended (e.g., she put all her money in her purse, took it to the bank of the mighty Mississippi, and threw it in). Another example concerns the processing of letters within a printed word, with the left hemisphere treating the word as a linguistic unit and processing the letters in parallel and the right hemisphere distributing attention sequentially over the letters. Thus, after left-hemisphere damage, reading may occur in a laborious letter-by-letter manner mediated largely by the intact right hemisphere.

Hemispheric specialization for language is, for the most part, universal and extends across the world's languages. However, there is informative variation. For example, the left hemisphere is superior for the identification of pitch for speakers of languages, such as Mandarin Chinese, Thai, and Vietnamese for which phonemic and lexical discriminations are made on the basis of pitch, but not for speakers of languages such as English for which pitch has no linguistic relevance (in fact, for speakers of English there is even some indication of right-hemisphere superiority for pitch discrimination). Another example concerns hemispheric specialization for two kinds of Japanese script: Kana, a syllabic script, versus Kanji, a visually elaborate logographic script borrowed from Chinese characters. While there is clear evidence of left-hemisphere superiority for identifying Kana characters, the evidence is less clear for identification of Kanji characters, for which there may even be right-hemisphere superiority. In general, right-hemisphere involvement in reading increases with things such as the visual complexity of printed characters.

Although no other contemporary species possesses anything approaching the language capabilities of humans, the left hemisphere is dominant for producing vocalizations in a number of other vertebrates, including some species of songbirds, rats, and amphibians. Though there is disagreement about whether these vocalizations are, in fact, direct precursors of human speech, the existence of so much asymmetry in other species raises the possibility that when language did develop, it was built disproportionately on pre-existing left-hemisphere skills. It has also been hypothesized that human language first evolved from manual and facial gestures rather than from vocalizations. Contemporary research with a number of species indicates a sufficient amount of left-hemisphere superiority for such gestures to suggest that, from this perspective as well, the asymmetric substrate for language may be quite old in evolutionary terms.

Space

Just as the left hemisphere was historically recognized as being specialized for language, the right hemisphere was thought to be specialized for a variety of nonverbal, perceptual functions, including the localization of stimuli in space. However, even more than in the case of language, the two hemispheres work in a complementary manner to process spatial relationships. More specifically, the right hemisphere is specialized for using a coordinate representation of spatial relationships to extract information about such things as distance and precise location. In contrast, the left hemisphere is specialized for using what has been called a categorical representation of spatial relationships in order to assign a spatial relation to a category such as 'connected to' or 'above.' As an illustration, consider an experiment in which a horizontal line is presented along with a single dot, with the dot appearing in one of the 12 locations, six above the line and six below. When the task is to indicate whether the dot falls within 1 cm of the line regardless of whether the dot is above or below the line (a coordinate judgment), there is a right-hemisphere advantage. However, when the task is to indicate whether the dot is above or below the line regardless of distance from the line (a categorical judgment), there is a left-hemisphere advantage. Such effects occur for other stimuli and tasks as well. For example, the right hemisphere is better able than the left to recognize that the distance between two objects or pictures has been changed, whereas the left hemisphere is better able than the right to recognize that the relative position of the two objects or pictures has been reversed (**Figure 1**).

The potential advantage of complementary specialization for categorical and coordinate spatial processing is illustrated by neural network computer simulations. A particularly interesting finding is that networks which are split in order that some of their hidden units

Examples of categorical questions

- Is the dot above the line?
- Is the arrow pointing left?
- ↑ Is the triangle touching the oval?

Examples of coordinate questions

- Is the dot within 1 cm of the line?
- Is the arrow longer than 1 cm?
- ↑ Is the triangle taller than the oval?

Figure 1 Examples of questions about categorical and coordinate spatial relationships. The left and right brain hemispheres are specialized for processing categorical and coordinate spatial relationships, respectively.

(simulated, neuron-like elements) contributed only to a categorical judgment and others contributed only to a coordinate judgment, performed better than unsplit networks in which all the hidden units contributed to both types of spatial judgments. These results suggest that there are computational advantages to segregate these two types of spatial processes. Other findings indicate that two tasks interfere with each other more when they require resources from the same cerebral hemisphere than when they can be performed by the opposite hemisphere. Thus, hemispheric specialization for complementary processes may permit those processes to be sufficiently segregated from each other so as to permit each process to proceed with little interference from its complementary counterpart. Consistent with this idea, greater hemispheric specialization for two complementary tasks in domestic chickens is associated with enhanced ability to perform those tasks at the same time: finding food (depending on a type of local-level visual discrimination for which the left hemisphere of the chicken is typically specialized) and being vigilant for predators (which depends on a more global type of visual discrimination and motion perception for which the right hemisphere of the chicken is typically localized).

Hemispheric specialization for spatial processing may be related to complementary hemispheric specialization for the identification of visual patterns. Specifically, the right hemisphere is specialized for extracting what are called the global aspects of visual stimuli (e.g., the outer contour of a face, or the distance relationships among facial features), whereas the left hemisphere is specialized for extracting what are the called local aspects of visual stimuli (e.g., details about the small, individual features of the face). It is interesting, in this regard, that both processing of global perceptual characteristics and of coordinate spatial relationships may depend on analysis of relatively low visual spatial frequencies (for which right-hemisphere superiority has been hypothesized), whereas processing of local detail and categorical spatial relationships may depend on analysis of relatively high visual spatial frequencies (for which left-hemisphere superiority has been hypothesized; **Figure 2**).

Studies with contemporary animal species suggest that complementary hemispheric specialization for these different aspects of visual processing may have a long evolutionary history. In fact, it has even been hypothesized that all contemporary vertebrate groups have inherited a basic pattern of asymmetry from a common chordate ancestor. Whether or not the various forms of asymmetry are homologous in this manner is not clear, but the parallels among species are provocative; consider, for example, some of the asymmetries in the domestic chicken that were described earlier.

The existence of animal models has made it possible to expand the methods for testing hypotheses about

Figure 2 A large letter H (the global level) made up of small letter J's (the local level). The right and left brain hemispheres are specialized for processing global and local information, respectively.

hemispheric specialization by using techniques and manipulations that are not possible with humans. To illustrate this, consider what has been learned about the ontogeny of hemispheric specialization from studies of the domestic chicken, in which the left hemisphere is typically specialized for visual pattern discrimination and the right hemisphere is typically specialized for detecting predators and for attack and copulation behaviors. During the last 5 days before hatching, when the visual system is undergoing rapid development, the head of the chick embryo is positioned in the egg such that the left eye (which projects to the right side of the brain) is pressed against the body and the right eye (which projects to the left side of the brain) is turned outward toward the translucent shell. If the egg is exposed to light during this critical period, the chick shows the typical asymmetries when it hatches. If there is no light during this critical period, the direction of asymmetry is random.

Furthermore, the typical asymmetries can be reversed by manipulating the embryo during this critical period so that only the left eye receives light. These results indicate that hemispheric specialization may be determined by the interaction of several biological and environmental variables, leading to speculation about similar interactions in humans. Furthermore, the results indicate how valuable animal studies are likely to be in sorting out the contributions of various factors.

Sexual Differentiation

The foregoing summary of hemispheric specialization for language and spatial processing was based on research with a typical right-handed population. Although there is sufficient commonality to make such a summary useful, it glosses over the fact that there is individual variation in the magnitude and even the direction of hemispheric asymmetry. We have already noted that the incidence of left-hemisphere dominance for producing speech is lower among left-handers than among right-handers, although most left-handers show the same asymmetry as right-handers. In general, this same pattern with respect to

handedness characterizes other forms of hemispheric specialization as well. That is, on the average, left-handers show asymmetries in the same direction as right-handers (with, of course, the exception of handedness), but with smaller average differences that can be attributable to more variability among left-handers in the direction of asymmetry.

After handedness, the most-studied dimension of individual variation is biological sex, or sexual differentiation. To be sure, there are reliable sex differences in cognition. For example, women tend to outperform men on a number of verbal, language-related tasks, whereas men tend to outperform women on a number of visuospatial tasks. Not surprisingly, this has led to a search for neurological correlates. With respect to language, an early hypothesis was that women have more bilateral representation of language, giving them an advantage for verbal processes (because both hemispheres are involved) but putting them at a disadvantage for various processes for which the right hemisphere is specialized (because some of the right hemisphere's functional space is devoted to language). There are, in fact, findings consistent with at least part of this hypothesis, even though the evidence is not uniform. For example, the incidence and seriousness of various aphasias after left-hemisphere brain damage tend to be less in women than in men, consistent with the possibility that the right hemisphere is more involved in language for women than for men. Some functional imaging studies provide converging support for this idea. For example, it has been reported that during phonological tasks (e.g., a rhyming task), brain activation in men is largely lateralized to the left inferior frontal gyrus, whereas brain activation in women is more diffuse and involves the inferior frontal gyrus in both hemispheres. Such results are not always found, however, and a recent meta-analysis of several brain imaging studies showed no consistent differences in asymmetric activation patterns between men and women.

It is instructive to consider possible reasons for the discrepant findings that have been reported. Something as broad as language consists of a number of specific processes, ranging from auditory (the early stages of speech perception), visual-orthographic (the early stages of reading), phonological, syntactic, semantic, and so on. There are already some indications that sex differences vary across these different aspects of language. In addition, there is evidence that functional asymmetry in women varies to some extent across phases of the menstrual cycle. For example, both behavioral and functional brain imaging studies suggest increased asymmetry during menstruation, when estradiol and progesterone plasma concentrations are at their lowest, and greater symmetry in the mid-luteal phase, when estradiol and progesterone plasma concentrations are high. Thus, the pattern of sex differences in a particular study may

depend on the hormone state of the women tested. Another complicating factor is that, even when sex differences are found, they do not necessarily indicate a fundamental difference in neural organization. For example, men and women may use different cognitive or emotional strategies to perform a task or bring different levels of motivation to a task, all of which can affect the pattern of brain activation. These kinds of strategy differences could arise for many reasons other than a difference in neural organization, including things such as socialization and a host of other environmental experiences. Such strategy differences could also be sensitive to subtle variations in a task and occur differentially across studies that, at first glance, seem to involve the same demands.

There are no consistent findings with respect to sex differences in hemispheric asymmetry for localizing stimuli in space. In addition to the complicating factors already noted, the study of spatial localization is complicated further by the fact that hemispheric specialization is different for processing categorical and coordinate spatial relations. To be sure, many behavioral and functional imaging studies of spatial processing have included both men and women, providing ample opportunity to observe consistent sex differences. The fact that none have emerged suggests that, if there are any, they are small relative to the overlap between men and women.

Although many aspects of sexual differentiation have been studied in other species, and there is ample evidence of hormonal effects on the developing brain, not much is known about the differences between males and females in functional hemispheric asymmetry. To some extent, this reflects a paucity of studies that were designed specifically to detect sex differences. At the same time, however, as the number of studies with other species has grown exponentially, so has the number of studies that include both males and females thereby providing an opportunity to observe differences between them. As we formulate more precise hypotheses regarding the manner in which hemispheric asymmetry in humans is related to biological sex and influenced by circulating hormones, the existence of animal models will provide fertile ground for testing them.

Putting the Brain Back Together

In this article, characteristics of hemispheric asymmetry in humans have been illustrated by focusing on language and the processing of spatial relationships. In each domain, hemispheric asymmetry for specific processes can be thought of as complementary, with each side being superior for different, and sometimes contradictory, aspects of a task. Given the ubiquity of functional asymmetry across processing domains and across species, it seems reasonable to view such asymmetry as having evolutionary

advantages. A plausible view is that hemispheric specialization for complementary processes permits those processes to be sufficiently segregated so as to reduce maladaptive interference between them. While this would have important advantages, this arrangement would require that the results of those complementary processes be shared efficiently across the brain hemispheres, so as to create an integrated, unitary view of the world and plan of action. More generally, cognitive neuroscience has done an increasingly good job of taking the brain apart, by studying hemispheric specialization and by identifying specific processing modules within each hemisphere. Indeed, the rate of progress has accelerated with the use of more sophisticated measures of brain activation and increasingly clever behavioral manipulations. In our enthusiasm for taking the brain apart, we should not overlook the fact that modern functional imaging techniques demonstrate that even simple tasks involve neural networks dispersed across both brain hemispheres. As we go forward, a significant challenge will be to understand the manner in which the different elements of these neural networks and the activities of the two hemispheres fit together and coordinate their activity, at both biological and behavioral levels.

Glossary

Explicit/declarative memory – Memories that one is consciously aware of and uses deliberate thought to store and use. This type of memory encompasses both memories for life events, called episodic memories, and general knowledge for facts, called semantic memories. **Huntington's disease** – Degenerative neurological disease that leads to loss of neurons within the striatum itself, and leads to motor and cognitive deficits on tasks requiring the striatum.

Implicit/nondeclarative memory – Memories that can be acquired and used without conscious awareness or intention to learn or apply information.

Parkinson's disease – Degenerative neurological disease affecting a specific group of neurons in the midbrain that produce the neurotransmitter dopamine. The progressive loss of neurons causes diminished dopamine transmission in the striatum and leads to motor and cognitive deficits on tasks requiring the striatum.

Priming – A type of implicit memory where previous experience with some material makes future processing of the same material easier.

Procedural memory – Memories for 'how' to do something, such as riding a bike.

discovered that some learning and memory abilities could develop normally, and these types of learning and memory have been termed 'implicit.'

Implicit learning and memory refer to a heterogeneous set of abilities that, as a whole, mainly are characterized in opposition to explicit (or declarative) memory, which involves awareness for how a memory was acquired and the contents of memory. Implicit (or nondeclarative) learning and memory, on the other hand, refer to situations where there is a lack of awareness of what has been learned, a lack of intention to learn, or difficulty describing what has been learned. Rather, evidence of implicit learning and memory is provided through changes in performance on a task as a result of experience with the task.

Priming and skill learning are two major branches of implicit learning and memory, and some forms of classical conditioning additionally belong under this umbrella term. Priming refers to a change in processing of a stimulus as a result of a previous encounter with the same or a related stimulus, and facilitated processing may occur as a result of a single exposure to a stimulus. In contrast, skill learning refers to the gradual improvement in performance of some task with practice. Despite a range of differences between these two categories of implicit learning and memory, there are several commonalities. Both priming and skill learning may be demonstrated in the absence of awareness of what is being learned, both may be characterized by some degree of automaticity, and both may be relatively long lasting. Classical conditioning involves learning an association between an initially neutral stimulus and a significant stimulus that elicits reflexive behavior such that the neutral stimulus comes to elicit the automatic response with training.

Just as the psychological characterization of implicit learning and memory relies on its contrasts with explicit memory, the neural characterization has emphasized independence from the MTLs that are damaged in amnesics. Studies across different neurological patient populations and increased use of neuroimaging methods

Implicit Learning and Memory

Studies of patients with neurological damage have resulted in taxonomy of memory that emphasizes separable memory functions that rely on distinct brain regions. Five decades ago, it was discovered that patients with damage to their medial temporal lobe (MTL) or related diencephalic structures suffered from a severe inability to remember new facts and events. The deficit was selectively mnemonic and not related to attention, language, perception, or reasoning deficits. However, it was also

have contributed to a better understanding of how the brain supports the wide range of abilities covered by the term implicit learning and memory.

Priming

Perceptual and Conceptual Priming

Priming is commonly divided into perceptual and conceptual priming. Perceptual priming involves facilitated processing of the perceptual features of stimuli and involves words and pictures, and visual, auditory, and tactile information (see **Figures 1(a)–1(d)**). A common task involves studying a list of words and a later indirect test that allows influence of the studied words. For example, a subject may be asked to complete a word stem or fragment (ASSA____ or_SS_SI_) or to identify briefly presented words as words or nonwords. Previously studied words are more likely to be used to complete fragments than other possible words and are more quickly identified. In conceptual priming, previous experience with materials can be expressed through use of information to answer general knowledge questions without necessarily intentionally using the studied information.

Perceptual priming is modality specific, that is, priming across modalities (e.g., visual to auditory) is ineffective. Manipulations that alter perceptual features of studied items, such as font, alter perceptual priming, and priming is greatest when there is perceptual similarity between study and test. Conversely, manipulating the depth of processing of semantic or conceptual information about stimuli does not affect perceptual priming. Conceptual priming, by contrast, occurs across modalities and is enhanced when deeper semantic processing is emphasized at study, but is unaffected by perceptual manipulations.

Increased processing fluency observed in priming could be supported through tuning of neural regions involved in processing the stimuli themselves. Studies using fMRI to study brain activity during exposure to stimuli, show decreased neural responses to repeated stimuli, suggesting a more efficient response as a result of experience. This decreased response to repeated stimuli, as measured with functional magnetic resonance imaging (fMRI), is referred to as neural priming. Decreases in response to stimulus repetitions have been observed in cortical regions that would be expected to be involved in initial processing of stimuli, such as prefrontal regions for conceptual priming and posterior visual cortices for perceptual priming (**Figure 1(e)**). These decreases may be lateralized according to spatial presentation of basic visual shapes and localized to specific cortical regions depending on whether the materials are faces or houses. Damage to lateral occipital regions can selectively impair perceptual and not conceptual priming,

whereas patients with damage to the MTL, the striatum, or cerebellum perform normally on priming tasks. These findings are consistent with a general proposal that priming involves greater fluency in the processing of the stimuli *per se* that depends on neocortical regions and that the specific region involved depends on modality of the study and test materials.

Associative Priming

Associative priming generally uses the types of materials described above, but combines words into pairs (e.g., ELEPHANT-MOTEL). Subsequent tests may then require completing word stems when words are presented in the studied combinations or in combination with novel words or studied words that were part of a different pairing (e.g., ELEPHANT-GRA__). The results from these types of priming studies in patients with MTL damage are mixed, but there is some evidence from fMRI studies that MTL regions are engaged during associative priming.

Stimulus–Response Mappings

An alternative to the view that repeated experience with a stimulus makes stimulus processing more efficient is that what is learned is a proper response mapping. By this view, repetition benefits derive from redeploying a previous response instead of relying on a more efficient perceptual analysis. This idea was tested by repeating perceptually identical stimuli while changing response requirements (see **Figure 1 (f)**). Changing response requirements decreased neural priming, which returned when stimulus–response mappings returned to those initially primed. Furthermore, across subjects, behavioral priming and response time costs, resulting from switching response requirements, were associated with prefrontal cortical activity and not with activity in visual cortical regions.

The paradigms used in studies employing neuromaging have deviated from those used in neuropsychological studies owing to the need for simplified responses in neuroimaging. The results described above, obtained with a simple yes/no button press decision, may differ from the paradigms commonly used in neurologically impaired populations. However, the contribution of stimulus response learning to priming is one aspect of how repeated encounters with stimuli influence behavior.

Skill Learning

Skill learning is also referred to as procedural learning, which captures the idea that learning is expressed as facilitation of the procedures involved in task

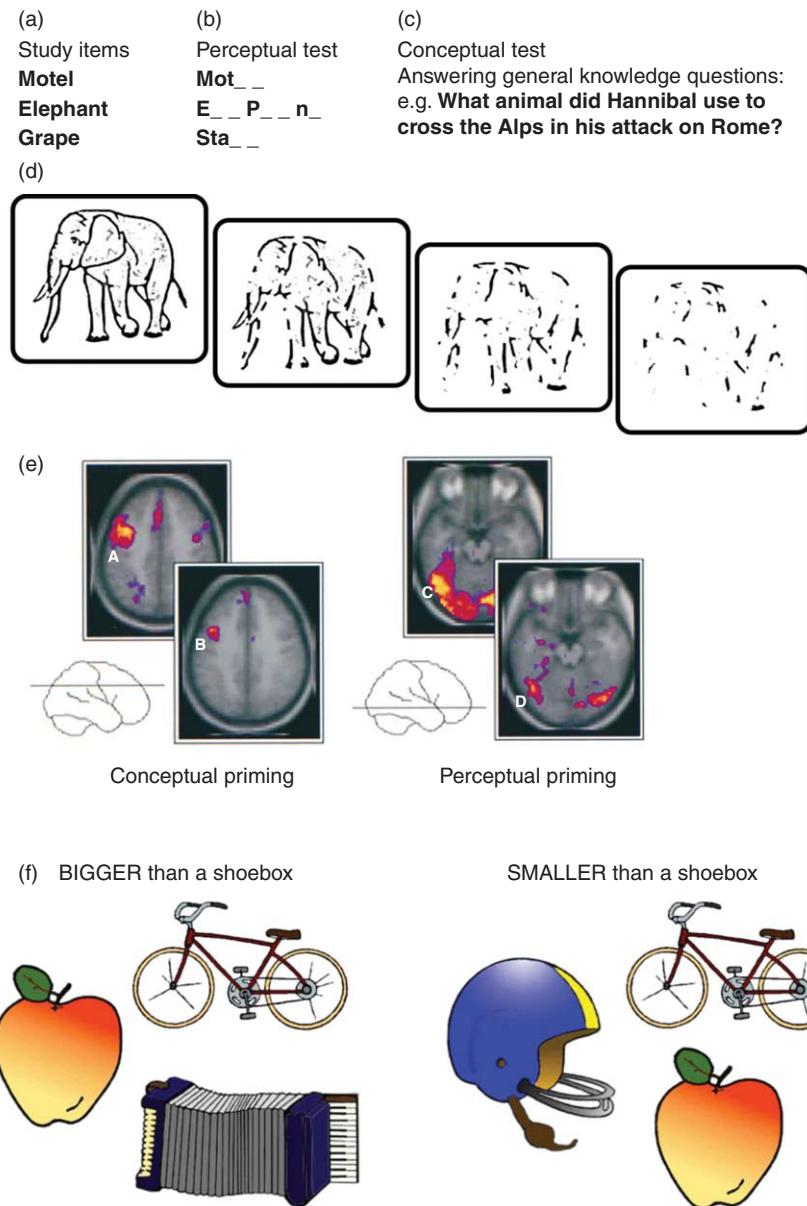

Figure 1 (a) Example of study items on a priming task. (b) In perceptual priming tests, participants are asked to complete word stems or fragments. (c) Perceptual priming can also use pictures, and previous study of pictures will allow identification of earlier, more degraded visual presentations. (d) In a conceptual priming test, the semantic properties of the studied items will facilitate answering general knowledge questions. Changing the font of items will affect the perceptual test (b) but have no effect on measures of conceptual priming (d). (e) Example of fMRI data from studies of perceptual and conceptual priming: (A) shows a comparison of brain activity when processing novel items and (B) shows a comparison of novel and repeated items in a conceptual priming task. The difference between novel and repeated seen in (B) indicates that within the same regions that are engaged when processing the novel items, there is a decrease in activity when previously encountered items are presented. In (C) and (D), the same comparisons and patterns are shown for a perceptual priming task. The line drawings indicate from where in the brain the displayed horizontal slice was taken. (f) Example stimuli from a priming task where participants first indicate with a yes/no response whether each item is BIGGER than a shoebox. Next they must instead indicate whether the item is SMALLER than a shoebox. In this way, only the response cue changes while the items that must be processed in order to make the decision remain constant. The response time slowing incurred when the response mapping is switched, suggests that, in some cases, priming is related to learning a particular response mapping rather than a representation of item information being more accessible. (e) Reprinted from Schacter DL and Buckner RL (1998) Priming and the brain. *Neuron* 20(2): 185–195.

performance. As such, skills differ from other types of memory because memory must be assessed by performance of the task itself. In some cases, the implicit nature of learning is because it is difficult to express what is being learned. A distinction is often made between knowing how and knowing that. For example, when learning to ride a bicycle, one is aware of learning, but the knowledge one can verbalize is not supporting performance or the how. In other cases, the structure to be learned is not explicitly signaled, but embedded incidentally in the task being performed.

The overview of skill learning is grouped into motor, perceptual, and cognitive skills, reflecting how the tasks used to assess skill learning have been classified rather than a true division of psychological or neural processes supporting performance.

Motor Skill Learning

Mirror tracing

On a mirror-tracing task, participants trace the outline of geometric figures while viewing the figures reflected in a mirror. The ability to trace becomes more accurate and rapid with practice, and the ability may be transferred to

novel figures not seen during practice. Patients with damage to the MTL, as in amnesia, or to the striatum, as in Parkinson's or Huntington's disease, can perform this task normally. In contrast, damage to the cerebellum leads to impaired mirror tracing. Evidence from positron emission tomography (PET) imaging has shown activation in a frontal-parietal-cerebellar network when performing the task, consistent with the pattern seen in neurological populations.

Motor adaptation

In motor adaptation tasks, an external perturbation is introduced such that motor behavior must be adjusted to perform a task. A common task requires participants to manually track a visual target while a manipulandum exerts a predictable force (Figure 2(a)). The ability to compensate for the forces and accurately track the target is learned gradually. The cerebellum has been implicated in learning both through study of neurologically impaired populations and neuroimaging in healthy populations and is thought to be critical in updating internal models of motor output from trial to trial (Figure 2 (b)). This process of updating behavior in response to error is distinct from that attributed to the striatum, which has been

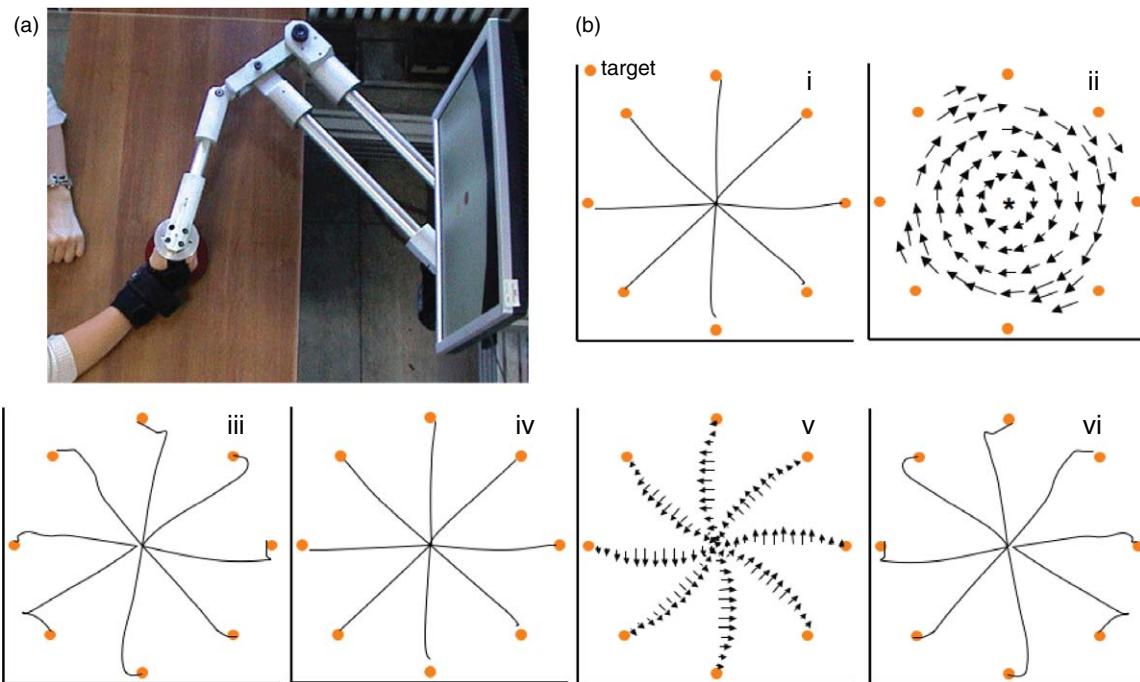

Figure 2 (a) Experimental setup for a motor adaptation task. The subject grips the handle of the manipulandum. A cursor corresponding to the position of the handle is displayed on the video monitor facing the subject. A target position for the subjects reaching movement is also displayed. With practice, the subject learns to compensate for the forces produced by the robot arm. (b) Cartoon of a subject's hand paths across stages of training: (i) Typical hand path in the null field. (ii) Example of a force field produced by a robot arm. (iii) Subject's hand path in the field before training. (iv) Hand path after extended training in the field similar to paths in null field. (v) Forces applied by a subject to counter the force field effects after training. (vi) After-effects seen when targets presented with null field conditions are intermixed during training.

linked to errors attributable to changes in the target on this type of task. The parietal cortex is thought to play an important role in transforming visuo-motor representations during online visually guided reaching consistent with its general role in spatial processing, whereas the cerebellum may not be critical for the within-trial online corrections.

Rotary pursuit

Rotary pursuit tasks require participants to maintain contact between a handheld stylus and a small target area on a rotating disk. The ability to maintain contact improves with practice. Amnesics can perform normally on this task, whereas patients with Huntington's disease are impaired and studies of patients with Parkinson's disease have yielded mixed results. Neuroimaging evidence suggests involvement of both the striatum and cerebellum in addition to cortical regions while executing the motor task, whereas activity in the supplementary motor area (SMA) and posterior parietal cortex has been linked to learning on the task. It has also been suggested that learning may be associated with increased activity in motor preparation areas and decreased activity visual processing areas, reflecting a shift from reliance on continuous external visual feedback to reliance on internally generated models allowing movement preparation and smooth execution.

Sequence learning

Motor sequence learning has been studied extensively using many task variations. In general, participants press a button in response to the spatial location of a visual stimulus (**Figures 3(a)** and **3(b)**). Unbeknownst to the participant, the sequence of visual stimuli sometimes follows a repeated pattern. The latency to push the buttons decreases with practice, in particular for the repeated pattern.

Patients with damage to the MTL can learn these tasks normally, whereas damage to the striatum impairs sequence specific learning. Although neurologically healthy participants often do not report awareness of the embedded pattern or display substantial knowledge when

probed, explicit knowledge can develop. Even in such cases, parallel implicit learning occurs as a result of the motor actions, and awareness of the sequence does not necessarily translate into ability to rapidly perform the motor skill. Patients with damage to the striatum or cerebellum may report sequence awareness and still be impaired on the performance of the motor skill. The striatum has also been implicated in sequence learning in neuroimaging studies. In addition, involvement of the SMA is commonly seen, consistent with the importance of motor planning, and the parietal cortex is consistently implicated and has been linked to learning of the spatial sequence. Damage to the cerebellum leads to impaired implicit sequence learning, as does damage to the striatum, but the particular role of the cerebellum is not clear. Evidence from neuroimaging has suggested that the cerebellum may be critical in the execution of the learned skill.

Perceptual Skills

Mirror reading

Learning to read mirror-reversed text has commonly been used to assess perceptual skill development. Amnesics can improve their mirror reading skill without recognizing previously studied specific words and can retain the skill for several months. The role of the striatum is not entirely clear. Parkinson's patients often show intact mirror-reading skill, whereas Huntington's patients with intact memory for specific words show a mirror-reading impairment, perhaps due to some visuo-spatial deficit in Huntington's disease. Consistent with the importance of visuo-spatial transformations in mirror reading, neuroimaging has implicated parietal cortex in addition to the striatum.

Visual prototype learning

Prototype learning commonly takes the form of observing dot patterns that are deviations from a single prototype. After studying multiple prototype distortions, subjects are told that the patterns were from a

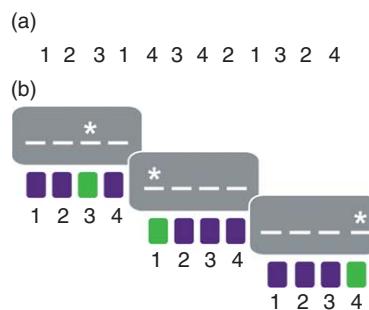

Figure 3 (a) Repeating sequence used in motor sequence learning task. (b) Participants press a button corresponding to the spatial location of the asterisk onscreen.

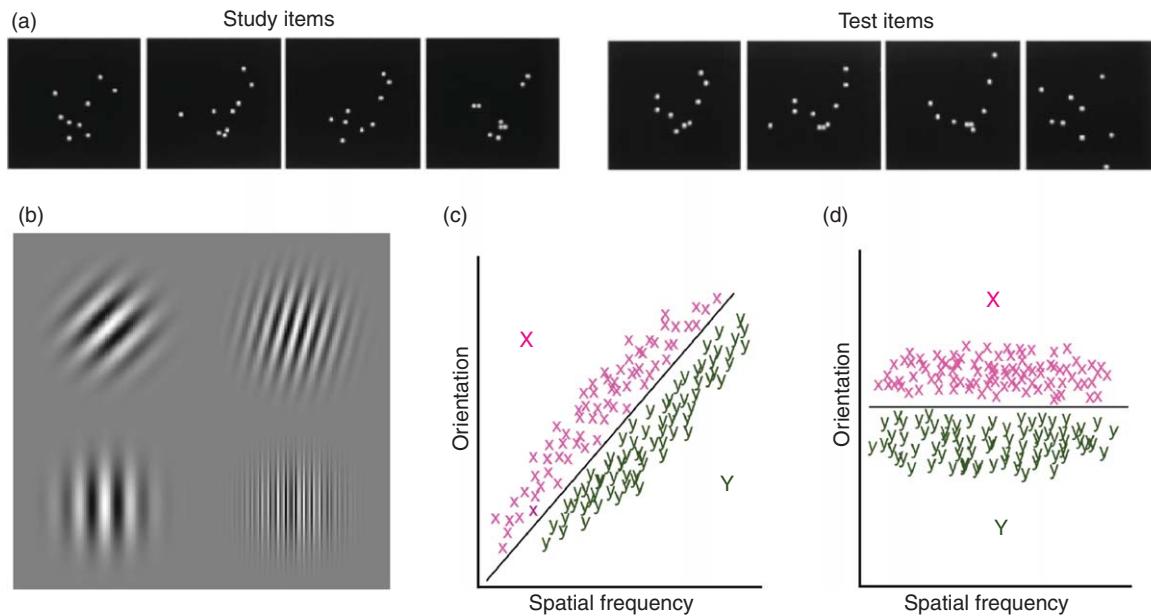

Figure 4 (a) Examples of dot patterns used as study and test items used to assess visual prototype learning. Study items were high distortions of a prototype dot pattern. From left to right are shown the training prototype, low and high distortions of the training prototype, and random dot patterns. (b) Example Gabor patches that vary in spatial frequency and orientation from trial to trial are used in perceptual categorization experiments. (c) Plot of stimuli that might be used in an information-integration category-learning task. X's denote the spatial frequency and orientation of exemplars from category X and Y's denote category Y exemplars. An optimal decision bound requires integrating information about orientation and spatial frequency prior to making a decision and is indicated by the diagonal line. (d) In a rule-based category learning task, the optimal decision boundary follows a rule that can easily be verbalized (indicated by the horizontal line). (a) Reproduced from Reber PJ, Stark CEL, and Squire LR (1998) Cortical areas supporting category learning identified using functional MRI. *Proceedings of the National Academy of Sciences of United States of America* 95: 747–750.

single category and that they must classify subsequently presented patterns as category members or not (**Figure 4(a)**). Amnesics can perform such categorization like healthy controls, but unlike healthy individuals, they are impaired when asked to explicitly recognize previously seen items. Patients with striatal damage also perform normally on this type of learning. Neuroimaging studies have implicated early visual areas, which show decreased activity when category members are classified. Interestingly, when healthy subjects are asked to intentionally learn the category, subsequent classification involves increased activity in MTL and prefrontal regions, in contrast to the pattern of activity seen after incidental learning.

Perceptual categorization

In perceptual categorization, subjects are asked to intentionally learn to classify visual patterns by trial and error. However, the complexity of the rules governing category membership can make it difficult to verbalize a strategy for performing categorizations. For example, Gabor patches that vary in frequency and orientation may be used as stimuli and nonlinear combinations of the perceptual dimensions govern category membership (see **Figure 4(b)**). No two stimuli need be alike because the perceptual dimensions can be varied

continuously. Therefore, a general perceptual rule has to be applied to each new stimulus. Amnesics can learn such categorization tasks. Damage to the striatum impairs learning of complex nonlinear category boundaries, but sometimes leaves learning of simple linear boundaries intact.

Contextual cueing

The implicit learning abilities discussed here all share the characteristic that they appear not to depend on the integrity of the MTL. However, implicit learning impairment has been demonstrated in patients with MTL damage. Contextual cueing is a task where visual displays with repeated spatial configurations allow facilitated detection of a target. The representation of the spatial configuration is thought to depend on the MTL regardless of the fact that subjects are not informed of the regularity, do not report awareness of the repetition, or necessarily show recognition of repeated configurations. Amnesics are not able to take advantage of the repetition, and neuroimaging studies have shown involvement of the MTL. Thus, implicit learning is not necessarily independent of the MTL. This depends on the task domain and specific capacities needed to perform a task.

Cognitive Skills

Category learning

Several category-learning tasks are similar to the perceptual categorization or prototype learning tasks. However, rather than involving continuous stimulus dimensions that are difficult to verbalize, they involve multiple discrete features. The combination of some features may be diagnostic of category membership while other features may be irrelevant. These types of categories can be learned by patients with damage to the MTL, but although the exact category rules can be difficult to verbalize, healthy participants often explicitly generate hypotheses and may thus achieve enhanced performance relative to patients with brain damage (Figure 5(a)).

Probabilistic category learning

In probabilistic classification tasks, stimuli are probabilistically associated with categories, and subjects learn based on trial-by-trial feedback. Single features and combinations of these features each predict the category

outcome with a certain probability. A frequently used cover story is that subjects must predict whether it will be sunny or rainy based on a deck of four cards (Figure 5(b)) Based on feedback, categorization should eventually improve, but, because the category association is probabilistic, feedback on any single trial may be misleading. Subjects are deemed accurate when they select the more likely outcome and will perform best if they predict the more frequent outcome across many trials. This structure is thought to make memory for cue–outcome relations on individual trials unhelpful, and although subjects routinely learn to perform with 70–80% accuracy they report a feeling of that they have not learned.

Amnesics, in some cases, can learn this task despite poor memory for details about testing. However, healthy subjects can exhibit explicit knowledge about the task structure when probed more specifically, and there is neuroimaging evidence for engagement of the MTL in such cases, suggesting that healthy subjects may use different or additional knowledge when possible. The necessity for integrating across multiple trials

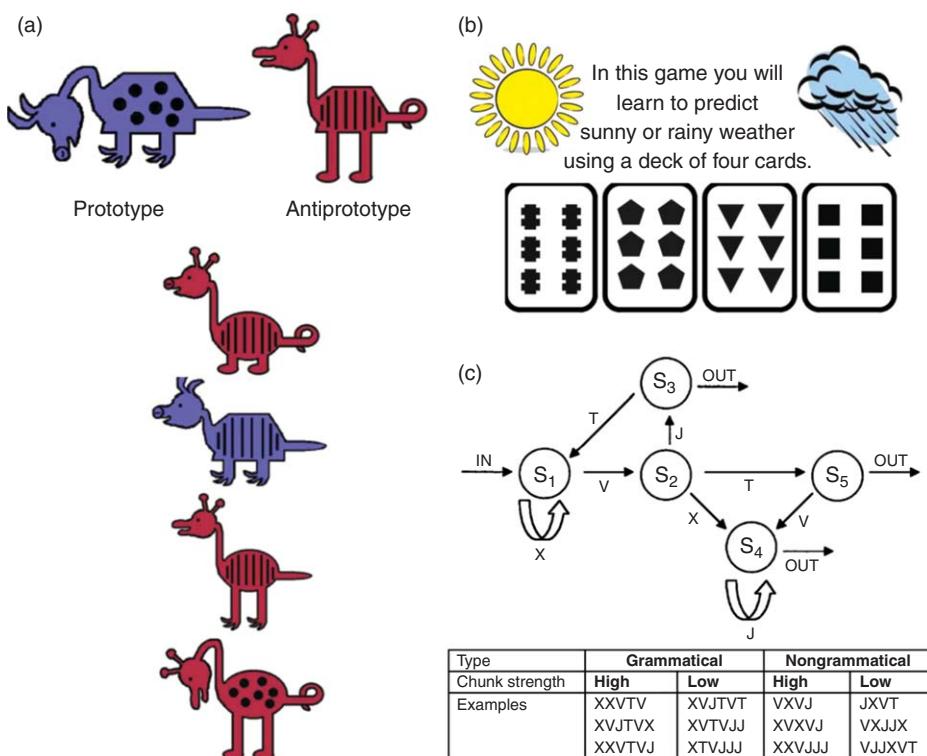

Figure 5 (a) Example stimuli from a categorization task. Subjects study examples of cartoon animals. Subsequently, they are told that they saw animals called ‘Peggles’ and now they must decide whether or not the following animals are Peggles. (b) Example of stimuli used in probabilistic classification tasks. One or more of the cards are presented on each trial and a prediction of sunny or rainy outcome is made. (c) Finite-state grammar used to generate letter strings. (d) Examples of training and test strings that are either grammatical or not and have high or low chunk strength. (a) Adapted from Bozoki A, Grossman M, and Smith EE (2006). Can patients with Alzheimer’s disease learn a category implicitly? *Neuropsychologia* 44(5): 816–827. Visual feature learning in artificial grammar classification. *Journal of Experimental Psychology: Learning, Memory, and Cognition* 30(3): 714–722.

on this task has been suggested to parallel gradual learning of stimulus-response learning, which in animals depends on the striatum. In humans, patients with damage to the striatum show impaired learning. However, it appears that the critical involvement of the striatum is tied to learning from trial-by-trial feedback. When the same task is learned through observation of multiple trials where cues and outcomes are presented simultaneously, patients with Parkinson's disease can show that they have learned to make accurate category predictions. Consistent with this, neuroimaging studies show that the MTL rather than the striatum is engaged when learning by observation. Thus, it appears that the task can be learned in an implicit or explicit way and that this engages different neural systems, as is the case in visual prototype learning.

Artificial grammar

Artificial grammars consist of letter strings generated based on an underlying set of rules. Multiple letter-string exemplars are presented to subjects. Subsequently, subjects are told that they saw exemplars generated according to a specific set of rules and that they now must distinguish between new letter strings that either are or are not generated according to the same rules (see **Figure 5(c)**).

Multiple types of knowledge may be acquired. For example, abstract rules about generating grammatical strings or more specific knowledge about string features such as similarity between chunks of letters within grammatical strings (chunk strength) can be learned. Evidence from neuroimaging is mixed, with one study finding MTL activity related to chunk strength and caudate activity related to rule adherence. Some studies have found prefrontal, occipital, and parietal cortex activity and others have found decreases in occipital cortex activity as a function of string fragment priming. Similarly to the prototype distortion task, damage to the MTL, striatum, or cerebellum does not impair grammar learning, which may rely on number of implicit processes, such as rule abstraction and priming, to support various aspects of performance.

Classical Conditioning

Eyeblink conditioning

Eyeblink conditioning is perhaps the most extensively studied form of implicit learning. In this paradigm, a conditioned stimulus (e.g., a tone or a light) predicts the occurrence of an air puff to the eye. Repeated pairings result in the acquisition of an eyeblink timed to prevent the air puff on the eyeball. The neural circuitry underlying acquisition, execution, and retention of this behavior is primarily localized to the cerebellum and has been outlined in exquisite detail. Studies in animals,

using a range of techniques, have outlined the specific regions of the cerebellum critical for the unconditioned eyeblink response, the conditioned response, and for the representation of conditioned stimuli, thus providing a detailed model system for studying memory formation in general.

Neuropsychological studies of patients with cerebellar damage and fMRI studies in healthy adults have confirmed the necessity of the cerebellum for this form of learning in humans as well. As with the other forms of procedural learning described herein, awareness of contingencies does not appear to be critical for learning, and amnesics with damage to the MTL acquire a conditioned eyeblink.

However, two forms of eyeblink conditioning, delay and trace conditioning, exist, and map on to procedural and declarative memory, respectively. When a temporal gap is inserted between the conditioned stimulus offset and the air puff onset (trace conditioning), additional neural processes are necessary. Acquisition of trace eyeblink conditioning requires the hippocampus, as has been shown in animals and in humans with damage to the MTLs. Moreover, it is suggested that trace eyeblink conditioning in humans depends on awareness of the contingency between the conditioned stimulus and the air puff. Such awareness does not aid learning for delay conditioning, consistent with a distinction between procedural and declarative forms of eyeblink conditioning.

Characteristic of Implicit Learning and Memory

Awareness

A central challenge inherent to the study of implicit learning and memory relates to the role of awareness in learning. In patients with amnesia, it is relatively easy to demonstrate that memory is not accompanied by awareness of previous study. By contrast, while healthy subjects may use implicitly learned information without knowingly retrieving it, the possibility of contamination from explicit memory makes it important to carefully control or measure such contributions. On some tasks, being aware of what is learned will not necessarily help. For example, the ability to verbally characterize what you are doing when riding a bike is not likely to critically contribute to the bike riding. However, on the other tasks, the role of awareness and whether learning can truly be called implicit remain the most controversial issues related to implicit learning and memory. Nonetheless, the ability to show evidence of learning in amnesics who have no explicit memory for the material suggests that awareness need not accompany learning.

Automaticity

Implicit learning and memory are often characterized by automaticity relative to explicit memory. A common focus when studying skill learning is on the development of automaticity. Skill acquisition often requires executive control in its initial phases, and measuring whether performance becomes insensitive to interference from concurrent performance of an additional task is a common way to operationalize automaticity as it develops with practice. Most people recognize such a change in automaticity when riding a bike or driving a car. In the case of priming, automaticity can refer to a similar ability to exhibit intact learning and memory in the face of interference with executive control resources. In addition, automaticity captures the idea that previously studied information is used automatically without intentional efforts to access previously studied information.

Longevity

For both priming and skill learning, retention of memory has been demonstrated after months and years, which is impressive considering the limited practice afforded and that further practice outside the laboratory is unlikely. However, those may also be the factors that allow implicit memories to remain undisturbed. If interference is a critical factor in forgetting, as is thought to be the case for explicit memory, then the idiosyncratic materials used in the laboratory to measure implicit learning may be a benefit. How implicit memory is supported long term will become better understood as more is learned about how such memories are consolidated and how factors such as sleep and amount of practice affect them.

Implicit Learning and Memory: Neural Aspects

Cerebral Cortex

Across both priming and skill learning, distinct neocortical regions are involved depending on task modality and the specific requirements of a task. Frontal and occipital cortical regions are involved in priming depending on whether conceptual or perceptual processing is necessary. When skill learning depends on visual processing, occipital regions are engaged, parietal cortex is involved in tasks requiring spatial processing, and motor and supplementary motor cortex is involved when motor skills are acquired.

Striatum

The striatum appears to play a more general role in skill learning, across task domains. The striatum is a complex, heterogeneous structure and may contribute to skill learning in several key ways. The anatomy of the striatum has been described as consisting of distinct fronto-striatal loops with distinct striatal territories connected to discrete cortical regions (e.g., caudate with dorsolateral prefrontal cortex and putamen with premotor cortex). In addition, these partially segregated loops can communicate through the striatum. As such, the striatum can support multiple aspects of skill learning.

Tasks that rely on incremental trial-and-error learning, such as stimulus-response learning, engage the striatum as measured with fMRI and are generally impaired in populations with striatal damage or when dopaminergic signaling is manipulated. This is consistent with demonstrations of dopamine-modulated plasticity at fronto-striatal synapses that can support stimulus-response learning and with a general role for the striatum in processing feedback. In particular, the striatum is thought to be critical when feedback is received in response to internally generated plans that subsequently are updated.

Another role proposed for the striatum is chunking action sequences into units. By chunking a series of actions into a single unit, execution becomes more reliable and rapid. On the other hand, chunking leads to more stereotyped and less flexible behavior. Evidence for unitizing comes from recordings in rodents where repeated performance results in neural activity signaling the onset and offset of an action sequence instead of activity at every step of the sequence. Such a mechanism would be relevant for sequencing tasks.

Feedback processing is most commonly associated with anterior aspects of the striatum involving the caudate. The putamen has instead been associated more specifically with motor learning. In some cases, acquisition of motor sequences has been associated with anterior striatum and execution of well-learned sequences with the posterior striatum. Future research is needed to understand how distinct striatal regions support distinct aspect of implicit learning and how these contributions change as learning progresses.

Cerebellum

The role for the cerebellum in skill learning is similar to that of the striatum, in that it involves adjusting an internal model in response to feedback. However, the cerebellum has been associated with tasks where continuous sensory feedback is provided, and novel mappings between

visual information and motor behavior are developed (e.g., mirror-tracing and motor adaptation tasks).

When it comes to learning a discrete response, such as a conditioned eyeblink, the role of specific regions within the cerebellar system has been identified, and it has been detailed how various aspects of conditioned stimuli and responses depend on specific regions to support the resulting implicitly learned behavior, which is a specific well-timed motor action. Interestingly, although timing is critical, the cerebellum alone is unable to support learning when a temporal gap is inserted between a predictive cue and the air puff.

Thus, the cerebellum is critical for several types of implicit motor learning. However, the detailed knowledge about the neural substrates of classically conditioned responses developed primarily in animal stands in contrast to the more limited knowledge of the cerebellum's role in other types of motor learning frequently studied in humans. Future research may bridge this gap and leverage the extensive knowledge developed in animal models.

Medial Temporal Lobe

Involvement of the MTL is often observed when explicit knowledge plays a role. However, this is not uniformly the case. There are examples of MTL damage leading to impaired implicit learning and, using neuroimaging, demonstrations of MTL activity on implicit learning task such as contextual cueing. In addition, MTL activity has been linked to learning of higher-order relations on sequence learning tasks or item associations in priming tasks, suggesting that the MTL may be involved when relations among items are critical regardless of explicit knowledge or awareness of what is being learned. Additionally, evidence from eyeblink conditioning has shown that the MTL becomes critical when associations need to bridge across time.

Conclusion

The brain exhibits an impressive breadth of ways to learn about the environment. Multiple mechanisms are available to process novel and repeated information regardless of any intention to learn. In general, the psychological distinction between different learning and memory processes has been supported by finding dissociable neural signatures, by using neuroimaging techniques in healthy populations and by finding differences between patient populations with brain injuries. As suggested by the descriptions above, without the presence of neurological damage, multiple types of memory may contribute to performing a task. Both implicit and explicit processes

may contribute or both priming and skill learning may play a role. Although the use of different experimental paradigms aims at testing specific skills, most tasks do not yield pure measures of the targeted mechanisms. However, some principles have emerged suggesting that the striatum and cerebellum play general roles and that changes occur in the cortical regions that initially process stimuli and that these regions vary depending on the task modality. It remains a challenge to dissect further the cognitive and neural processes that support implicit learning and memory and, in particular, to further understand how these processes interact and change with practice.

Glossary

Apraxia of speech – A communicative disorder involving the voluntary production of speech.

Articulatory code – The representation of speech sounds derived by internally simulating movements needed to produce those sounds.

Paralinguistic – The nonverbal elements of communication.

Paraphasic error – A speech error involving the substitution of an incorrect but related sound or word, as in ‘tree’ for ‘free,’ or ‘chair’ for ‘bed.’

Phoneme – One of a small set of speech sounds used in a particular language; it is the smallest unit of sound that leads to a difference in meaning.

Pragmatics – The field of linguistics addressing the way that meaning changes as a function of context.

Semantics – The study of language meaning.

Suprasegmental – A vocal effect that extends over more than a single speech sound.

analysis, which determines structure–function relationships by noting deficits associated with damage to particular brain regions, and neuroimaging methodologies, which identify brain activity modulated by demands on the processes presumed to underlie language and communication. These two approaches are somewhat complementary, as lesion analysis can be used to identify brain regions necessary for a particular language or communicative function, while neuroimaging is useful for identifying a complete set of brain regions that participate in the underlying computational processes.

Patient Studies

Aphasias

Many historians of science argue that the modern era of neuropsychology begins with the work of Paul Broca, a nineteenth-century neurologist. Broca prompted scientific discussion as to whether language ability could be localized in the brain with his classic report of two patients with profound language-production deficits following large left frontal lobe lesions. Localization received further support from Broca’s contemporary, Carl Wernicke, who reported two patients with severe language-comprehension deficits, apparently due to the presence of a lesion in the posterior portion of the left temporal lobe. Although Wernicke’s aphasics can speak fluently, their speech includes made-up words known as ‘paraphasias’ (e.g., ‘treen’ for ‘train’), and their sentences are often incoherent. In contrast, the incidence of aphasic deficits in patients with lesions in the right hemisphere is far less common.

Even today, cognitive neuroscientists’ understanding of the relationship between brain activity and language ability derives largely from the study of brain-injured patients. The logic of these studies is that the damaged area plays a critical role in the compromised function. Consequently, the left hemisphere is considered to be the language hemisphere, while the right hemisphere is the

Language is a system for evoking cognitive models through the systematic use of sounds, gestural signs, or printed symbols. Language involves several different kinds of representations, each governed by rules and regularities in the way in which they can be combined. Speech, for example, can be understood as being structured at the level of phonemes, or speech sounds, lexemes, or words, and grammatical constructions that allow speakers to combine a finite array of words into a potentially infinite set of sentence meanings. Moreover, communication involves more than language, including paralinguistic and inferential components, such as tone of voice, or prosody, facial expressions, co-speech gestures, and the utilization of background and contextual knowledge.

Study of the neural substrate of language and communication has primarily involved two methodologies: lesion

'minor' hemisphere. Since damage to the front portion of the brain is associated with difficulty in speaking, it is assumed that left frontal areas play a crucial role in language production. Similarly, since damage to the posterior portion of the brain is associated with difficulty in understanding language, it is assumed that left posterior temporal areas play a crucial role in language comprehension.

Although the modern model of the neural basis of language is considerably more complex than that outlined by nineteenth-century neurologists, such as Broca and Wernicke, a good deal of contact with its historical predecessor remains. Consequently, we begin with a brief account of each of the seven basic aphasic syndromes, or common clusters of symptoms, and follow with a synopsis of localization claims agreed to by the twenty-first-century neurologists and neuropsychologists.

Broca's aphasia

Common features in the speech of Broca's aphasics include effortful speech replete with pauses, false starts, and unclear words. Their conversational speech is not grammatical, consisting mainly of nouns, with a few verbs. The so-called 'function words' (determiners, prepositions, and conjunctions) and 'bound morphemes' (e.g., '-s' to denote the plural, or '-ly' to indicate an adverb) are often omitted from the speech of Broca's aphasics. These patients experience word-finding difficulty, both in conversational speech, and in picture-naming tasks. When asked to repeat a word or a phrase, Broca's aphasics are often unable to do so, producing the same sort of halting utterances characteristic of their conversational speech. Although comprehension in Broca's aphasics is generally good; careful testing suggests that they have difficulty when adequate understanding of a sentence depends critically on grammatical information, without the support of background knowledge and contextual information.

As classically defined, Broca's area is the third frontal convolution of the inferior frontal gyrus. The proximity of this area to primary and premotor cortices coupled with the speech-production deficits associated with this syndrome, led to an early characterization of Broca's aphasia as 'expressive' aphasia, to be contrasted with the fluent 'receptive' aphasia described by Wernicke, which in turn was supported by the proximity of Wernicke's area to primary auditory cortex. However, extensive study of the relationship between lesion sites and particular deficits has led to the conclusion that it is the existence of lesions to the anterior portion of the insula that is crucial for the prediction of whether a given patient will suffer from the speech-production deficit known as 'apraxia of speech.'

Another characterization of Broca's aphasia is as 'agrammatic' aphasia, due to the putative involvement

of Broca's area in knowledge of grammar. This characterization derives both from the ungrammatical nature of their output, and the demonstration that comprehension deficits in Broca's aphasia seemed to depend specifically on knowledge of grammar. However, the tight linkage between Broca's area and grammatical knowledge has also fallen out of favor due to reports of grammatical processing deficits in patients with other aphasia syndromes, as well as the demonstration that similar grammatical deficits could be induced in neurotypical adults by various methods of stimulus degradation, or through the imposition of stressful conditions.

Wernicke's aphasia

Language production in Wernicke's aphasia is fluent, though it often contains paraphasic errors. These patients' primary deficit, however, is in language comprehension. They experience moderate-to-severe difficulty on repetition and naming tasks, and while their comprehension of written words is often better than their auditory word comprehension, they are impaired both in their ability to read and to write.

As classically defined, Wernicke's area is the posterior region of the left superior temporal sulcus. However, systematic study has failed to uphold a strict one-to-one relationship between Wernicke's aphasia and lesions to this region. Some investigators have reported Wernicke's aphasia in patients with lesions in frontal regions, post-Rolandic temporo-parietal areas, and other temporal lobe regions, especially the middle temporal gyrus.

Conduction aphasia

As in Wernicke's aphasia, conduction aphasics are characterized by fluent language production containing frequent paraphasic errors. Moreover, conduction aphasics are unable to repeat words or phrases that are read to them. Unlike Wernicke's aphasics, however, conduction aphasics' ability to understand language is largely preserved. Similar to most aphasics, these patients occasionally experience difficulty in naming tasks, and their reading and writing ability is sometimes impaired.

Conduction aphasia is classically associated with lesions to the arcuate fasciculus, the white matter tract that connects Broca's area in frontal cortex to Wernicke's area in the temporal lobe. This aphasic syndrome – intact comprehension accompanied by the inability to repeat spoken words – was actually predicted by Wernicke based on his model in which the arcuate fasciculus connected Wernicke's area, where the sound images of words were stored, to Broca's area, where the motor images of words were stored.

Wernicke argued that speech production was normal in conduction aphasics because the connection between conceptual centers and Broca's area was intact; speech

comprehension was normal because the connection between Wernicke's area and the brain's conceptual centers was intact. Repetition was compromised because this task required a connection between Wernicke's area and Broca's area, without the conceptual centers as an intervening step. Indeed, Wernicke's account is consistent with the report that conduction aphasics' behavior on repetition tasks often suggests that they understand the phrase to be repeated, but are unable to produce a verbatim reproduction.

Global aphasia

Global aphasia is characterized by the complete inability either to speak or to understand language, and is typically associated with large lesions affecting up to 75% of the left hemisphere. Lesioned areas include the Broca's area, the insula, the arcuate fasciculus, Wernicke's area, the anterior superior temporal gyrus, the middle temporal gyrus, and the underlying white matter, along with motor, somatosensory, and auditory cortices.

Anomic aphasia

Anomic aphasia is characterized by severe word-finding difficulties, while fluency, comprehension, and repetition are all relatively intact. Many more severe aphasic syndromes resolve over time to anomic aphasia, and thus, this syndrome is associated with a wide variety of left hemisphere lesions.

Transcortical motor aphasia

Lesions to the superior aspect of the anterior frontal lobe often give rise to speech production difficulties akin to those in Broca's aphasia. While their spontaneous output is often telegraphic in character, transcortical motor aphasics show a remarkable ability to repeat even very long sentences. Over time, these patients' speech-production ability typically improves, and their condition resolves to anomic aphasia.

Transcortical sensory aphasia

Relatively small lesions in the posterior middle temporal gyrus, or occasionally in the posterior parietal region, have been associated with transcortical sensory aphasia. Larger lesions that include the superior temporal cortex are often associated with Wernicke's aphasia. Similar to their counterparts with Wernicke's aphasia, transcortical sensory aphasics have fluent output, impaired comprehension, and experience difficulties in naming tasks. Unlike Wernicke's aphasics, however, patients with transcortical sensory aphasia have preserved repetition, as they are able to repeat words, sentences of considerable length and complexity, and even words in languages they do not speak. Transcortical sensory aphasia is an acute condition, resolving eventually to mild anomic aphasia.

Aphasia and the neural substrate of language

While aphasic syndromes discussed above provide a useful heuristic for describing the communicative deficits of left hemisphere stroke patients, they have proven less useful as guides for identifying the neural substrate of language. That is, classification of a patient as a Broca's aphasic, for example, need not imply the patient's lesion site includes the inferior frontal gyrus. Conversely, a patient with damage to the inferior frontal gyrus will not necessarily present with Broca's aphasia. However, neurologists have enjoyed more success in localization efforts by restricting their attention to the relationship between lesion sites and specific language deficits, irrespective of the general aphasia type of the patients who experience those deficits.

For example, the repetition problems experienced by conduction aphasics have been linked to the ability to keep recently encountered auditory information active for a few seconds, in order to facilitate the processing of stimuli that unfold in time – as in the case of spoken language. Cognitive psychologists refer to these processes alternately as echoic memory, or the phonological store. Besides lesions to the arcuate fasciculus, conduction aphasics typically have lesions in the posterior superior temporal gyrus. Moreover, patients with other aphasic syndromes who present with repetition deficits also have lesions in the posterior superior temporal gyrus. Consequently, this brain region has been implicated as an essential component of the phonological store.

Similarly, the impaired semantic comprehension associated with Wernicke's aphasia has been linked specifically to damage to the middle temporal gyrus. As patients with damage to the middle temporal gyrus and the underlying white matter are impaired on word comprehension irrespective of their aphasia syndrome, this brain region has been implicated as an essential component of the lexical–semantic network. Analogous reasoning has implicated the anterior superior temporal gyrus in the comprehension of complex sentence structures, and the arcuate fasciculus for transmitting information from the temporal lobe language areas to motor speech areas in the frontal lobe. Patient studies suggest that the precentral gyrus of the insula is crucial for articulatory planning, while Broca's area proper (the third frontal convolution of the inferior frontal gyrus) is implicated in end-stage articulatory processes.

Right Hemisphere Damage

Although patients with right hemisphere damage show preservation of core language abilities, such as naming, fluency, and the ability to understand individual sentences, they often present with other, more subtle communicative deficits. For example, their speech, while including words that are well formed phonemically,

often has a flat quality sometimes described as ‘robotic.’ Moreover, their conversation is frequently marked by diversions from the topic at hand, tangential remarks, and offensive comments. In experimental studies of their comprehension, these patients have also been shown to have deficits in the comprehension of various pragmatic language phenomena.

Aprosodia

Prosody is suprasegmental information in the speech signal that can be used to convey affective or grammatical information. Aprosodia is thus impaired ability to produce or comprehend prosodic contours on speech. Prosodic information is conveyed by variations in pitch, loudness, duration, voice quality, and rhythm. As noted above, one classic aspect of right hemisphere syndrome is aprosodic output, conveying a flat affect. Although aprosodic output is sometimes accompanied by deficits in affective processing, such as inappropriate emotional responses to events, it is clearly dissociable from the latter. Affective processing deficits can occur with or without aprosodic speech, and aprosodic speech can occur in patients whose emotional responses are entirely normal.

Regarding the comprehension of prosody, some evidence suggests greater left hemisphere involvement in processing prosody that signals linguistic distinctions, and greater right hemisphere involvement in processing affective prosody. More recent studies have attempted to relate these patterns of lateralization to the acoustic underpinnings of linguistic versus affective prosody. Patient studies suggest that right-hemisphere-damaged patients’ preserved ability to appreciate linguistic prosody can be traced to their reliance on rhythm cues thought to be preferentially processed in the (intact) left hemisphere. Their deficits in the appreciation of emotional prosody may be linked to an impaired ability to detect pitch differences preferentially processed in the right hemisphere.

High-level communicative deficits

Right hemisphere damage has also been associated with deficits in the comprehension of a number of pragmatic language phenomena, or language whose meaning depends on extra-linguistic knowledge about the physical and social context as well as background knowledge about the way the world works. These pragmatic language-comprehension deficits include difficulty in appreciating humor, sarcasm, discourse appropriateness, the communicative intentions of one’s interlocutor, and knowledge of what one’s interlocutor does and does not know (i.e., theory of mind).

Neuroimaging: Language Production

The advent of twentieth-century neuroimaging techniques ushered in a new era of the cognitive neuroscience of language by enabling researchers to discover brain areas underlying various language and communicative processes in healthy adults. These studies typically involve monitoring local changes in various kinds of metabolic activity caused by experimental manipulation of the cognitive demands on the language system. Positron emission tomography (PET), for example, is typically used to measure cerebral blood flow in particular brain regions. Functional magnetic resonance imaging (fMRI) is used to monitor changes in the oxygenation value of hemoglobin in the blood and, besides being a less-invasive method than PET scanning, is superior to PET in both spatial and temporal resolution.

One major advantage of noninvasive imaging techniques is that they allow the investigator to see an entire network of brain regions that participate in the cognitive task of interest, rather than being restricted to the identification of a few essential nodes in that network. As such, neuroimaging has led to the understanding of a language area in the brain that had largely escaped the attention of neurologists, due to the fact that it is typically spared in left hemisphere strokes. The so-called ‘basal temporal language area’ is comprised of a region in the posterior inferior temporal cortex, and is activated in a variety of language neuroimaging paradigms.

Findings from neuroimaging studies of language production are briefly discussed in this section, while studies of language comprehension are covered in the section entitled ‘Neuroimaging: Language comprehension.’

Speech

As motion is inherent to the act of speaking, neuroimaging techniques are not well suited for the investigation of speech-production processes. However, studies to date have implicated the left basal temporal language area, the left anterior insula, the left frontal operculum, and the right cerebellum. Activity in the left anterior insula and the left frontal operculum have been specifically related to articulatory planning, consistent with the neuropsychological literature on apraxia of speech. Semantically driven speech output, as in a naming task, involves enhanced activity in left posterior inferior frontal cortex. Finally, motor control of speech activates bilateral sensorimotor cortices.

Writing

If speech production is a somewhat understudied area in the cognitive neuroscience of language, the study of the neural correlates of writing is virtually uncharted

territory. A handful of studies on the production of written words, however, point to the importance of the left superior parietal lobule and the left inferior posterior frontal cortex.

Neuroimaging: Language Comprehension

Sound

Speech perception and phonological processing

Hearing spoken words activate bilateral superior temporal gyri. Neuroimaging thus implicates right hemisphere brain regions in speech perception, a fact difficult to detect with the lesion localization technique. The dominant role of the left hemisphere in the processing of speech may relate to hemispheric specialization in tuning for different sorts of auditory information. Recent investigations support a left hemisphere bias for processing rapid acoustic transitions versus a right hemisphere bias for spectral variations. The former are important for discriminating between different consonants, while the latter is important for tone languages such as Mandarin.

Many details concerning the anatomy and physiology of the human auditory system are unknown. Based on knowledge of primates and other mammals, however, a number of investigators have suggested the existence of multiple parallel processing streams in the human auditory system. A ‘what’ stream (sometimes referred to as ‘ventral’ by analogy to the visual system) in the posterior central parietal occipital junction, primarily in the left hemisphere, serves as an interface between sound and meaning representations. A ‘where’ or ‘how’ stream (sometimes referred to as ‘dorsal’ by analogy to the visual system) involves the inferior parietal and frontal cortices and is thought to be important for auditory–motor integration important in some accounts of speech perception.

The import of motor areas for speech production is motivated by the fact that phonemes are defined by articulatory features, and that reference to these motor features might facilitate the recognition of speech sounds whose acoustic properties are highly variable across speakers. Recent studies of phoneme perception report the activation of both auditory areas in the temporal lobe, including Heschl’s gyrus and the planum temporale, and motor areas in the frontal lobe, including the mouth motor area and inferior precentral cortex.

Phonological store

Neuroimaging studies to date vary somewhat in their localization of the phonological store, or ‘loop’ as it is sometimes called. This variability may be attributable to the extent to which the experimental task requires participants to employ an articulatory code to activate phonemes. In tasks that do not promote the use of an articulatory code, the activation involves the left superior

temporal sulcus – consistent with the observations of repetition deficits in patients with damage to this area. In tasks that do promote the use of an articulatory code, the activation is more dorsal, at the junction between the posterior superior temporal cortex and the inferior part of the supramarginal gyrus. Some data also implicate the pars triangularis (in Broca’s area) as part of a network of brain areas supporting the transient store of phonological information.

Prosody

Prosody conveys suprarexical meaning, that is, meaning above the level of an individual word. Linguistically, prosody can cue whether a statement is a question or an assertion. It can also convey affective information such as the mood of the speaker, or the correct affective response to the message being communicated. Although the neural substrate of prosody appreciation has received little attention, a few studies report activation in the right inferior frontal gyrus in response to spoken language with affective prosody compared to neutral intonation.

Word Meaning

Spoken words

fMRI indicates that accessing the meaning of a spoken word activates the left inferior frontal gyrus, left posterior middle temporal cortex, posterior temporo-parietal cortex, and anterior inferior temporal cortex. Meta-analysis of multiple studies points to a number of brain areas specifically involved in accessing the meaning of spoken words, and distinct from cortical areas implicated in the processing of phonological properties. In the frontal lobe, semantic areas include the upper portion of the inferior frontal gyrus, the dorsal part of the pars opercularis, the ventral part of the pars triangularis, and down to pars orbitalis. In the temporal lobe, semantic areas included the middle and inferior temporal gyri, the temporal pole, and the angular gyrus. Regions of the posterior superior temporal sulcus (Wernicke’s area) and the middle temporal sulcus have been activated both by tasks manipulating demands on phonological processing and those manipulating semantic processing.

Written words

Reading words activates much the same brain areas as does hearing spoken words, including the left posterior middle temporal cortex, posterior temporo-parietal cortex, and anterior inferior temporal cortex. Moreover, visually presented words also activate the posterior fusiform and lingual gyri. Interestingly, activation of the latter two areas is also observed in picture-naming paradigms, suggesting their role in reading may be related to a more general function of connecting visual images to their associated meanings.

Real-time neuroimaging measures

Owing in part to the limited temporal resolution of functional neuroimaging based on hemodynamic measures (i.e., blood flow in PET and blood oxygenation levels in fMRI), the portrait of the brain regions involved in word comprehension is rather static. Reading a word, for example, involves cognitive steps, including visual encoding of the stimulus, potentially matching it to its phonological instantiation, and retrieving associated semantic information, all through a dynamic series of neural processes unfolding at the millisecond level. Although the image of multiple brain regions activated over the course of seconds is an inadequate picture of the underlying processing stream, information from functional neuroimaging can be supplemented with complementary data from methods, such as electroencephalography (EEG) and magnetoencephalography (MEG), with less accurate spatial resolution, but millisecond-level temporal resolution.

Event-related potentials (ERPs) derived from the EEG reveal a series of components sensitive to manipulations of the perceptual demands of word recognition (the P1, N1, and P2 components), the semantic demands of word recognition (the N400), and the demands on memory (the N400, whose amplitude is reduced by repetition) as well as the late positive complex (LPC), whose amplitude is typically enhanced by the recognition of a previously presented stimulus. Evoked magnetic fields (EMFs) derived from the MEG reveal a similar series of components, and the greater spatial resolution of the MEG affords more accurate localization of the neural sources of these components.

MEG studies of word comprehension suggest that words are processed through repeated activation cycles in an extended network of brain areas. When the stimulus is a spoken word, the initial activation is in bilateral superior temporal cortices; when it is a written word, the initial activation is in striate and extra-striate cortices. Activity then spreads anteriorly – along the ventral aspect of the inferior temporal cortex for visual stimuli, and along the middle temporal gyrus for auditory stimuli – involving the left superior temporal sulcus, left inferior prefrontal regions, and bilateral medial prefrontal areas for both written and spoken words. Visually presented words continue to elicit activity in inferotemporal and posteromedial areas not activated for spoken words; likewise, spoken words elicit sustained modality-specific activity in the perisylvian area.

Importantly, following the initial feed-forward sweep of activity along the visual and auditory ‘ventral’ streams, distributed source models show waves of activity spreading back and forth between activated temporal and frontal lobe areas. The computational role of cells in these areas likely changes as a function of time and the nature of the input (feedforward vs. feedback), making the attribution

of a single function to a particular cortical area difficult, and potentially misleading.

Understanding Sentences

Functional neuroimaging studies that have contrasted people’s comprehension of increasingly complex linguistic stimuli – for example, their comprehension of individual words versus the same words embedded in sentences – have revealed a concomitant increase in the volume of cortex activated by these stimuli, along with increasing activation of the right hemisphere. Presumably, the recruitment of additional brain areas reflects the added computational demands of understanding sentences. Besides activating the relevant meanings of individual words, understanding sentences involves combining those meanings using one’s knowledge of grammatical rules and regularities. The relationship between semantics and syntax is a matter of some debate in linguistics, with traditional accounts arguing for two qualitatively distinct and independent processing modules, and more recent accounts that suggest individual words and grammatical constructions both involve associations between form and meaning, but at varying levels of abstraction.

Investigation of the neural substrate of sentence comprehension has thus centered on the possible dissociation between the processing of meaning from that of grammar. Early support for the traditional view came from lesion studies, with the apparent dissociation between deficits in grammar in Broca’s aphasics from deficits in semantics in Wernicke’s aphasics. However, the importance of Wernicke’s area (and surrounding regions of the temporal lobes) for semantics has been upheld, whereas the importance of traditionally defined Broca’s area as a dedicated grammar module has not.

Other data argued to support the traditional distinction between meaning and grammar derives from the apparent dissociation of ERP responses to violations at the level of meaning (such as the N400 component) from violations at the level of grammar (such as the early left anterior negativity, or ELAN, the left anterior negativity, or LAN, and the P600). At present, the validity of these dissociations is questionable, owing to the presence of N400 modulation in response to grammatical violations, and the report of P600 modulations in response to particular sorts of semantic violations. While the difference between knowledge of meaning and knowledge of grammar is indisputable, current data leave open the issue of whether this difference is best construed as a difference in degree or a difference in kind.

Grammar

Manipulating the grammatical complexity of language stimuli modulates activity in classical Broca’s area, as well as the left posterior inferior frontal gyrus, and the

anterior aspect of the left superior temporal gyrus. In addition, some studies have implicated the basal ganglia and the insula. Moreover, while left hemisphere brain areas have shown greater sensitivity to manipulations of grammatical complexity, such manipulations also result in modulation of activity in the right hemisphere homologues of the regions mentioned above.

Meaning

Neuroimaging researchers have had difficulty in identifying brain regions as specifically sensitive to grammatical processing, as these manipulations invariably affect the difficulty of semantic processing, or the processing of meaning. Left frontal lobe areas implicated in the processing of grammatical regularities also seem to be activated in paradigms designed to manipulate semantic processing difficulty, and both sorts of activations may reflect the operation of working memory in sentence processing. One suggestion, however, is that a ventral region of inferior frontal cortex (pars orbitalis) underlies semantic judgments, while a dorsal region (pars opercularis) is related to judgments about grammaticality.

The influence of various cognitive and linguistic factors on deriving sentence meaning has perhaps been studied more fruitfully with scalp-recorded ERP measures such as the N400. First noted in experiments contrasting sentences that ended sensibly and predictably with others that ended with an incongruous word, the N400 has proven to be extremely sensitive to semantic context. For example, N400 amplitude shows a strong inverse correlation with the predictability of the eliciting word within a given sentence context. N400 amplitude also declines across the course of a congruent sentence, starting large and becoming smaller with each additional open-class word. Similar amplitude decreases do not occur for words in grammatical but meaningless word strings, suggesting N400 amplitude reflects the buildup of contextual constraints as a sentence proceeds.

Neural generators of the N400 sentence congruity effect likely include the majority of the left temporal lobe, with additional activity in the right anterior temporal lobe. The amplitude of this ERP component is greatly reduced in patients with lesions in the left temporal lobe or the temporoparietal junction, and slightly reduced in patients with lesions in the perisylvian region of the right hemisphere. Dipole modeling of the MEG counterpart, the N400m, consistently points to sources in the left superior and middle temporal gyri, and individually variable activity in homologous regions of the right hemisphere. Intracranial recordings in epileptic patients indicate the contribution of ventral temporal and medial temporal lobe areas to the scalp-recorded N400 effect. Neuroimaging studies manipulating sentence congruity also point to the importance of activation in the left inferior frontal lobe, although this activity may be more

closely related to a late positive-going effect in the ERP likely related to memory retrieval processes.

Understanding Text and Discourse

Just as neuroimaging studies have registered an increase in the extent of activation to sentences relative to words, the task of understanding sentences in the context of connected texts, such as narratives, or in discourse, also results in greater areas of activation than does the comprehension of individual sentences. This is because the comprehension of a text or a discourse goes beyond the individual meanings of its constitutive sentences. The connection between two successive utterances, for example, is often left implicit, thus requiring the reader to infer the ‘bridge’ between them. Understanding a particular sentence as being coherent with what has come before often involves the application of real-world background knowledge about the topic of discussion, as distinct from the particular meanings of the words employed. Similarly, comprehending remarks in discourse involves an understanding of the communicative situation, including the social relationships between the participants, as well as conversational norms known as ‘communicative maxims.’

The goal in text comprehension is typically the construction of a situation model, a cognitive model of the object, activity, or event described in the text. The construction of this model requires the integration of linguistic information provided in the text with background and local contextual information. Perhaps not surprisingly, neuroimaging studies of text and discourse comprehension implicate brain regions extending beyond those implicated in the comprehension of individual words and sentences. Text comprehension has been observed to activate the anterior temporal lobes bilaterally, extending into the temporal poles, the full extent of the left superior temporal sulcus, the inferior frontal gyri, and left hemisphere frontomedial and parietomedial regions.

In contrast to the patient literature linking right hemisphere damage to higher-level semantic and pragmatic processes, data from neuroimaging studies do not indicate a privileged role for the right hemisphere in text and discourse comprehension. The right hemisphere frontal activations have previously been observed for spoken materials independent of content and context, suggesting they relate to auditory processing of speech. The most consistent right hemisphere activation to date has been that of the anterior temporal lobe at coordinates very similar to those of its left hemisphere counterpart. The anterior temporal lobes have been suggested to play a role in autobiographical, emotional, and episodic memory, as well as category-specific retrieval processes, leading to the suggestion that their role in narrative text comprehension is related to their role in the encoding of episodic

memories. Further study is required to ascertain the functional significance of text-related activations.

In fact, the study of language and communication in naturalistic contexts as in text and discourse comprehension highlights their many different components. The above review highlights brain regions involved in the transformation of acoustic and visual information to meaning in comprehension, as well as the transformation of meaning to motoric output in production. However, besides the processes specific to language, text comprehension involves both long-term and working-memory processes, executive function and attention shifts, emotional processing, inferential reasoning, the attribution of human intentions, and presumably, many other processes as well. In many ways, then, we can consider the neural substrate of language to be the entire brain.

Glossary

Amygdala – A nuclear complex in the dorsomedial portion of the temporal lobe that forms part of the limbic system. The amygdala comprises several functionally and anatomically distinct nuclei: the central nucleus, the medial nucleus, the cortical portions, and the basolateral complex or basolateral amygdala (BLA; basal, lateral, and accessory basal nuclei). The amygdala has many connections to and from subcortical and cortical brain areas.

Basolateral amygdala (BLA) – The BLA comprises the basal, lateral, and accessory basal nuclei of the amygdala. Extensive evidence indicates that the BLA is the portion of the amygdala which is critical in mediating modulatory influences on memory consolidation.

Calcium-calmodulin-dependent protein kinase II (CaMKII) – A protein kinase activated by calcium. In neurons, CaMKII activation in response to increases in cellular calcium is a key biochemical event downstream of glutamate receptor activation associated with synaptic plasticity.

Caudate nucleus – A major component of the basal ganglia, together with the putamen and globus pallidus. The caudate nucleus has been shown to play a crucial role in formation of some types of memory, such as response memories.

Consolidation hypothesis – Originally proposed by Georg E Müller and Alfons Pilzecker in 1900, the consolidation hypothesis refers to the stabilization of a new memory over time by neural processes activated by recently learned information.

Corticosterone – The main glucocorticoid hormone in rodents. Glucocorticoids are secreted by the adrenal cortex and regulate several aspects of the brain function, including consolidation of emotional memory.

Cyclic adenosine monophosphate (cAMP) response element-binding protein (CREB) – A protein activated by cAMP that increases gene transcription by binding to specific regions of DNA. CREB has been shown to play a major role in stimulating gene transcription associated with synaptic plasticity and memory consolidation.

Declarative memory – Declarative or explicit memory is defined as the conscious memory for facts and events.

Entorhinal cortex (EC) – Cortical area located in the anterior part of the parahippocampal gyrus. The EC provides major inputs to both the hippocampus and the

amygdala and is importantly involved in memory consolidation. The EC is one of the first areas to be affected in patients with Alzheimer's disease.

Epinephrine – Usually referred to as adrenaline, epinephrine is a catecholamine hormone released by the adrenal medulla. Epinephrine modulates memory consolidation, probably by activating vagal afferents to the brain.

Extracellular signal-regulated protein kinase (ERK)

– ERKs are a subset of the mitogen-activated protein kinase (MAPK) family of protein kinases involved in intracellular signaling. ERK-mediated signaling downstream of receptor activation in neurons plays a major role in synaptic plasticity and memory formation.

Hebbian synapse – A concept describing memory formation at the synaptic level. In his book published in 1949, the psychologist DO Hebb proposed a hypothesis of memory based on the assumption that when two neural cells are activated simultaneously, structural or metabolic changes would increase the efficiency of communication between the cells. Such a mechanism would be the cellular basis for the consolidation and storage of long-term memory.

Hippocampus – The hippocampus is part of the limbic system, located in the medial temporal lobe. It plays an important role in the formation of new memories, particularly declarative memory involving spatial or contextual information.

Long-term potentiation (LTP) – It is a cellular phenomenon by which synapse efficiency is persistently increased. Described by Terje Lømo and Tim Bliss in 1973, LTP is operationally defined as a long-lasting increase in the amplitude of synaptic response following high-frequency stimulation of afferent fibers.

Considered by many as an example of Hebb's rule at work, LTP is the leading model for the synaptic changes that might be involved in underlying memory formation.

Magnetic resonance imaging (MRI) – An imaging technique that provides detailed images of portions of the body in any plane. MRI is especially useful for brain imaging because it provides high levels of contrast between different soft tissues. MRI is based on the use of a powerful magnetic field that aligns the nuclear magnetization of hydrogen atoms in the tissues.

Functional MRI (fMRI) is a specialized application of MRI used to measure changing neural activity in brain areas.

Mitogen-activated protein kinase (MAPK) – The MAPK family of protein kinases consists of serine-/threonine-specific protein kinases that mediate cellular responses to extracellular chemical messengers such as neurotransmitters and growth factors. MAPKs regulate a number of cellular functions, including gene expression, mitosis, cell proliferation, differentiation, and survival. In neurons, the MAPK signaling pathway has been shown to play a major role in synaptic plasticity and memory formation.

Norepinephrine – Norepinephrine or noradrenaline is a catecholamine that acts as a neurotransmitter in both the brain and peripheral nervous system upon release by noradrenergic neurons. Norepinephrine in brain areas, including the amygdala, has been shown to mediate modulatory influences on consolidation of emotional memory.

Nucleus accumbens (NAcc) – It is a brain structure that is part of the basal ganglia. The NAcc is connected to the BLA and plays a role in modulating memory consolidation.

Nucleus basalis magnocellularis (NBM) – It is a region of the rat brain that is homologous to Meynert's basal nucleus of primates. The NBM is located in the ventromedial region of the globus pallidus and contains mostly cholinergic neurons.

Nucleus of the solitary tract (NST) – The NST, located in the brainstem, is the site of the termination of afferent fibers running in the facial, glossopharyngeal, and vagus nerves. The NST receives projections from vagal afferents, and noradrenergic projections from the NST in turn influence other brain regions including the BLA, regulating memory consolidation.

Positron emission tomography (PET) – An imaging technique that produces a three-dimensional image of functional processes in body tissues. PET is based on the detection of gamma rays emitted indirectly by a radionuclide introduced into the body bound to a biologically active molecule (for instance, a glucose analog).

Procedural memory – Procedural memory, sometimes referred to as motor skill memory, is the long-term memory of skills and procedures. Unlike declarative memory, procedural memory seems not to depend on the functional integrity of the temporal lobe structures.

Protein kinase A (PKA) – PKA or cAMP-dependent protein kinase is a protein kinase activated by the second messenger cAMP. The cAMP/PKA pathway leads to stimulation of gene transcription and is considered one of the main cellular signaling mechanisms involved in mediating and regulating synaptic plasticity and memory formation.

Protein kinase C (PKC) – A family of protein kinases consisting of several isozymes activated through the

same signal transduction pathway as phospholipase C. Thus, the activation of most PKC isoforms depends on calcium and diacylglycerol. PKC activation downstream of glutamate receptor activation in neurons is associated with synaptic plasticity and memory formation.

Retrograde amnesia – Amnesia can be defined as an impairment of one or more aspects of memory function. Retrograde amnesia refers to the impairment in the ability to retrieve memories acquired prior to the trauma, lesion, or neuropathology that produced the impairment.

Stria terminalis (ST) – A brain structure that serves as a major output pathway of the amygdala. Lesions of the ST prevent the modulatory influence of the amygdala in other brain regions.

Early History: The Perseveration–Consolidation Hypothesis of Müller and Pilzecker

The concept of memory consolidation refers to the stabilization of a new memory over time by neural processes activated by recently learned information. The ‘perseveration–consolidation hypothesis’ was originally proposed by Georg E Müller and Alfons Pilzecker in 1900. In a series of studies with human subjects conducted between 1892 and 1900 at the University of Göttingen, Germany, Müller and Pilzecker showed that the retention of recently learned information was disrupted by the presentation of novel information shortly after the original learning. The consolidation hypothesis offered an explanation for Théodule Ribot’s observation (1890) that with brain injury or disease, more recent memories are lost, whereas remote memories are preserved.

Although the consolidation hypothesis provided a conceptual framework for explaining retrograde amnesia seen after head injury, as noted by William McDougall as early as 1901, about half a century passed before it became a major influence on experimental studies of learning and memory. In 1946, Russell and Nathan published a study summarizing a large number of cases of retrograde amnesia induced by head injury. The patients could not recall events occurring minutes, hours, or days prior to the injury. According to the consolidation hypothesis, recent memories are selectively lost after head injury because they were not consolidated prior to the injury, and were thus not stored.

In 1949, Donald O Hebb published his seminal book, *The Organization of Behaviour*, which provided a foundation for the contemporary concept of synaptic plasticity as

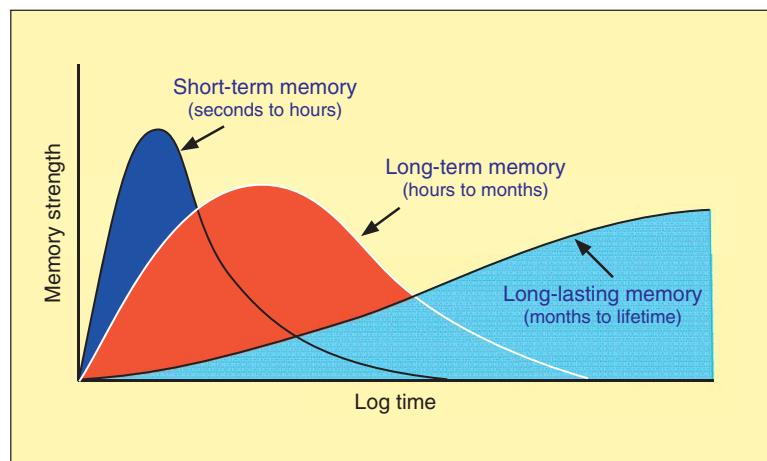

Figure 1 Stages of memory formation. Evidence indicates that short-term and different phases of long-term memory are processed as temporally independent parallel stages. Reproduced from McGaugh JL (2000) Memory: A century of consolidation. *Science* 287: 248–251.

the cellular basis of memory formation. Hebb's dual-trace hypothesis of memory proposed that an initial short-term trace based on neural reverberation induces neural alterations (based on the now famous 'Hebbian synapse', a concept which proposed a process of associative learning at the synaptic level), resulting in the storage of long-term memory. Although Hebb did not discuss the consolidation hypothesis or cite Müller and Pilzecker, his proposal that reverberating neural activity leads to the stabilization of neural circuits is clearly a more explicit version of the perseveration–consolidation hypothesis. The consolidation hypothesis as proposed by Müller and Pilzecker and modified by Hebb and others has, for over a century, guided neurobiological research on memory formation and is now supported by extensive evidence (Figure 1).

Experimental Manipulation of Memory Consolidation

The first evidence of experimentally induced retrograde amnesia was provided by the independent studies of both Duncan and Gerard in 1949, showing that the amount of memory impairment induced by electroconvulsive shock (ECS) after training varied inversely with the interval between training and ECS administration. In the 1960s, a number of findings were instrumental in increasing our understanding of the neural mechanisms involved in experimental retrograde amnesia. The demonstration that electrical stimulation of the amygdala after training induced retrograde memory loss stimulated the investigation of brain systems mediating consolidation. Studies showing that the administration of protein synthesis inhibitors after training blocks memory consolidation in animals provided a stepping stone for the investigation

of molecular mechanisms mediating memory formation. Importantly, the finding that protein synthesis inhibitors impaired long-term memory without blocking short-term memory provided strong support for the view that recent and remote memories are based on different neural processes. The application of protein synthesis inhibitors continues to this day as a widely used tool for the investigation of the molecular basis of memory, despite increasing evidence that protein synthesis inhibitors can induce nonspecific effects, such as stimulation of neurotransmitter release, which might confound the interpretation of the findings. Finally, the finding by McGaugh that memory retention in rats is enhanced by the posttraining administration of stimulant drugs showed that memory consolidation can be experimentally enhanced as well as impaired, strongly indicating that memory consolidation is sensitive to different types of posttraining manipulations. Together, these early studies provided the basic framework upon which subsequent experimental work on memory consolidation has relied up to the present day.

The introduction of posttraining manipulations contributed a powerful approach for the experimental investigation of memory consolidation. When an animal is given a treatment (e.g., a brain lesion or an injection of an inhibitory or stimulant drug) before being trained in a memory task, or prior to memory retention testing, any resulting alteration in behavioral performance might be due to the treatment's effects on sensory and motor functioning in place of or in addition to effects on learning and memory. Such treatments thus confound the interpretation of the findings, making it difficult to assess the treatment-induced influence on mechanisms mediating memory formation and expression. On the other hand, the use of posttraining injections of drugs that transiently

affect neurobiological substrates of memory consolidation without producing permanent damage or long-term functional impairment enables the investigation of memory consolidation without affecting behavior during either the training or retention testing.

Stages of Memory Consolidation

Most experimental research on memory consolidation has focused on a time window of several hours after learning. However, evidence that memory consolidation may continue for weeks, months, and perhaps even years in humans, suggests that there are different stages of memory consolidation. The early stage is very likely to be that suggested by Müller and Pilzecker, and Hebb. Evidence that different stages of consolidation rely on different cellular mechanisms and brain systems has been provided by human and animal studies showing that lesions of the hippocampus generally impair memory of recently learned information (i.e., within days or weeks prior to the lesion), whereas the ability to recall older memories is preserved. Thus, although the hippocampus and related structures are crucially involved in mediating the consolidation of several types of memory, other brain areas appear to play a more prominent role as loci of consolidation and storage at later stages.

The time-limited role of the hippocampus for the storage of some types of memory has led to the widely accepted view of systems consolidation, in which neural alterations associated with memory consolidation and storage occur first in the hippocampus followed by the gradual consolidation of a more distributed memory trace in neocortical areas. This view is supported by findings from animal studies where the effects of pharmacological manipulations of different brain areas on memory consolidation depend on the time interval between training and intervention. Thus, memory consolidation and storage would involve the sequential activity of the hippocampus followed by cortical areas such as the entorhinal and posterior parietal cortices. More recently, evidence suggesting that the memory-related engagement of cellular mechanisms involved in synaptic plasticity occurs in the hippocampus and cortical areas with a similar time course has indicated the need for a more complex model in which long-term consolidation in humans depends on a complex and integrated interplay between the hippocampus and cortical areas rather than on a simple sequential activation of brain structures.

Multiple Memory Systems

An important aspect of memory formation is the evidence that different types of memory are mediated by relatively

independent brain systems. Considerable evidence indicates that the early consolidation of cognitive or declarative memories relies mostly upon the medial temporal lobe (e.g., hippocampus), whereas the formation of procedural and habit memories depends on the basal ganglia (e.g., caudate putamen and striatum). Converging evidence from animal and human studies suggests that multiple memory systems can be activated simultaneously and in parallel by learning, and interact and compete with each other in influencing the behavioral responses after learning. For instance, a rat trained to find a reward (such as food) in the right arm of a maze might simultaneously learn two types of memory: where to go to find food (a memory based on spatial location) and what behavioral response to make (i.e., turn right to get into the arm where the food is). Experimental evidence using different amounts of training and functional inactivation of the hippocampus and caudate nucleus prior to testing indicates that formation of the place memory relies primarily on the hippocampus and the response memory involves the caudate nucleus. In addition, evidence indicates that both hippocampus- and basal-ganglia-based types of memory receive neuromodulatory influences from the amygdala.

Molecular Basis of Memory Consolidation

In addition to the investigations of the neural basis of memory consolidation at the systems level, extensive research has investigated the challenging issue of understanding the cellular modifications triggered by learning that enable the long-term storage of memories. Early researchers, including Ramon y Cajal and Hebb, have hypothesized that the storage of information relies on activity-dependent modifications of synaptic efficiency in neurons stimulated by learning. The concept of synaptic plasticity, that is, neural stimulation can induce changes in synaptic efficiency that permit the strengthening of associations between neurons, has become the guiding principle of research investigating the basic cellular mechanisms mediating memory consolidation.

The seminal demonstration by Bliss and Lomo in 1973 that high-frequency stimulation of the rabbit hippocampal perforant path produced a long-lasting increase in synaptic response (a phenomenon called long-term potentiation, LTP) provided the first consistent experimental evidence that a mechanism based on synaptic plasticity might be the key molecular process mediating memory formation. Subsequent work provided insight into the biochemical machinery underlying LTP. A major finding was that hippocampal LTP induction is blocked by the antagonism of the *N*-methyl-D-aspartate (NMDA) type of glutamate receptor channel. The observation by Morris and colleagues that NMDA receptor

blockade could also block spatial learning in rats marked the beginning of a long series of studies using pharmacological and genetic manipulations of specific brain areas, which together indicated that many of the basic molecular mechanisms underlying LTP induction and maintenance are also required for learning and memory consolidation. In addition to rodent models, the investigation of the molecular basis of memory has greatly benefited from work with other model organisms such as *Drosophila*, and notably the work of Eric Kandel with the sea snail *Aplysia*.

Currently, the most widely accepted view of the molecular basis of long-lasting declarative memory formation proposes that the synapses activated by learning in the hippocampus and other areas undergo long-lasting facilitation triggered by the activation of NMDA receptors and a vast repertoire of other neuronal receptors, such as α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) and metabotropic (mGluR) glutamate receptors, as well as protein kinase signaling pathways, leading to *de novo* protein synthesis, alterations in gene expression, structural reinforcement of activated synapses, and the growth of new synaptic connections. LTP, or a cellular process similar to LTP, appears to be involved in mediating at least some components of some types of memory. Extensive genetic and pharmacological evidence indicates that early molecular events downstream of excitatory receptor activation that are likely to mediate both synaptic plasticity and memory consolidation include activation of calcium-calmodulin-dependent protein kinase II (CaMKII), the phospholipase C (PLC)/protein kinase C (PKC), the cyclic adenosine monophosphate (cAMP)/protein kinase A (PKA), the mitogen-activated protein kinase (MAPK)/extracellular signal-regulated protein kinase (ERK), and the phosphatidylinositol 3-kinase (PI3K) signaling pathways. Late-phase LTP and memory consolidation depend on PKA-induced activation of the cAMP response element-binding protein (CREB) transcription factor, *de novo* protein synthesis, and expression of specific immediate-early genes, such as c-fos, Arc, and zif268, as well as the synthesis of neurotrophins such as brain-derived neurotrophic factor (BDNF). More recently, studies have focused on epigenetic mechanisms regulating gene expression, such as processes involving chromatin remodeling, histone modification, and DNA methylation, which have been shown to play an important role in the consolidation of long-term memory. This complex sequence of biochemical events is proposed to produce stable changes in synaptic strength. It is worth noting that the widely accepted view of long-term memory consolidation as an LTP-like cascade of biochemical events leading to increased efficacy of specific synapses has been challenged by several findings (e.g., those of the nonspecific and complex effects of protein synthesis inhibitors and lack of effect of NMDA receptor antagonists under various learning circumstances), as well as by other hypotheses such as

those based on posttranslational modification and impermanent redundant neural circuits.

Short- and Long-Term Memory

As noted above, at least two components of memory can be discerned based on both their duration and cellular processes: short-term memory, which endures for a few hours, and long-term memory, which can last for days and even years. Although the prevailing view for many years has been that the early and late stages of memory are serially linked, current evidence suggests that short- and long-term memory are based on parallel and independent processes (Figure 1). Studies of memory and synaptic plasticity in different species and experimental models (e.g., short- and long-term facilitation in *Aplysia*) indicate that treatments can block short-term plasticity without affecting long-term plasticity. In rats, the evidence that some drugs infused in brain areas, including the hippocampus and entorhinal cortex (EC), after training block short-term memory but not long-term memory is critical as it indicates that short- and long-term memory can be dissociated into independent processes.

Regulating Memory Strength: Endogenous Modulation of Consolidation

The findings that long-term memories consolidate slowly in humans as well as in a wide variety of animal species, and that memory formation can be enhanced by post-training administration of a number of chemical agents, raise the question of why our brains are designed in such a way as to enable facilitatory influences on memory formation by chemical mediators within a relatively wide time window after learning. Extensive evidence indicates that hormones normally released by novel, stressful, and arousing experiences (Figure 2), are among the chemical agents capable of influencing consolidation. These hormones include epinephrine, corticosterone adrenocorticotropic hormone, corticotrophin-releasing hormone, corticosterone, substance P, cholecystokinin, vasopressin, and β -endorphin. Such evidence strongly suggests that the slow memory consolidation process enables hormonal responses and other neuromodulatory systems activated by the learned experience to regulate the strength of memory formation and storage after learning. This mechanism of the endogenous modulation of consolidation may thus serve as an adaptive function by which emotionally arousing experiences (e.g., events perceived as potential danger and threats to one's survival) are generally better remembered.

Among endogenous hormonal systems modulating memory consolidation, stress hormones released by the

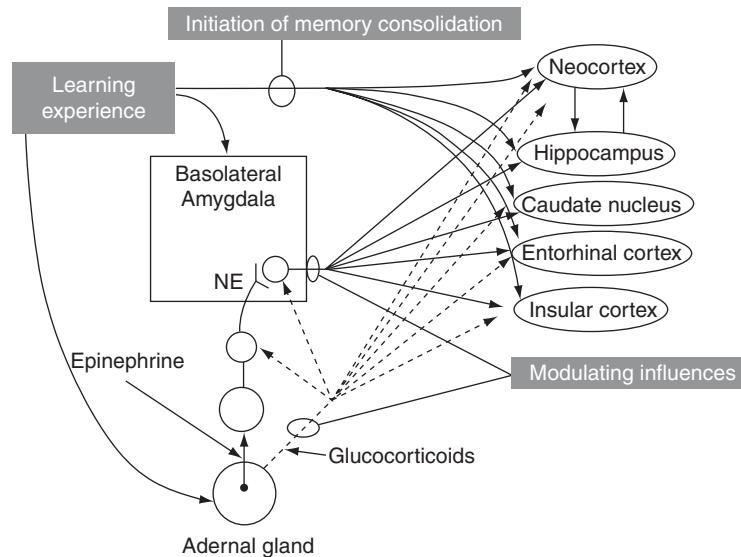

Figure 2 Neurobiological systems regulating memory consolidation. Shown in the figure is the release of peripheral stress hormones after learning activates the noradrenergic system in the basolateral amygdala, which in turn influences neural plasticity in other brain regions including the hippocampus, entorhinal cortex, insular cortex, and neocortical areas. Adapted from McGaugh JL (2000) Memory: A century of consolidation. *Science* 287: 248–251.

adrenal medulla (epinephrine) and adrenal cortex (corticosterone in the rat and cortisol in humans) have been studied most extensively. Both epinephrine and corticosterone produce dose- and time-dependent enhancement of memory consolidation. Epinephrine does not freely pass the blood-brain barrier and is likely to act on consolidation by activating peripheral β -adrenergic receptors on vagal afferents projecting to the nucleus of the solitary tract (NST) in the brainstem. Noradrenergic projections from the NST in turn influence other brain regions, including the basolateral nucleus of the amygdala (BLA; **Figure 2**). Glucocorticoids such as corticosterone readily enter the brain and activate neuronal glucocorticoid receptors.

Extensive evidence indicates that the activation of β -adrenergic receptors within the BLA is critical for mediating the modulatory influences of both epinephrine and glucocorticoids on consolidation. For instance, both lesions of the BLA and intra-BLA infusion of β -adrenergic receptor antagonists block the enhancing effect of posttraining systemic administration of the synthetic glucocorticoid dexamethasone on memory retention in rats. Conversely, infusions of β -adrenergic agonists into the BLA enhance memory consolidation. In addition, the findings that either footshock stimulation or administration of memory-enhancing drugs produces an increase in norepinephrine (NE) release in the BLA, whereas memory-impairing drugs decrease NE release, supports the view that activation of the noradrenergic system in the BLA is an endogenous system crucial in regulating memory consolidation.

In addition to preventing the effects of systemic injections of NE and glucocorticoids on consolidation, BLA lesions can block the effects of other drugs on consolidation, including memory-impairing drugs such as diazepam and the general anesthetic propofol. Also, in addition to β -adrenergic receptors, a variety of neuronal receptors and cell signaling pathways within the BLA are involved in mediating the modulatory influences of the BLA on consolidation. Thus, memory consolidation can be modulated by the pharmacological manipulation of neuronal receptors, including α -adrenergic, dopaminergic, serotonergic, opioid, cholinergic muscarinic, γ -aminobutyric acid (GABA)ergic, bombesin, and glutamate metabotropic and ionotropic receptors, as well as by agents acting directly on protein kinase signaling cascades downstream of receptor activation, such as the cAMP/PKA and MAPK/ERK pathways.

Although most of the research investigating the neural mechanisms involved in regulating consolidation has been carried out in animal models, human studies have supported the view that stress hormones and amygdala activation influence memory. In studies examining the effects of β -adrenergic receptor antagonists or a placebo on the memory of pictures accompanied by an emotionally arousing story, human subjects given a placebo showed better retention of the pictures presented during the most emotionally arousing part of the story, whereas the enhancing effect of emotional arousal was prevented in subjects given a β -adrenergic receptor antagonist. In addition, emotional arousal fails to enhance memory of the arousing material in human subjects with selective

lesions of the amygdala. Imaging studies using positron emission tomography (PET) and magnetic resonance imaging (MRI) scans have found that long-term memory retention of emotionally arousing stimuli is highly correlated with the degree of amygdala activation during learning.

Regarding the glucocorticoid modulation of memory consolidation in humans, most studies show impaired cognitive performance after glucocorticoid exposure. These findings are probably related to the pronounced impairing effects of glucocorticoids on memory retrieval (as opposed to their enhancing effect on consolidation), as well as to the long-term detrimental effects of glucocorticoids on hippocampal function. However, some studies have shown a memory-enhancing effect of glucocorticoids in human subjects. For instance, cortisol has been shown to enhance memory of emotionally arousing pictures in human subjects, and dexamethasone enhanced declarative memory in patients with major depression. The important regulatory action of glucocorticoids on memory consolidation and retrieval has led to the investigation of glucocorticoid receptor agonists and antagonists as potential therapeutic agents for the treatment of cognitive deficits associated with neuropsychiatric disorders as well as for the treatment of disorders associated with traumatic memories such as posttraumatic stress disorder (PTSD).

Interaction of Brain Systems in Modulating Memory Consolidation

The evidence reviewed above indicates that the BLA is a critical site in mediating and integrating neuromodulatory influences on memory consolidation. The BLA may be a locus for learning-induced synaptic plasticity leading to long-term storage of emotionally motivated memory within the BLA. However, extensive evidence indicates that the primary role of the BLA is to regulate memory storage in other brain areas activated by it after learning. The BLA projects to many brain regions, including the hippocampus, basal forebrain, nucleus accumbens (NAcc), striatum, and various cortical regions.

A major pathway connecting the BLA to other brain areas (including the NAcc and dorsal striatum) is the stria terminalis (ST), and the BLA-ST pathway provides a major efferent projection enabling BLA influences on memory consolidation in other brain regions. Lesions of the ST block the effect of electrical stimulation of the amygdala on memory for aversively motivated training without affecting acquisition. ST lesions also prevent the memory-enhancing effects of posttraining intra-amygdala infusions of NE; systemic injections of epinephrine and drugs affecting the glucocorticoid, opioid, and cholinergic systems; and infusions of the muscarinic cholinergic

agonist oxotremorine directly into the striatum. As found with ST lesions, NAcc lesions block the memory-enhancing effect of posttraining systemic administration of the synthetic glucocorticoid dexamethasone, suggesting that BLA projections to the NAcc via the ST are crucial for mediating BLA influences on memory consolidation. As the dorsal hippocampus has a high density of glucocorticoid receptors, the hippocampus is a likely locus of the glucocorticoid modulation of memory consolidation. In fact, BLA or NAcc lesions block the enhancing effect of infusion of a glucocorticoid receptor agonist directly into the hippocampus after training. As with lesions, the infusion of a β -adrenergic receptor antagonist into the BLA prevents the memory-enhancing effect of intra-hippocampal infusion of a glucocorticoid receptor agonist.

In addition, several electrophysiological studies indicate that the amygdala is crucial in modulating hippocampal LTP. For instance, either lesions or functional inactivation of the amygdala can block the impairing effects of stress on hippocampal LTP and spatial memory, and lesions of the BLA, but not central amygdala, attenuate LTP induction at perforant path-dentate gyrus synapses. Conversely, BLA stimulation facilitates dentate gyrus LTP. Both NE and corticosterone are involved in the influence of BLA activity on hippocampal LTP.

Several cortical areas are also major loci of memory consolidation. The rhinal cortices (perirhinal and ECs) constitute an interface between the hippocampus and the neocortex. Extensive evidence indicates that the EC plays a major role in memory consolidation in a way that involves interplay with the hippocampus and cortical areas such as the posterior parietal cortex. The EC receives direct projections from the BLA, and the firing of BLA neurons produces neuronal activation in the EC. The finding that excitotoxic lesions of the BLA prevent memory enhancement induced by posttraining infusions of the cAMP analog 8-Br-cAMP (an agent that stimulates the cAMP/PKA signaling pathway) into the EC indicates that the BLA is crucial in mediating the modulatory influences of the EC on consolidation. Importantly, a recent study has shown that BLA activity after associative learning increases transmission from perirhinal to entorhinal neurons and indicated that BLA-mediated facilitation of rhinal interactions may be a major mechanism for the formation of emotional memory.

Other cortical areas have been shown to depend on BLA activity to influence memory consolidation. Infusions of a β -adrenergic receptor antagonist into the BLA prevented the memory-enhancing effect of infusions of 8-Br-cAMP into the insular cortex, and BLA lesions blocked the enhancing effects of infusions of oxotremorine into the rostral anterior cingulate cortex. The nucleus basalis magnocellularis (NBM) provides cholinergic projections to the cortex. The finding that functional

inactivation of the NBM impairs aversive learning suggests that ACh-mediated activation of the cortex is crucial for emotional memory. The release of ACh in the auditory cortex is essential for the consolidation of plasticity-related changes in cortical function after Pavlovian conditioning. The BLA is a major source of afferents to the NBM, and evidence indicates that the BLA-ST pathway modulates cortical activity via projections to the NBM. Importantly, the enhancement of consolidation induced by infusions of NE into the BLA was prevented in rats with selective lesions of the NBM induced by the p57 nerve growth factor 192 IgC-saporin. These and other lines of evidence strongly suggest that BLA-cortical cholinergic projections mediated by the NBM are crucial in enabling the modulatory influence of the amygdala noradrenergic system on consolidation.

Together, the evidence reviewed above indicates that the BLA modulates memory consolidation by regulating neuronal activation and synaptic plasticity in brain areas involved in long-lasting consolidation and storage, such as the hippocampus and several cortical areas (**Figure 2**).

Consolidation and Reconsolidation

The traditional consolidation theory has been challenged in recent years by evidence that reactivation of a previously consolidated memory during retrieval might again render this memory susceptible to disruption by amnesic treatments, a process generally referred to as reconsolidation. Although the concept of memory reconsolidation was initially proposed in the 1960s, it was only in 2000 that a new wave of studies showing that administration of drugs to animals after retrieval could impair memory assessed at subsequent retention tests sparked considerable interest in reconsolidation. Although reconsolidation has been defined by experiments using intracerebral infusions of protein synthesis inhibitors, several studies have extended the candidate mechanisms involved in reconsolidation-like processes to a number of neuronal receptors and signal transduction pathways. Thus, experiments using systemic or intra-cerebral injections in rodents have shown that memory for emotionally motivated tasks can be impaired by postretrieval administration of a variety of pharmacological agents, including benzodiazepines, antagonists of glutamatergic, noradrenergic, and glucocorticoid receptors, and inhibitors of protein kinases such as PKA and ERK/MAPK. These studies argue in favor of the so-called ‘reconsolidation hypothesis’ based on findings of amnesia produced by postretrieval interventions. As with consolidation and extinction, brain areas mediating the effects of postretrieval amnesic treatments include the dorsal hippocampus and basolateral amygdala.

Other studies, however, have provided evidence against reconsolidation, showing negative results (i.e., lack of the effect of postretrieval treatments) or opposite effects related to memory extinction. Another major caveat for the reconsolidation hypothesis is that many of the findings interpreted as possible reconsolidation impairments have been shown to be transient or reversible. The recovery of the deficits induced by postretrieval interventions can be either spontaneous or triggered by reminders. This has led to the interpretation of many findings as temporary retrieval deficits rather than reconsolidation blockades. Other studies, however, have provided evidence for reconsolidation by showing long-lasting memory impairment after postretrieval administration of amnesic treatments, with no detectable recovery. Evidence has been also provided suggesting that, as with consolidation, memories can undergo reconsolidation at both the cellular and systems level.

Taken together, the evidence suggests that the occurrence of reconsolidation-like processes in animals in an experimental setting depends on several factors including duration of exposure to the original context, absence of significant extinction, time interval between learning and retrieval, and encoding of new information at the time of retrieval. At this point, it seems clear that under specific conditions, either temporary or long-lasting labialization of recently learned memory traces can occur. It may be possible to reconcile the apparent discrepant findings regarding the reconsolidation phenomenon by viewing consolidation and reconsolidation as different but integrated components of the long-term processes underlying memory storage.

Mirror Neuron Mechanism

G Rizzolatti, Università di Parma, Parma, Italy

Glossary

Mirror neurons – A distinct class of neurons found in the premotor cortex and inferior parietal lobule of a monkey. These neurons are discharged when the monkey executes a given motor act or observes the same motor act performed by another individual.

Motor act – Unlike the term movement that describes a displacement of body parts, motor act indicates movement with a goal.

Motor cortex – Defined as that part of the frontal lobe that lacks the layer containing granular cells. Its electrical stimulation, at low threshold, elicits discrete movements of contralateral body parts.

Voluntary movement – Manifestations of a centrally generated intention to act. The way in which intention is generated is irrelevant for the notion of voluntary movement. It may result from bodily needs such as hunger or thirst, or from higher-order deliberations based on one's own beliefs and desires. What counts for voluntary movements is that the individual has a goal and that this goal determines movements leading to its achievement. Unlike for reflexes, in voluntary behavior stimuli do not determine a motor response, they only set the occasion for it. According to their needs, animals may or may not respond to the same stimulus.

mirror mechanism has been demonstrated in humans using noninvasive techniques. Here we discuss the main functions in which mirror mechanism is involved.

Action and Intention Understanding

When we see a person acting upon an object, we are able, typically, to extract two main information: what this person is doing and why. If, for example, Mary' hand enters in contact with a cup of coffee, John immediately knows whether she is grasping it or not, and, according to how she grasped it, he can also understand why she is doing it (e.g., for drinking coffee). How can John understand the goal of the motor act and the intention behind it? A possibility is that he is using an inferential reasoning elaborating, through some cognitive mechanism, the acquired visual information. The alternative possibility is that, in most cases of everyday life, this is not necessary and these cognitive operations are performed by a specific mechanism that directly transforms visual information into a motor format. The discovery of mirror neurons supports the existence of this second mechanism.

The Mirror Mechanism: Monkey Data

Figure 1 shows a lateral view of the monkey motor cortex. The areas where mirror neurons are located are areas PFG, AIP, and F5. This figure (upper part) illustrates as well the defining characteristic of these neurons. They discharge both when the monkey performs a motor act and when it observes another individual (a human being or another monkey) doing a similar motor act. The degree of similarity between the effective executed and observed motor acts varies from one neuron to another. In general, however, the identity of goals is sufficient. Mirror neurons do not discharge in response to the presentation of food or other interesting objects.

Convincing demonstration that mirror neurons play a role in the capacity to understand other's motor act is based on experiments in which monkeys could not see what an agent was doing, but had clues to understand it. In one of these experiments, the monkey heard the sounds of a motor act (such as ripping a piece of paper) without seeing it; in another series, the monkeys knew that behind

Introduction

One of the most exciting events in neurosciences over the past years has been the discovery of a mechanism that directly ties action and action perception. This mechanism – the mirror mechanism – is of great interest because it enables to give a neurophysiological explanation to a large number of cognitive abilities ranging from action to intention understanding, and from imitation to some aspects of social cognition.

The mirror mechanism has been originally found in monkeys by using single-neuron recordings. These studies showed that there are neurons (i.e., mirror neurons), in the premotor cortex and in the inferior parietal lobule, that discharge both when the monkey executes a specific motor act (e.g., grasping) and when it observes another individual doing a similar motor act. Subsequently, the

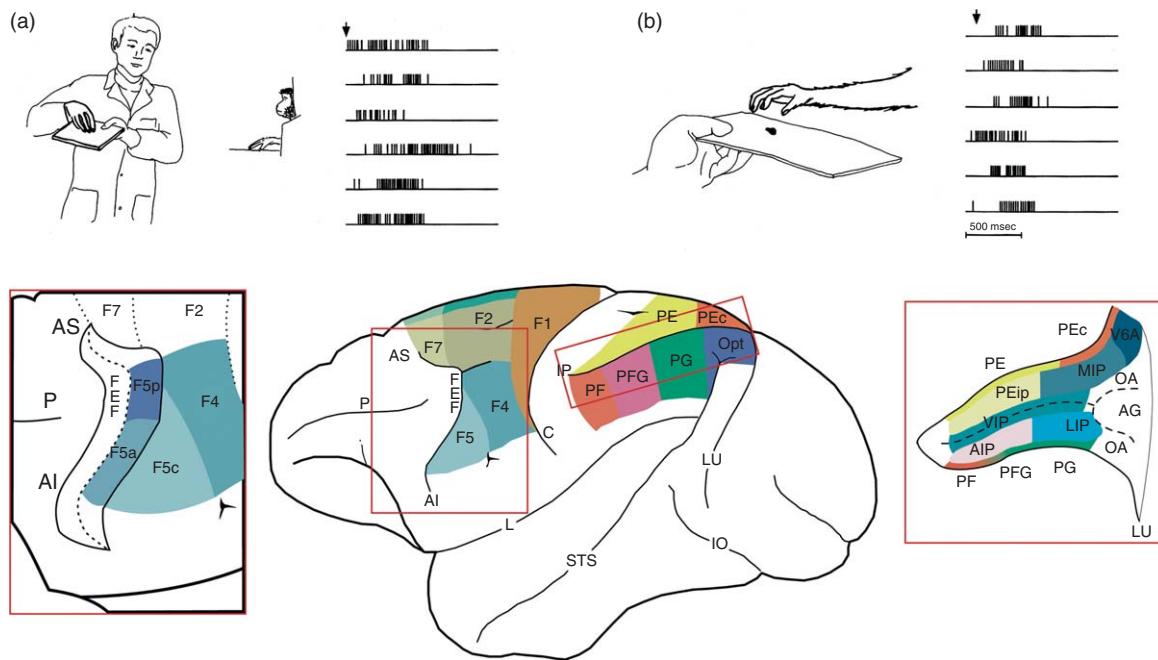

Figure 1 Example of a mirror neuron and anatomy of agranular frontal and posterior parietal cortex of the macaque monkey. Upper part: F5 mirror neuron. The neuron discharges when the monkey grasps an object (a) and when it observes another individual grasping it (b). Lower part: The central part of the figure shows the cytoarchitectonic parcellation of the agranular frontal cortex (areas indicated with F and Arabic numbers) and of the parietal lobe (areas indicated with P and progressive letters). The enlargement of the frontal region (rectangle on the left) shows the parcellation of area F5. The rectangle on the right shows the areas buried within the intraparietal sulcus. AI, inferior arcuate sulcus; AIP, anterior intraparietal area; AS, superior arcuate sulcus; C, central sulcus; CA, calcarine fissure; CG, cingulate cortex; FEF, frontal eye field; IP, intraparietal sulcus; L, lateral sulcus; LIP, lateral intraparietal area; LU, lunate sulcus; MIP, medial intraparietal area; POs, parieto-occipital sulcus; P, principal sulcus; STS, superior temporal sulcus.

a screen there was an object, but could see the hand/object interaction that represents the typical trigger feature for most mirror neurons. The monkey saw the hand of the experimenter disappearing behind the screen and could only image mentally the action goal. The results showed that in both conditions the mirror neurons fired providing that the set of external contingencies allowed the monkey to understand the action done by another individual. In other words, what counted was the meaning of the motor act seen, heard, or even imagined.

Some recent experiments on parietal cortex revealed a new aspect of mirror neuron functions. Single neurons were recorded from ventral intraparietal area (VIP) and from area PFG. Peripersonal neurons were selected. These neurons respond to tactile stimuli on specific monkey body part and to visual stimuli moved near the tactile receptive fields (peripersonal space). There were no visual responses to stimuli presented far from the monkey. However, when the experimenter stood in front of the monkey, neurons began to respond to visual stimuli presented in the experimenter's peripersonal space in a spatial position congruent to that of the monkey's visual field (**Figure 2**). These results indicate that, besides the action of others, mirror neurons also provide information on peripersonal space and body of others.

Originally, mirror neuron responses were described as essentially independent of the distance between the monkey and the location of the motor act. The distance issue has been recently reexamined more formally in a larger sample of neurons. The results showed that 50% of mirror neurons responded with the strength regardless of the position of the stimulus. For the remaining 50% of neurons, half of them were selective for stimuli presented within the monkey's peripersonal space, while the other half discharged only for stimuli presented far from the monkey. These findings show that mirror neurons are not only important for understanding what the others are doing, but also prime the motor behavior most adequate for stimulus location.

The Mirror Mechanism in Humans

The mirror mechanism is present in humans as well. Majority of the brain imaging studies showed that, in healthy volunteers, observation of other's actions determines the activation of the ventral premotor cortex, the posterior part of the inferior frontal gyrus (a sector of Broca's area), besides the visual areas, and of the inferior parietal lobule that is of the same cortical regions where mirror neurons are located in the monkey. Further fMRI experiments showed

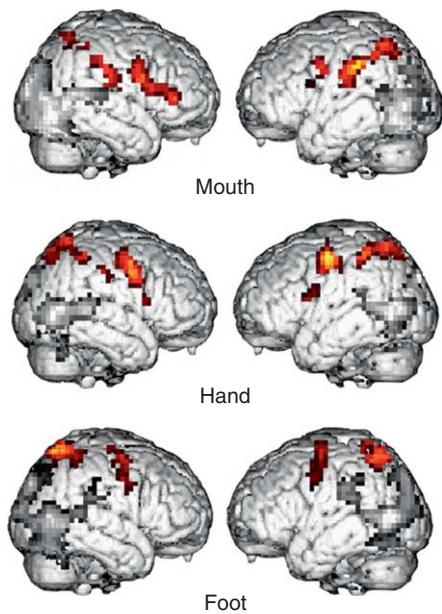

Figure 2 Somatotopy of premotor and parietal cortices as revealed by action observation. Upper panel: Cortical areas activated during the observation of object-related mouth actions (biting an apple). Middle panel: Cortical areas activated during the observation of object-related hand actions (grasping a cup or a ball). Lower panel: Cortical areas activated during the observation of object-related foot actions (kicking a ball or pushing a brake). Projections of the activations foci on the lateral surface of a standard brain (Montreal Neurological Institute (MNI)). Reproduced with permission from Buccino G, Fink GR, et al. (2001) Action observation activates premotor and parietal areas in a somatotopic manner: An fMRI study. European Journal of Neuroscience 13: 400–404.

that the mirror network is somatotopically organized. The somatotopic organization is present both in the premotor cortex and in the parietal lobe (**Figure 3**).

Evidence proving the existence of the mirror mechanism in humans comes from transcranial magnetic stimulation studies. Observation of other's actions increases the excitability of the motor cortex of the observer. Most interestingly, the facilitation concerns exactly those muscles involved in movement execution. Finally, magnetoencephalography (MEG) and electroencephalography (EEG) studies showed that mere observation of others' actions determines the desynchronization of cortical motor rhythms, similar, although of less intensity of that observed during active movement.

In recent years, a possibility was raised that the activation of the motor areas during action observation and action execution could result not from the activations of mirror neurons, but from the activation of two different neural populations located in the same areas: one active during action observation, the other during action execution. Recently, a functional magnetic resonance imaging (fMRI) study tested this hypothesis using the adaptation technique. The results showed that the responses in the right inferior parietal lobe (IPL) were attenuated when

the participants observed a recently executed action relative to one that had not been previously performed. This adaptation across action and perception convincingly demonstrates that the IPL responds selectively to the motor and perceptual representations of actions.

Intention Understanding in Monkey

The problem of intentionality has been traditionally considered a philosophical problem. However, recent neurophysiological experiments appear to provide a neural basis for motor intention. This is true both for the intention of the person who is acting and for understanding the intentions of others.

To approach the problem of the neural substrate of intention, it was investigated whether the discharge of neurons coding motor acts of a given action reflect the intention of that action. Monkeys were trained to grasp objects for two different goals: to place them into a container or to bring them to their mouth. The initial motor acts, reaching and grasping, were identical in the two conditions, whereas the goals of the two actions were different. After training, grasping neurons were recorded from IPL and their discharge studied in the two conditions mentioned above. The results showed that the majority of IPL grasping neurons discharged with a different intensity according to the final goal of the action in which grasping was embedded (action-constrained neurons). Grasping in order to bring food to the mouth was the most represented motor act. Examples of action-constrained grasping are shown in **Figure 4**.

A very interesting finding of these studies was that many action-constrained neurons have mirror properties as well, discharging in response to the observation of motor acts done by others. To find out whether the visual responses of these neurons were influenced by the actions in which the motor acts were embedded, action-constrained mirror neurons were tested in the same two conditions used for studying their motor properties. Monkeys, instead of grasping objects, observed the experimenter performing the two actions. The results showed that the majority of IPL mirror neurons were differently activated when the observed motor act belonged to one action or another. Examples are shown in **Figure 4**.

What could explain this behavior? If one examines the motor behavior of action-constrained grasping neurons, it is frequently found that the neuron's discharge continues if grasping is performed within the appropriate action, while it stops abruptly in the inappropriate action. This prolonged discharge suggests activation of neurons coding the next step of the executed action. In agreement with this interpretation are data on the receptive field properties of parietal neurons showing that motor acts performed actively, or even passive movements, activate neurons that code the next motor act in

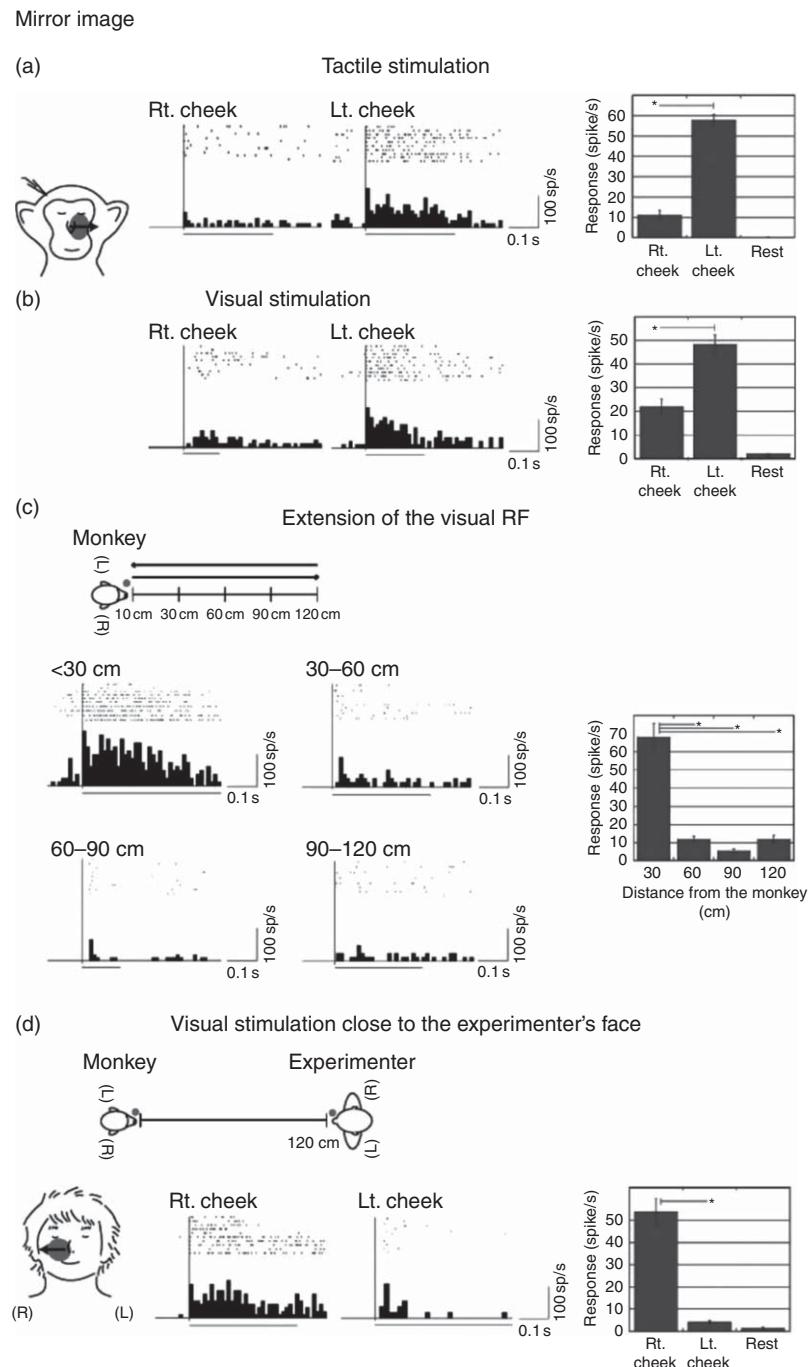

Figure 3 Example of a mirror peripersonal matching neuron. (a) and (b) Responses to tactile and visual stimulation. Receptive field (RF) on the left cheek; visual RF located close to the same part of the face. Rasters and responses histograms of neuron activity are aligned on stimulus movement onset (long vertical line). (c) Visual response in the peripersonal space in the monkey. Note that the responses are present only when the stimulus is near the left cheek (<30 cm). (d) Visual responses evoked by moving stimuli close to the experimenter's right cheek. Reproduced with permission from Ishida H, Nakajima K, Inase M, and Murata A (2009) Shared mapping of own and other's bodies in visuo-tactile bimodal area of the monkey parietal cortex. Journal of Cognitive Neuroscience (doi:10.1162/jocn.2009.21185).

an action sequence. Thus, it is very likely that when an action-constrained grasping neuron is activated by the observation of a grasping motor act, it triggers the whole motor chain in the observer, who, in this way, has an internal representation of the action that the agent intends to do. Thanks to this mechanism, the observer may understand the agent's intention.

Intention Understanding in Humans

In humans as well, there is evidence from an fMRI study that the mirror mechanism is involved in understanding the intention behind the observed motor acts. This study had three conditions. In the first condition

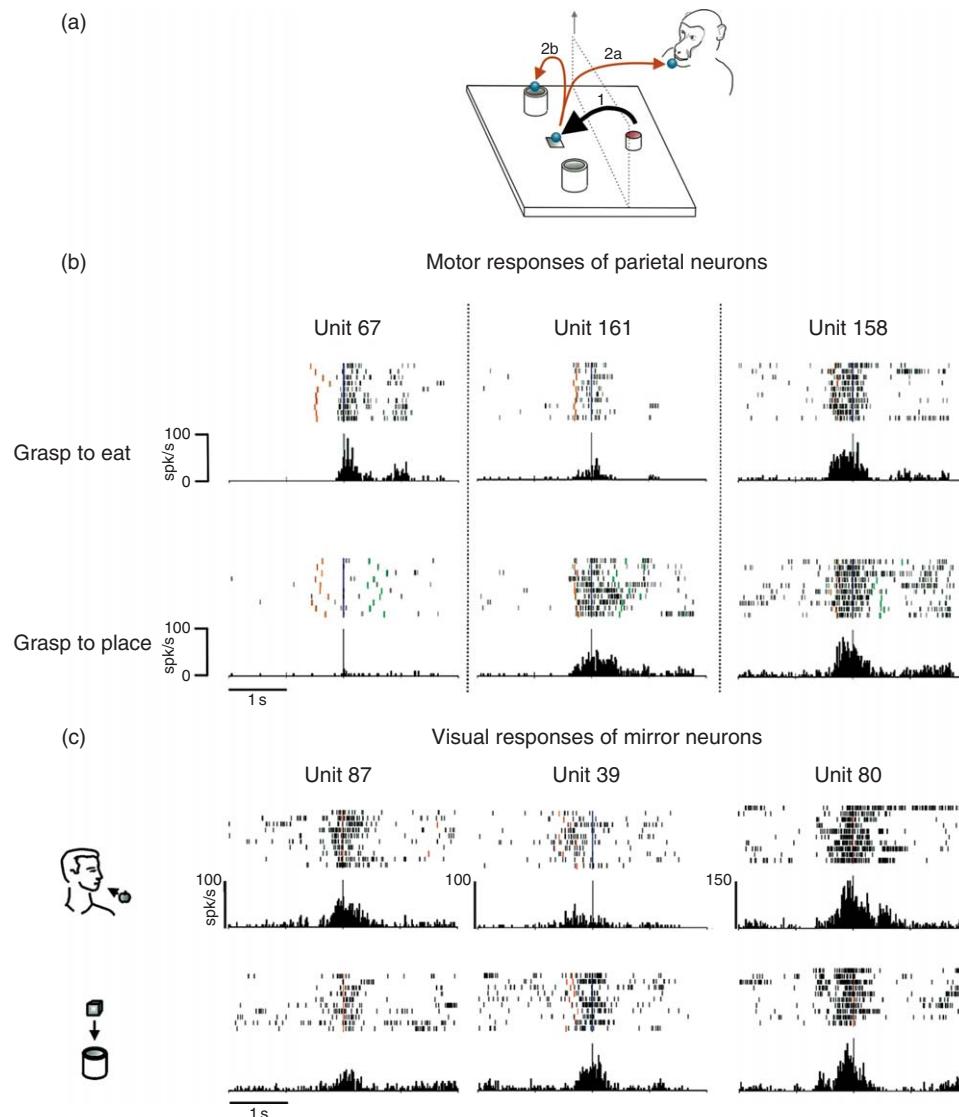

Figure 4 Motor and visual responses of mirror neurons in IPL. (a) The apparatus and the paradigm used for the motor task. (b) Motor responses of three IPL neurons during grasping in conditions grasp to eat and grasp to place. Rasters and histograms are synchronized with the moment when the monkey touched the object to be grasped. Red bars, monkey releases the hand from the starting position; green bars, monkey touches the container; x axis, time, bin 0 20 ms; y axis, discharge frequency. (c) Visual responses of three IPL mirror neurons during the observation of grasping to eat and grasping to place done by an experimenter. Conventions as in the motor task. Reproduced with permission from Fogassi L, Ferrari PF, Gesierich B, Rozzi S, Chersi F, and Rizzolatti G (2005) Parietal lobe: From action organization to intention understanding. *Science* 308: 662–667.

(context), the volunteers saw some objects (e.g., a teapot, a mug, and a plate with some food on it) arranged as if a person was ready to drink the tea or the same objects arranged as if a person had just finished having his/her breakfast; in the second condition (action), the volunteers were shown a hand that grasped a mug without any context; in the third condition (intention), the volunteers saw the same hand action within the two contexts. The context suggested the intention of the agent, that is, grasping the cup for drinking or grasping it for cleaning the table.

The results showed that in both action and intention conditions there was an activation of the areas endowed with a mirror mechanism. Crucial was the comparison between intention and action conditions. This comparison showed that the understanding of the intention of the doer determined a marked increase in activity of the right frontal node of the mirror network.

These data clearly show that the mirror neuron mechanism play an important role in intention understanding. This does not imply, of course, that other more cognitive ways of reading minds do not exist.

Indeed, recent fMRI studies showed that, in some specific conditions, the understanding of motor acts by others require, besides the mirror mechanism, the activation of areas outside the mirror network. For example, when tasks require a top-down inference either to assess the meaning of a motor act in an implausible context or to judge whether the intention of the observed action was ordinary or unusual, there is an increase of activity in the posterior superior temporal sulcus (STS) region, posterior cingulate cortex, and the medial prefrontal cortex.

Imitation

The data reviewed so far show that mirror system is involved in action and intention understanding. From the very beginning of mirror neuron studies it was clear, however, that, in humans, the motor system, unlike in monkeys, also resonates in response to the observation of intransitive movements, including those without any obvious meaning. What could be the reason of this resonance?

The most likely interpretation relates to the capacity of humans, unlike monkeys, to imitate the actions done by others. Note that the term imitation has several meanings. There are, however, two main senses in which it is most commonly used. One defines imitation as the capacity of an individual to replicate an observed motor act; the other defines imitation as the capacity to acquire, by observation, a new motor behavior and to repeat it using the same movements employed by the agent. In both cases, imitation requires the capacity to transform sensory information into a motor activation.

Evidence that the mirror mechanism is involved in imitation as an immediate replica of the observed motor act was demonstrated by an fMRI study. In this study, volunteers were tested in two main conditions: observation and observation-execution. In the observation condition, participants were shown a moving finger, a cross on a stationary finger, or a cross on empty background. The instruction was to observe the stimuli. In the observation-execution condition, the same stimuli were presented, but, this time, the instruction was to lift the right finger, as fast as possible, in response to them. The crucial contrast was between the trials in which the volunteers made the movement in response to an observed action (imitation) and the trials in which the movement was triggered by the cross (a nonimitative behavior). The results showed that the activation of the mirror system and, in particular, of the posterior part of inferior frontal gyrus (IFG) was stronger during imitation.

Further evidence that the mirror system plays a fundamental role in this type of imitation was provided by repetitive TMS (rTMS), a technique that provokes a transient depression of the stimulated region. In a group

of volunteers, the caudal part of the left frontal gyrus (Broca's area) was stimulated while they (1) pressed keys on a keyboard, (2) pressed the keys in response to a point of red light indicating which key to press, or (3) imitated a key pressing movement done by another individual. The data showed that rTMS lowered the participants' performance during imitation, but not during the other two tasks.

More complex is the mechanism involved in imitations learning. In this case, imitation appears to result from the interaction of two distinct processes: (1) segmentations of the action to be imitated into its individual elements, and their transformation into the corresponding potential movements of the observer; and (2) organization of these potential movements into a temporal and spatial pattern that replicates that shown by the demonstrator. There is evidence that the first step is achieved through the mirror mechanism, while the second step is mostly due to the activity of the prefrontal lobe and, in particular, of area 46 that memorizes and recombines the motor elements in the new pattern.

Empathy

So far we discussed the mirror mechanism underlying the understanding of cold actions, that is, of actions devoid of clear emotion content. Does the mirror mechanism also mediate the understanding of emotions of others?

Before answering this question, it is important to remind that emotions are mental states accompanied by motor and vegetative reactions. Furthermore, electrical stimulation of emotional centers (e.g., anterior insula) elicits viscero-motor responses in both monkeys and in humans. This finding indicates that the emotional structures, and the anterior insula in particular, are endowed with a motor machinery similar to that of the cortical centers controlling the cold actions but, with in addition, a control on vegetative responses.

Do these emotional centers respond, besides their specific (e.g., pain) stimuli, to the observation of the emotions in others? A series of studies showed that this is the case. The strongest evidence in favor of it came from brain imaging studies of two basic emotions: disgust and pain.

Studies of disgust showed that when an individual is exposed to an unpleasant odor, there is an intense activation of the amygdala, the insula, and the anterior cingulate. Prompted by these data, an fMRI study was carried out that investigated whether the insula sites that show activation during the experience of disgust also show activation during the observation of faces expressing disgust. The study consisted of two sessions. In the first, the participants were exposed to unpleasant and pleasant odorants; in the second, they watched a video showing the

face expression of people sniffing an unpleasant, a pleasant, or a neutral odor. In accord with previous data, three main structures became active during the exposure to smells: the amygdala, the insula, and the anterior cingulate. The most interesting result of the study was that the same foci within the insula and the anterior cingulate that were activated by the exposure to disgusting odorants were also activated by the observation of disgust. This indicates that the same viscero-motor structures that control emotions are also activated by the vision of that emotion. "Your disgust becomes my disgust."

In addition to disgust, activations in the insula and in the anterior cingulate cortex were also observed in studies in which emotional reactions to pain were investigated using an event-related fMRI paradigm. In this study there were two conditions. In one the participants were subjected to a mildly painful electric shock from electrodes placed on their hand, in the second they were asked to watch the same electrodes positioned to the hand of a loved one. They were told that the loved person would receive the same shock to which they had been subjected earlier. The results showed that the same sites of the insula and of the cingulate cortex became active in both conditions. This result shows that both direct pain experience and its evocation are mediated by a mirroring similar to that found for disgust.

One should stress, however, that the notion that the activation of viscero-motor structures provides the basis for the recognition of emotion, does not exclude that emotions may also be recognized indirectly, using cognition. Some particular visual features representing the basic features of an emotion, like in emoticon, allows emotion recognition. This emotion recognition is, however, different from that mediated by the insula and the anterior cingulate, because only the latter creates a shared feeling between the observer and the person actually feeling the emotion.

Language

Although there is strong disagreement on the evolutionary roots of human speech, nobody denies that speech is something more than a mere collection of curious sounds. This point was clearly demonstrated by Alvin Liberman who showed that an efficient communication system could not be built by simply using tone combinations. According to him, the unique communicative property of speech derives from the capacity of speech sounds to elicit a motor representation of the heard sounds in the listener. There is evidence that this capacity has a precise neural correlate.

In a TMS experiment, the left hemisphere speech motor centers were stimulated and motor evoked potentials (MEPs) were recorded from the tongue muscles in volunteers instructed to listen carefully to acoustically presented verbal and nonverbal material. The stimuli were words and bitonal sounds. In the middle of words,

there was either a double 'f' or a double 'r.' 'F' is a consonant that, when pronounced, requires virtually no tongue movements, whereas 'r' is a consonant that, in contrast, requires, marked tongue muscle involvement to be pronounced. The results showed that listening to words containing the double 'r' produced a significant increase of MEPs amplitude recorded from tongue muscles compared with listening to bitonal sounds and words containing the double 'f' (**Figure 5**).

Similar results were obtained using TMS technique and recording MEPs from a lip muscle and a hand muscle in four conditions: listening to continuous prose, viewing speech-related lip movements, listening to nonverbal sounds, and viewing eye and brow movements. Compared to viewing eye and brow movements, listening to and viewing speech enhanced the amplitude of MEPs recorded from the lip muscles. All of these effects were seen only in response to stimulation of the left hemisphere.

These and other similar data indicate that in humans, in addition to the mirror mechanism transforming observed movements into potential movements, there is a further system transforming heard phonemes in the corresponding motor representation of the same sound. There is little doubt that this system could play an important role in language learning. It is matter of debate, however, whether, and at what extent, it intervenes in the comprehension of word meaning.

Autism

The distinction between a direct mirror-mediated comprehension of others and a comprehension mediated by inferential reasoning appears a fundamental distinction for understanding not only the behavior of people in general but also that of individuals with atypical behaviors as children with autism.

Autistic spectrum disorder is a heterogeneous syndrome characterized by a marked impairment in social interaction and communication. Restricted repertoire of activity and interests, repetitive motion, and hypersensitivity to certain sounds are other symptoms that often accompany the other deficits. It has been noted that some of the functions impaired in autism are those mediated by the mirror mechanism (intention and emotion understanding, language). The hypothesis has been therefore advanced that the inability of patient with autism to relate to others in an ordinary way depends on an impairment of the mirror system.

First evidence in favor of this hypothesis came from EEG studies. It is well known that EEG rhythms recorded from the motor cortical areas are blocked any time a person makes a voluntary movement. These rhythms are also suppressed when a person observes another person performing a movement. This phenomenon has been

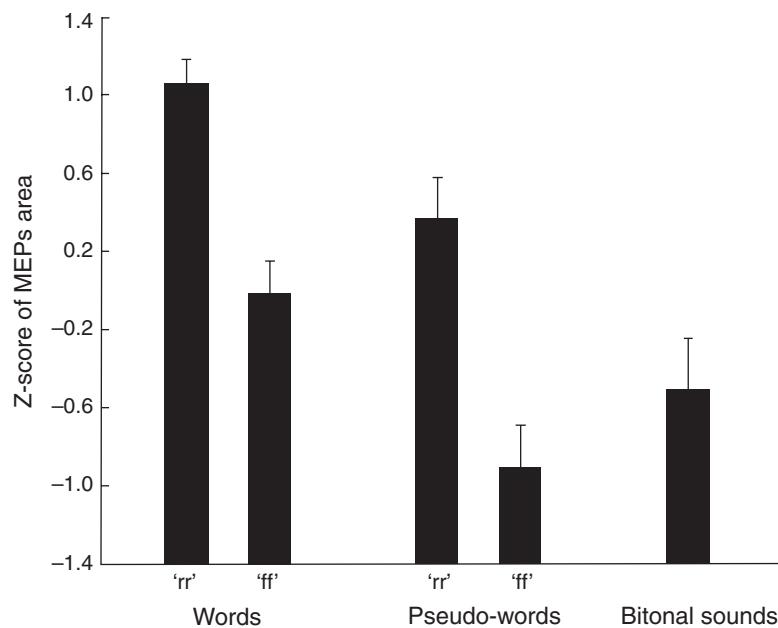

Figure 5 Speech listening modulates the activity in primary motor cortex. Average value of intrasubjects normalized MEPs total areas for words, pseudo-words and bitonal sounds. Data from all subjects; 'rr' and 'ff' refer to verbal stimuli containing a double lingua-palatal fricative consonant 'r,' and containing a double labio-dental fricative consonant 'f,' respectively. Reproduced with permission from Fadiga L, Craighero L, Buccino G, Rizzolatti G (2002) Speech listening specifically modulates the excitability of tongue muscles: a TMS study. European Journal of Neuroscience 15: 339–402.

used to test the functioning of the mirror mechanism in typically developed individuals and in autism. The results showed that individuals with autism present a suppression of motor cortical rhythms during voluntary movements,

but this suppression is lacking when they watch someone else performing the movement (**Figure 6**).

Strong evidence in favor of a deficit of the mirror mechanism came from an fMRI study. High-functioning

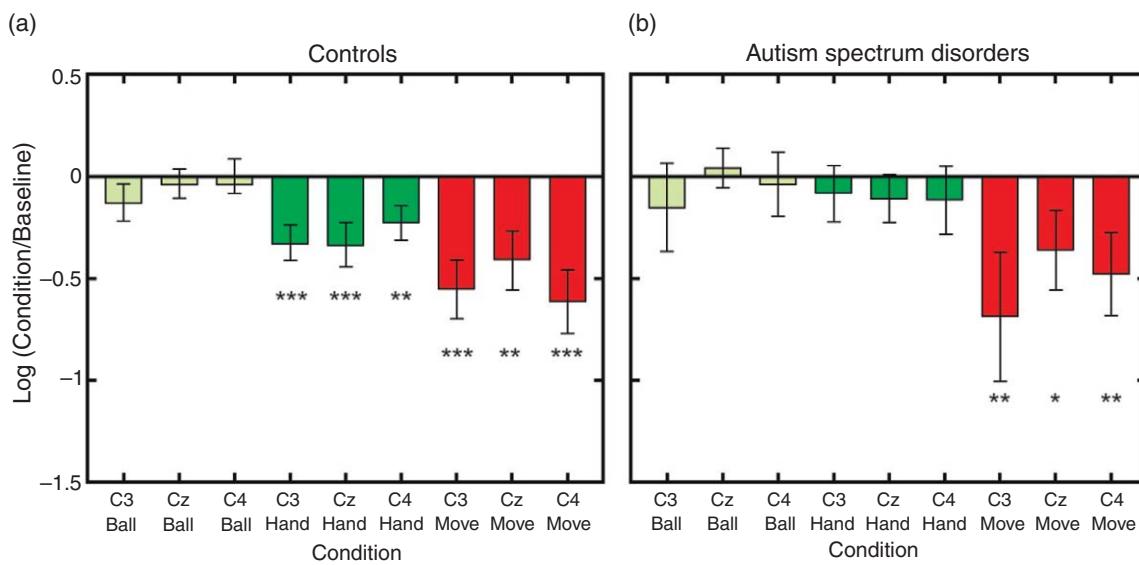

Figure 6 Absence of mirror EEG responses in autism. The charts show suppression of the mu rhythm in controls (a) and patients with autism spectrum disorder (b) during observation of movement of an inanimate object (ball, pale green) or movements made with a hand (hand, green), and during active hand movements made by the individual from whom recordings were being taken (move, red). The bars represent the amount of mu activity in central scalp locations; C3, Cz, and C4 refer to scalp coordinates of the 10/20 EEG system. Significant suppression of this activity, indicated by asterisks, is present for the hand observation condition only in controls, showing that patients with autism spectrum disorder fail to respond in a standard way to the observation of other people's actions. Reproduced with permission from Oberman LM, Hubbard EM, McCleery JP, Altschuler EL, Ramachandran VS, and Pineda JA (2005) EEG evidence for mirror neuron dysfunction in autism spectrum disorders. Brain Research. Cognitive Brain Research. 24: 190–198.

children with autism and matched controls were scanned while observing and imitating emotional expressions. The results showed a significantly weaker activation in IFG in children with autism than in typically developing (TD) children. Most interestingly, the activation was inversely related to symptom severity.

Recently, the deficit of the mirror mechanism in autism has been addressed from another perspective. TD children and children with autism were tested while they observed either an experimenter grasping a piece of food for eating or grasping a piece of paper for placing it into a container (**Figure 7**, right side). The EMG activity of the mylohyoid muscle (MH), a muscle involved in opening of the mouth, was recorded. The results showed that in TD children, the observation of food grasping determined the activation of MH muscle, while this activation was lacking in children with autism. In other words, while the observation of an

action done by another individual intruded into the motor system of a TD observer, this intrusion was lacking in children with autism. This finding indicates that, in autism, the mirror system is silent during action observation and the immediate, experiential understanding of others' intention is absent.

Both autistic and TD children were also asked to perform the two actions described above (grasp to eat and grasp to place) (**Figure 7**, left side). The EMG of MH muscle was recorded. In TD children, the muscle became active as soon they moved the arm to reach the food. In contrast, no MH muscle activation was observed during food reaching and grasping in autistic children. MH muscle activation appeared only when the children brought the food to their mouth.

These findings indicate that autistic children have a deficit in transforming their original intentions into motor

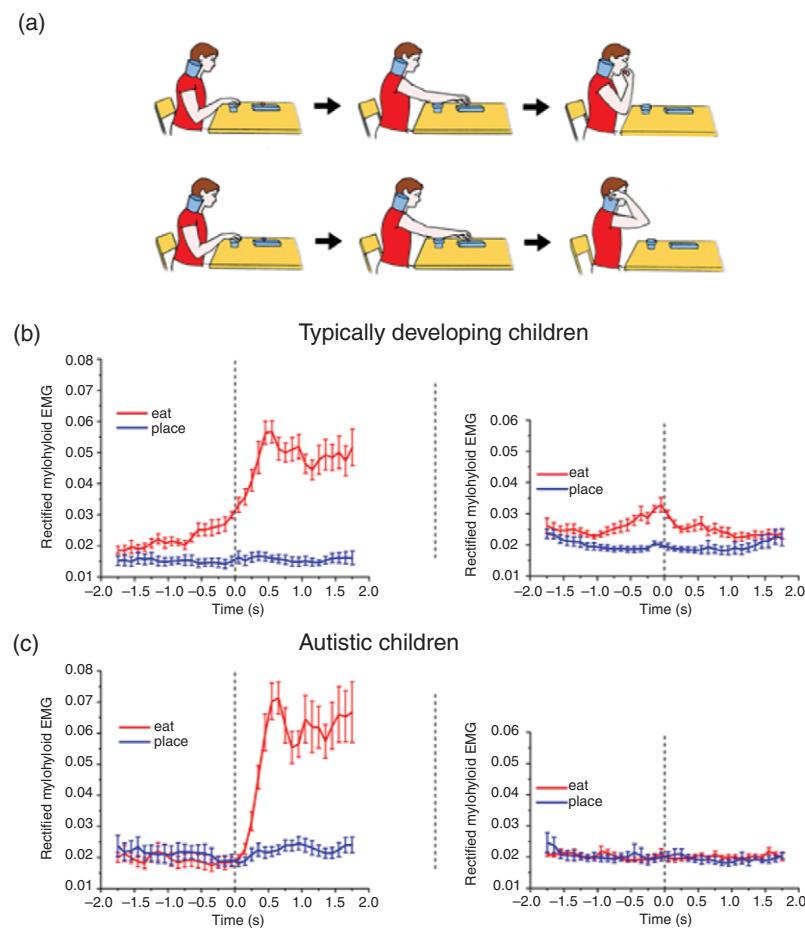

Figure 7 Motor behavior in typically developing children and children with ASD. (a) Schematic representation of the tasks. The individuals reach for an item on a plate, either to bring it to their mouth or to put it into a container placed on their shoulder. Time course of the rectified electromyographic activity of mouth-opening muscles during the execution (left side) and observation (right side) of the bringing-to-the-mouth action (red line) and of the placing action (blue line) for typically developing children (b) and for children with ASD (c). All curves are aligned with the moment of object lifting from the touch-sensitive plate (time = 0). The results demonstrate a lack of anticipatory motor activity during execution and a lack of mirror motor activation during observation of a given action in children with ASD. intentions. It is plausible that the deficit in understanding experientially the intentions of others is linked to this primary motor deficit. When the capacity of endogenously recruiting the appropriate motor chains is impaired, the possibility to activate them exogenously is lacking as well and so also the capacity to understand other's intention.

This new view on autism requires further experiments, yet it appears to be very promising for establishing new rehabilitation procedures based on the acquisition of motor cognition.

Glossary

Allocentric – A representation of a spatial environment referenced to an external coordinate system that is not dependent on the original view or direction navigated when first experiencing an environment.

Cognitive map – A representation of a spatial environment that contains information about the spatial layout of objects in that environment. By definition, cognitive maps are allocentric representations of space because they are not dependent on the original direction that a subject navigates and are instead general to any direction or viewpoint the observer experiences it from.

Egocentric – A representation of a spatial environment tied to a self or body-centered coordinate system.

Functional magnetic resonance imaging (fMRI) – A noninvasive method for looking at changes in neural activity in the human brain. It depends on changes in magnetic properties of deoxygenated hemoglobin, providing information on metabolic changes in various brain regions. fMRI is therefore an indirect measure for neural activity.

Hippocampal area – Comprises the hippocampus and surrounding cortical structures (i.e., parahippocampal region).

Hippocampus – A three-layered structure in the medial temporal lobes of the brain critically involved in memory and spatial navigation.

Parahippocampal cortex – Also known as ‘posterior parahippocampal cortex.’ Six-layered cortical tissue receiving strong input from visual areas; central to memory and spatial navigation.

Parahippocampal region – Cortical tissue surrounding the hippocampus, which is in turn composed of parahippocampal cortex, perirhinal cortex, and entorhinal cortex.

Lesion – Surgically or pathologically produced brain damage.

Place cell – A neuron that increases firing at specific spatial locations and not others. This increased firing is independent of the trajectory of the animal.

Place field – An area in space of increased firing of a place cell.

Path integration – Computation of the optimal, or shortest, path to a location based on previous paths.

Theories of Spatial Navigation and Navigation in Lower Mammals

Origin of the Cognitive Map Theory

How is it that we can return to a town we have not visited in many years and still have a feeling of where things are and the right way to go? When we learn the layout of one city, why is it we rarely confuse where things are in that city with a different city we know better? To explain these and other spatial memory phenomenon, in 1948, Edward Tolman proposed the idea that the brain forms comprehensive maps of a spatial environment, such that “the wider and more comprehensive...the more adequately it will serve . . . ” He termed these representations ‘cognitive maps,’ basing his ideas on observations of rat maze learning. If a rat first learned to find a reward by entering a tunnel and turning right, and then found the entrance blocked and replaced by several tunnels branching toward and away from the reward, the rat quickly learned to take the arm that went most directly to the reward. Furthermore, when the entire maze was rotated, the rat still navigated around the obstruction to find where the food had been. These results could not be accounted for by classical learning theory, the dominant theoretical paradigm at the time, which explained rodent navigational behavior based on learning associations between stimuli and responses such as “white wall, turn right.” Tolman’s data suggested that the

rodent representation for space was not dependent solely on egocentric coordinates, which would be based on the original set of stimulus-responses pairings learned, but instead on allocentric coordinates, a novel type of representation that was direction independent and referenced to landmarks in the room.

Neural Basis of Cognitive Maps in Rodents

Since Tolman's proposal an extensive literature in the rat points to a critical role for the hippocampus, a three-layered structure in the medial temporal lobes, in allocentric spatial learning. Electrophysiological recordings from the hippocampus showed that as a rat foraged in an open area, a significant percent of cells robustly increased in firing rate for certain locations of the room. These place cells also showed direction independence, thus fulfilling the criteria for an allocentric representation of space. Furthermore, recordings from large numbers (>30) of hippocampal neurons simultaneously demonstrated that the firing field (or place field) of each place cell had a fairly sharp tuning for a certain region of the environment. These place fields had firing rates of up to 40–50 Hz which fell off rapidly with distance, thus coding for a certain region of the room quite sharply. The collection of place fields recorded during a single session was shown to comprise a spatial code of the entire room.

The presence of hippocampal place cells in the rodent led O'Keefe and Nadel in 1978 to propose the idea that the hippocampus computes cognitive maps of place, representations of location in an environment referenced to the position of external cues or landmarks. In the rodent, the predictions of the cognitive map model have proven (largely) correct. Cognitive maps, which can be thought as collections of place fields representing a spatial environment in its entirety, rotate with the environment and are environment specific, thus suggesting a map-like quality to these representations. Hippocampal computational models that implement cognitive maps quantitatively account for a large amount of spatial neurophysiological data on the rat.

While the evidence for the involvement of place cells and the hippocampus in cognitive map formation is well demonstrated in the rodent, it is important to note that the rodent hippocampus also plays roles in other behaviors. Examples of stimuli encoded by rodent hippocampal neurons include odors and conjunctions of odors and places. A situation in which these types of representations typically manifest involves training of a rat to associate smells in certain locations with food reward. In these situations, hippocampal neurons come to represent specific odors, while other neurons code combinations of odors and spatial locations. These findings suggest that the neural mechanisms involved in representation of place in the rodent may not be unique to spatial representation and suggest a role for the hippocampus in more

than just spatial representation. Together, the place- and odor-representation findings suggest that the rodent hippocampus is important for representing stimuli in a manner that is task-driven and context dependent.

Neural Basis of Cognitive Maps in Primates

The conditions under which monkeys are tested in navigational paradigms have often differed from those of rodents due to the greater mobility of monkeys overall, compared to rats. In one particular study, monkeys navigated on a track from a head-restrained, moveable chair guided and controlled by a joystick. Monkeys were tested both on a real movement task (reward destinations were indicated by pointers on a monitor and monkeys navigated on the track to this location) and a virtual movement task (reward destinations were indicated by pointers on a monitor and the monkey moved the cursor on the monitor to this location). The study found that nearly half of the hippocampal and parahippocampal neurons recorded fired selectively at specific spatial locations (using criteria similar to that used previously in the rodent) in the virtual and real movement tasks, with a significantly greater number of neurons showing selectivity in the real navigation task compared to the virtual navigation task. These data argued for the presence of place cells in the primate hippocampus as well as the presence of place cells during both real and virtual navigation.

Some laboratories have developed technology for recording from freely moving and behaving monkeys and report different findings than Matsumara and colleagues. In one study, monkeys were tested in an unrestrained testing environment. Recording head direction, eye position, location in space, and neural firing rate, the location that the monkey viewed in space drove the firing rate of neurons in the hippocampus and parahippocampal region rather than spatial location. A subsequent study, however, which also examined freely moving monkeys, reported robust firing at specific spatial locations, regardless of the view direction from which the monkey approached the location. Additional studies are needed to resolve some of the discrepancies in findings with navigating monkeys and spatial coding. Both the place- and view-coding findings, however, show that the primate hippocampus forms allocentric representations of space because both the place- and view-based representations were direction independent in the studies mentioned.

Spatial Navigation in Humans

Behavioral Studies: Do Humans Employ Cognitive Maps?

Somewhat surprisingly, one of the first studies to carefully look for the presence of cognitive maps in humans reported little evidence for allocentric coding in the

human brain. Wang and Spelke set out to test behaviorally whether subjects use primarily egocentric or allocentric representations of space by having them view items arranged on a table and point to their locations in a darkened version of the room following blindfolded rotation. Consistent with an egocentric model of spatial representation, Wang and Spelke found errors accumulated during rotations rather than remaining constant across positions, inconsistent with an allocentric, or equal viewpoint representation of space. Subsequent studies also showed that subjects performed most accurately on viewpoints they had already experienced when pointing to a specific object from an imagined orientation, and that experiencing more viewpoints did not improve pointing accuracy to novel viewpoints. These findings were initially heralded as support for the idea that humans preferentially form egocentric rather than allocentric representations of space.

Part of the reason why these studies may have found support for the presence of egocentric rather than allocentric coding in the human (in contrast to what had been shown in the rodent) likely had to do with the testing situations employed by these studies. For example, the two studies mentioned relied, to some degree, on a bias toward a spatial representation from a specific viewpoint and not on a holistic representation of the room. Indeed, subsequent studies that naturally resulted in subjects referencing viewpoints outside of those they initially learned tended to demonstrate the presence of more allocentrically based representations. For example, when a salient landmark is experienced during active navigation, this information could override what viewpoints were best remembered egocentrically.

Why did Wang and Spelke find little evidence for allocentric representations during their task? Waller and Hodgson suggested that this could have arisen because Wang and Spelke did not interrogate subjects on their relative knowledge of items in the room compared to their absolute positions. Similar to Wang and Spelke, Waller and Hodgson showed that pointing accuracy increased following blindfolded rotation. Waller and Hodgson then went on to show that variations in errors in judging the relative distances of objects actually decrease following disorientation. Thus, pointing to objects appears to preferentially involve egocentric coding systems because the objects were originally centered on the first view-point experienced. Judging positions of objects relative to other objects, however, preferentially invokes allocentric coding as this system is instead initially referenced to landmarks in the room. The findings of Waller and Hodgon thus support the idea that both systems are active during spatial learning and therefore that our brain, similar to the monkey and rodent, codes both allocentric and egocentric references frames.

Brain Structures Underlying Human Spatial Navigation

The human hippocampus consists of several important and highly interconnected nuclei. These include CA1-4, dentate gyrus, and subiculum, which receive input from both lower brain modulating centers, higher neocortical locations, and local interconnections. Based on the hippocampus' apparent position at the top of a pyramid of inputs, it is in a unique position to integrate inputs from a variety of different sensory modalities and output this information for immediate action to motor regions. The parahippocampal region, found between six-layered neocortex and three-layered hippocampus, consists of entorhinal cortex, perirhinal cortex, and parahippocampal cortex, appearing histologically to represent a transition from hippocampus to neocortex. It receives reciprocal connections from the hippocampus and provides the majority of neocortical input to the hippocampus, thus containing many of the same inputs as the hippocampus (with the relative exception of lower brain modulatory centers the hippocampus receives via the fornix). A major source of input to the parahippocampal region, the retrosplenial cortex (an area of posterior cingulate cortex) provides ~20% of the cortical inputs into the entorhinal cortex. Since retrosplenial cortex also receives input from prefrontal cortex, it represents a way station for processing of multimodal input.

Patient lesion work

Lesions to the hippocampus, parahippocampal region, and retrosplenial cortex in humans produce a variety of deficits, including impairments in spatial processing. In one particular study, patients with hippocampal area lesions attempted to locate a sensor hidden under a rug in a room and then find the sensor again after a 30-min delay. Bohbot and colleagues reported that patients with parahippocampal lesions performed significantly worse than controls on this task, while patients with right and left hippocampal lesions did not. In subsequent studies, patients with parahippocampal lesions also showed deficits when navigating virtual environments, performing worse on exploration of a virtual environment than patients with lesions limited to the hippocampus or anterior parahippocampal cortex (i.e., perirhinal and entorhinal cortices). These studies suggest that the human parahippocampal cortex, and not the hippocampus, plays an important role in both real and virtual spatial navigation.

What role then does the lesion literature suggest that the hippocampus plays in spatial memory? Studies of the classic patient HM, who had damage to his hippocampus (and some surrounding structures), but whose parahippocampal cortex was largely intact, suggested a potentially different story than the rat. In one study, HM was tested

in the same navigation task used by Bohbot and colleagues. HM showed intact navigation to the location of the hidden sensor, comparable to controls, although was impaired when required to remember more than one location. These data suggested that HM had some intact allocentric memory, despite a lesion to the hippocampus. His hippocampal lesion appeared to produce the most pronounced impairments when he was required to remember more than one spatial location. In line with these findings, other studies reported that patients with damage largely prescribed to their hippocampus were similarly impaired at recalling the locations of several objects that had been placed in an open arena but not at drawing these objects correctly on a map. These findings further suggested that hippocampal lesions resulted in deficit in integrating multiple representations of objects in space and not simply locating a single object on a map. Thus, together these findings suggest that the human hippocampus may be most critical for integrating multiple representations of space, especially within different contexts. The lesion data suggest that the human parahippocampal cortex may be more involved in actual spatial representation of visually encoded environments than the hippocampus.

Some limitations with patient lesion work warrant consideration when evaluating what brain regions underlie navigation. Lesions impair both the computations a structure performs as well as the input it provides to other structures. Thus, damage to a structure, such as parahippocampal cortex, removes strong inputs to the hippocampus, thus altering its normal functioning as well. In both developmental amnesiacs and patients with even relatively recent lesions, significant remapping in brain structures may occur, which may still involve individual variability. Thus, other measures of brain function, particularly in nonpathological brain structures, are necessary to accurately identify the brain systems involved in navigation.

Functional imaging and virtual reality navigation

Since its inception about two decades ago, functional magnetic resonance imaging (fMRI) remains the dominant method in healthy volunteers for investigating the brain systems involved in human behavior. This is primarily because fMRI is noninvasive yet provides excellent spatial resolution (up to 1 mm) and acceptable temporal resolution (on the order of seconds) for most memory paradigms. fMRI relies on changes in the magnetic properties of hemoglobin as oxygen is delivered to tissue in the brain, and thus is not a direct measure of neural activity. This potential limitation with fMRI, however, appeared initially of less concern because, at least in visual neocortex because there is significant coupling between the fMRI blood-oxygenated-level-dependent responses (BOLD), synaptic activity, and single neural

firing. Unfortunately, the story in the hippocampal area appears more complicated. Current evidence suggests that activations in the hippocampal area largely reflect local field potential input from other brain regions rather than neural firing rate specifically, suggesting that the BOLD signal may largely represent input from nearby brain regions rather than the actual computations that structure performs. Despite this limitation, fMRI and positron emission tomography (PET) (which similarly measures changes in metabolism), remain a powerful technique for looking at changes in neural activity in brain regions and can provide valuable information about the types of information input for processing in a brain region.

Several fMRI and PET studies have looked specifically at the role of the hippocampal area in spatial processing. One of the first studies to look directly at virtual navigation using PET was a study by Maguire and colleagues, who looked at hippocampal activity as subjects navigated to spatial locations. Maguire and colleagues found that as subjects chose more accurate trajectories to locations, hippocampal blood flow increased in a linear fashion to the hippocampus. They also found significant hippocampal activation as subjects successfully navigated to locations compared with following arrows to locations.

In a subsequent virtual reality (VR) study, however, it was reported that the parahippocampal region, but not the hippocampus, was active during spatial navigation involving way finding (navigation requiring use of novel paths) compared with a control condition in which subjects traversed a virtual corridor back and forth. Subsequent work also demonstrated parahippocampal activation simply when subjects viewed spatial scenes compared to viewing faces or objects. What then explains the discrepancy between studies showing parahippocampal activations and those of Maguire and colleagues?

One possible explanation lies with some of the ambiguity in interpreting the BOLD signal in the hippocampal area as structures that provide input to each other (such as hippocampus and parahippocampal cortex) may make it difficult to disentangle where the BOLD signal originates. Another possible explanation, if we assume the BOLD signal at least conveys unambiguous information in both the hippocampus and parahippocampal region, is that different testing conditions tap into different navigational memory systems and thus, different testing conditions result in different brain activations. As discussed earlier, Wang and Spelke found that when subjects make absolute judgments about the positions of objects in a room, egocentric representations predominate. In contrast, in situations in which subjects are required to reference to landmarks, allocentric representations predominate. Thus, when subjects view static environmental scenes, there may be no particular reason for subjects to form allocentric representations of space, thus providing an

explanation for why hippocampal activation may not have been observed when subjects view static spatial scenes. The presence of parahippocampal and not hippocampal activation during way findings, however, suggests a more involved role in allocentric-based spatial navigation.

How do we reconcile fMRI findings with those of the lesion literature? One possibility is that the parahippocampal region not only processes view information experienced during navigation but also does some (preliminary) allocentric processing. This theory would help explain why parahippocampal lesions would have such a profound effect on navigation, in general, as its absence would greatly impair visual-based input to the hippocampus. This proposal also explains the presence of parahippocampal activations simply when subjects view scenes and spatial layouts but are not required to form allocentric representations. Since the parahippocampal cortex also does some allocentric-based, view point extraction, this proposal can also explain why there is greater parahippocampal activation when subjects use objects as landmarks to remember spatial routes compared to when these same objects do not serve as landmarks.

This proposal, however, does not directly address what types of cellular responses might be present in the parahippocampal region and what types of visual stimuli might preferentially drive its neurons during navigation. Rodent studies emphasize the critical role for the hippocampus in forming place cells although the human lesion and fMRI literature suggest a more complex picture at least in the human. fMRI and lesion work, however, are limited to the resolution of whole brain structures and cannot report on single neuron activity. Thus, direct recordings of single neuron from the human hippocampal area are necessary in attempting to resolve this issue.

Neurophysiology of Human Spatial Navigation

As discussed, the rodent and nonhuman primate both support the presence of place cells in spatial coding. Human behavioral literature suggests both egocentric and allocentric coding systems are involved in human spatial learning. Lesion and fMRI work suggest roles for both the hippocampus and parahippocampal region in navigation. At University of California, Los Angeles (UCLA) Medical Center, in conjunction with neurosurgeon Itzhak Fried, we have the opportunity to record from single neurons in the human brain in patients undergoing monitoring for seizures. In a study that we have reported previously and elaborated here with more patients and data, we report on single neuron recordings

from human patients undergoing seizure monitoring as they navigate a virtual environment.

Single Cell Recordings From Human Hippocampal Area during Navigation

The principle questions we wished to address were whether hippocampal area neurons responded at specific spatial locations, how they code landmarks, and whether these responses show allocentric coding properties. We additionally wanted to look at the view dependence and place dependence of neurons in these brain regions, given the previous literature. Would place representations show view dependence? Would representations for landmarks show place dependence? We recorded from hippocampal area neurons in 10 different patients as they navigated a virtual environment, binning firing rate according to behavioral epoch. We defined ‘place responsive cells’ to be cells that showed main effects of place with no main effects or interaction effects with view. We determined the number of cells responding to spatial positions (place) versus what was viewed during navigation (view) in an analysis of variance (ANOVA). We found cells in the hippocampus that responded robustly to place (see [Figures 1\(a\)–1\(c\)](#)); these neurons did not show changes in firing rate for viewing landmarks. We also found that cells showed effects of what landmarks a subject viewed ([Figures 2\(a\) and 2\(c\)](#)). These neurons were active from a variety of spatial positions (see [Figures 2\(b\) and 2\(d\)](#)) and thus, were place independent. We then tallied the total number of neurons responding to place and view across all the neurons we recorded. Place-responsive neurons were significantly clustered in the hippocampus compared to other brain regions, while view-responsive neurons were significantly clustered in the parahippocampal region compared to other regions ([Figures 3\(a\) and 3\(b\)](#)). Only place-independent view responses were clustered in the parahippocampal region; we did not observe any anatomical clustering of cells showing place–view interactions.

Our data both support previous ideas on human spatial navigation developed from the imaging and lesion literature as well as expand on it in important ways. Hippocampal neurons showed increased firing at specific spatial locations and not others – regardless of the patient’s trajectory – supporting the idea that these representations are both spatially specific and allocentric. These same neurons, however, did not respond to viewing landmarks. Interestingly, in many cases, these place-specific responses remapped depending on a subject’s navigational goals, demonstrating the context dependence of these responses. Thus, our data have several implications for theories of the human hippocampus. First, our data confirm the importance of the

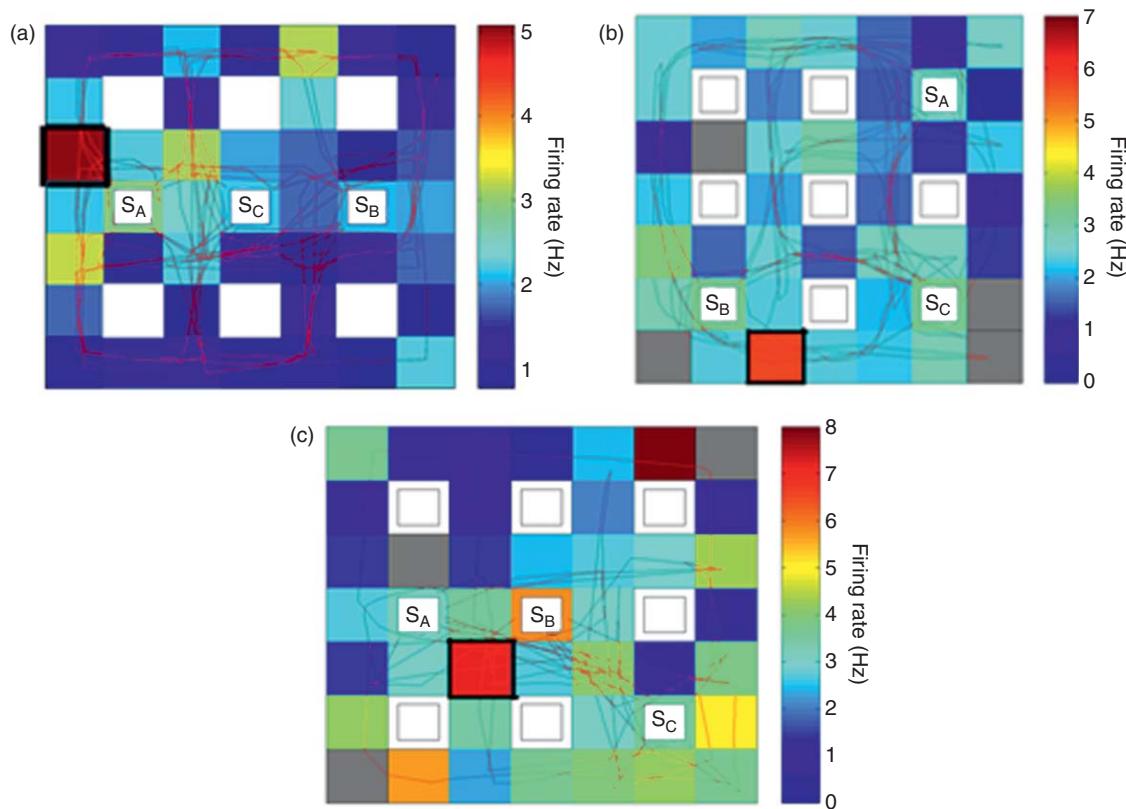

Figure 1 Place responsive cells. (a)–(c) Firing rate maps of hippocampal cells show significant place selectivity. Letters (S_A, S_B, S_C) indicate store locations, white boxes indicate nontarget buildings, gray boxes indicate unoccupied areas, red lines indicate the subject's trajectory, and black squares indicate regions of significantly high firing rate (determined using a resampling procedure at $p < 0.01$). From Ekstrom AD, Kahana MJ, Caplan JB, et al. (2003) Cellular networks underlying human spatial navigation. *Nature* 425: 184–188.

hippocampus in allocentric coding and extend previous work to demonstrate the conservation of place-selective firing from rodents to humans. Second, our data indicate that these place responses are context dependent, confirming a role for the hippocampus in representing information updated by the current experimental context.

Our data also confirm a role for the parahippocampal region in allocentric-based view coding. In our study, parahippocampal neurons showed increased firing when subjects viewed specific landmarks and did not show significant changes in firing rate for place (over the population of neurons recorded). While we found neurons that responded to viewing landmarks both independent and dependent on spatial position, only place-independent view responses were significantly clustered in the parahippocampal region. These data expand on previous ideas developed in the imaging literature and support a role for the parahippocampal region in both egocentric- and allocentric-view coding. These data support the parahippocampal region as an important source of input of visual information and also highlight its role in both egocentric and allocentric processing of spatial information.

Brain Activity in a Virtual Environment: Is it Comparable to Real Navigation?

One of the limitations with fMRI and clinical single cell recording is that subjects cannot navigate in an unrestrained manner, so all testing must be done with a computer laptop. The vast majority of research on the neural basis of spatial coding in the rodent, in contrast, has been conducted during real, locomotion-based, spatial navigation. In the literature, we reviewed previously regarding spatial navigation in patients with hippocampal area lesions, testing was performed during both real and virtual spatial navigation. As the reader will recall, both types of navigation depended on parahippocampal cortex. Similarly, monkeys tested both during real and virtual navigation showed formation of place representations in both conditions. One could still argue, however, that conclusions about spatial coding mechanisms derived in VR studies may not be the same as those observed during real navigation. Indeed, additional information is available during real navigation that is not available during virtual navigation. For example, real movement involves the additional input of head-direction and proprioceptive information into brain systems. Movement of the head

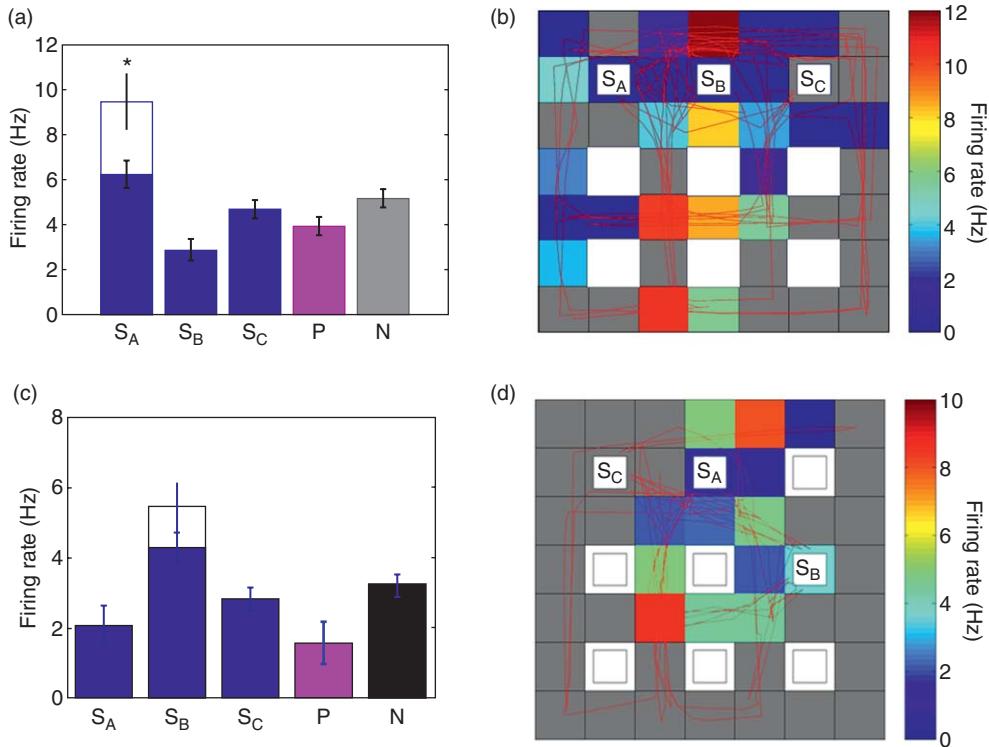

Figure 2 View responsive cells. (a) Mean firing rate for a parahippocampal cell that responded to viewing S_A (as compared with other stores, passengers (P) and control views (N)). The firing rate to viewing S_A (but not other targets) increased significantly when S_A was the goal (white bar). (b) Firing rate map shows that this cell responded to viewing S_A from disparate regions; gray regions indicate that S_A was not viewed from these locations. (c, d) Another parahippocampal neuron that responded significantly to viewing a store (in this case, S_B).

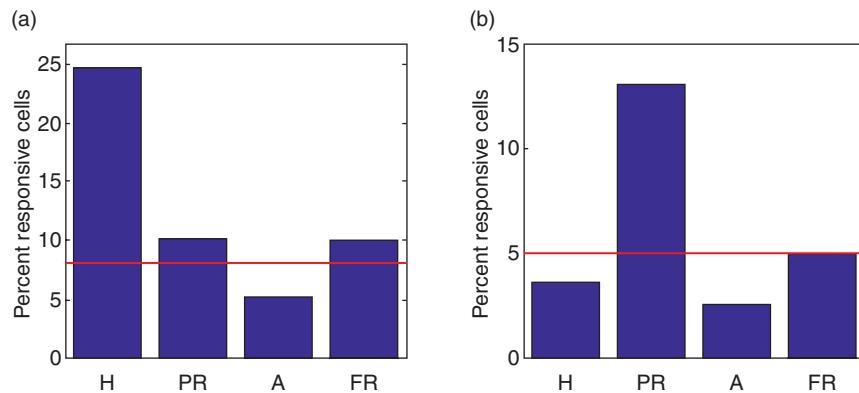

Figure 3 Anatomical clustering of responses. (a) Place-responsive cells were clustered in the H, hippocampus compared to A, amygdala; PR, parahippocampal region; and FR, frontal lobes. (b) View-responsive (location-independent) cells were clustered in the PR compared to other brain regions. Red line indicates bootstrapped type-I error rate.

invokes the head-direction system via the vestibular system, which provides important information about the subject's bearing not available in VR. Proprioceptive information, obtained through changes in muscle position, can provide information about speed. How does this additional information available during real navigation affect one's internal representation for space?

In several studies, the combination of proprioceptive information with head-direction information was shown to

provide the needed information for a rat to compute the optimal path to find a location, referred to as 'path integration.' A classic illustration of path integration comes from mother rats separated from their pups. When their pup is placed at a new location, rats can readily find the shortest path back to their nest. In support of the critical role of path integration in place coding, lesions of the vestibular system greatly impair path integration as well as the specificity and stability of place fields. Thus, vestibular and proprioceptive

input clearly provide important additional information to the navigator that are not present during virtual navigation.

Despite the lack of vestibular and proprioceptive input, human subjects can still path integrate in a virtual environment. Previous research suggests that humans can use optic flow and egocentric bearing in VR to guide themselves to visual targets. Human subjects can also readily find optimal paths to store locations in virtual space, similar to real-world path integration. But given that the inputs differ between real and virtual navigation, despite some of the similarities in how people navigate in both situations, how comparable is the utilization of information obtained during VR to that obtained during actual navigation? In one study, subjects trained in a virtual environment were more accurate at navigating a real-world version of the environment than subjects who received verbal instructions on how to navigate the environment. These data suggest that at least some aspects of what is learned during virtual navigation also apply to real-world navigation. Further studies that directly compare neural responses during virtual and real-world navigation, however, are needed to fully address how comparable VR and real-world navigation are.

Summary

How do we know where we are going when we navigate? What brain systems and neural representations are involved in this task? Are these systems conserved from lower mammals to humans and how can we test these questions in humans? In this article, we have attempted to address some of these questions. We first discussed the distinction between egocentric and allocentric representations as a way of distinguishing between navigation that is dependent on the original viewpoint learned (egocentric learning) and navigation that is independent of static view point (allocentric learning). Rodent electrophysiological studies demonstrated the presence of place cells, neurons in the hippocampus that increase firing for specific spatial locations in an allocentric manner. Nonhuman primate studies also support the presence of place cells as the basis for allocentric spatial coding. In humans, allocentric coding mechanisms have been more difficult to demonstrate, in part because certain coding systems may predominate under certain testing conditions. Under the correct testing conditions, such as making relative judgments about objects positioned in a room, subjects do indeed use allocentric coding schemes to solve a task. Human lesion work suggests the importance of the hippocampus and surrounding parahippocampal cortex in spatial representation, with a greater emphasis on the parahippocampal cortex in visual representation of an environment and the hippocampus in representing multiple spatial environments. fMRI research not only supports the role of the hippocampus in allocentric-based navigation but also

indicates the involvement of the parahippocampal cortex, particularly in extracting view information from spatial scenes. Both fMRI and lesion work are limited to broader statements about brain regions and brain circuits and cannot directly demonstrate whether place cells exist. Direct recordings from the human are rare and limited to clinical situations, yet offer promise for revealing the neural representations underlying spatial navigation. Recording from the human brain while subjects navigate a virtual environment, we report on both place responsive cells (clustered in the hippocampus) and view-responsive neurons (clustered in the parahippocampal region). These data support the idea that place cells are conserved from rats to humans. These data also show that our spatial coding mechanisms involve additional mechanisms, including a greater reliance on view than rodents.

Glossary

Agonistic behavior – Behavior during aggressive confrontations, comprising threat displays and attack elements and defensive reactions, submissive displays, and escapes.

Dominance – Transmitting genes into the next generation via reproductive success, expressed by preferred access to fertile mating partners. Different types of dominance may comprise despotic dominance or relative dominance in a linear or more complex hierarchy.

Violence – Aggressive behavior of high intensity and injurious, often impulsive, oblivious to signals of appeasement.

has been challenged by the rare, but repeatedly documented episodes of intensely injurious aggression in chimpanzees that pursue neighboring groups in order to kill them. The significance of lethal raiding parties in hominids constitutes a problem for the typology of aggressive behavior, since it focuses on rare events that are carefully planned and coordinated and, at the same time, involve intense autonomic and behavioral excitement. The adaptive purpose of these lethal raids eludes an adequate theoretical framework. Conventionally, once the frequency, duration, and intensity of aggressive behavior escalate beyond the species-typical levels, it is considered maladaptive and may constitute a behavioral pathology in need of intervention.

Much pharmacological, neurochemical, and molecular biology research on aggressive behavior uses laboratory mice, often recombinant inbred strains and transgenic lines. These animals are housed in groups, preventing the species-typical formation of demes (breeding units), and only a small proportion of these mice actually engage in territorial aggressive behavior that is characteristic of this pugnacious species. Under captive laboratory conditions, group-housed animals may develop a despotic social organization, with one male dominating all other group members.

Types of Aggression

Social experiences shape future aggressive acts via action on molecular events in discrete ascending aminergic pathways from the midbrain and pons to the basal forebrain, and the cascade of these events is increasingly understood. The adaptive significance of aggressive behavior is apparent in all phyla of living creatures subserving chiefly reproductive purposes. Maladaptive types of aggressive behavior are the focus of human and veterinary medicine and also of the criminal justice system. Types of aggression differ in terms of their origins, motivations, expression or functions, and all indications are by their neurobiological mechanisms. Clinicians distinguish between those types of aggression that include hostile, affective, impulsive, and reactive features from those that are characterized by proactive, premeditated, instrumental, controlled, and also predatory elements. Behavioral researchers, by contrast, focus on adaptive types of aggressive behavior, mostly as part of reproductive strategies such as aggression during the formation and maintenance of dominance hierarchies or territories. Animal species that disperse during the reproductively active lifespan as well as those that live cohesively, engage in aggressive behavior in order to secure the resources for reproduction or to protect the offspring.

The classic ethological thesis that ritualized displays are the major means to maintain a dominance hierarchy

Neurotransmitters

More than any other neurochemical system, brain serotonin remains the focus for neurobiological studies of mechanisms, particularly those mediating impulsive, hostile and intensely violent outbursts, as well as predatory-like aggression. Relative to plants, only present in trace amounts in mammalian brain, this phylogenetically old transmitter, arising from cells along the center of the neuroaxis and acting on at least 14 different receptor subtypes, has a significant role in aggression ranging from invertebrates to humans. Several neurotransmitters comprising amines, acids, neuropeptides, and neurosteroids interact with serotonin (5-hydroxytryptamine, 5-HT).

Glutamate

The ubiquitous excitatory and inhibitory transmitters, glutamate and gamma aminobutyric acid (GABA),

modulate the cellular and behavioral effects of serotonin at several levels of the ascending pathways from the midbrain and pons to the basal forebrain pathways. Previous research has established an excitatory role of glutamate in violent outbursts during seizures, although the precise role of glutamate activity during ictal and inter-ictal events remains to be defined. The few studies that have investigated how pharmacological manipulations of glutamate receptor subtypes affect aggressive behavior suggest a potential role of *N*-methyl-d-aspartic acid (NMDA) receptors in escalated aggressive behavior. Low-affinity channel blockers such as memantine or partial agonists to the glycine binding site on the NMDA receptor may offer potential options in the pharmacotherapeutic management of escalated aggressive behavior due to their favorable side-effect profile. Regulatory changes in NMDA receptor systems occur also in individuals who are repeatedly victimized by aggressors as revealed by prevention of their sensitized response to psychomotor stimulants with protective administration of NMDA receptor antagonists. It will be of considerable interest to learn how glutamate modulates the ascending monoaminergic, especially dopaminergic and serotonergic projections to limbic and cortical target areas.

Gamma Aminobutyric Acid

In contrast to glutamate, GABA and particularly the GABA_A receptor complex have been consistently implicated in the neural control of several types of aggressive behavior. Especially positive allosteric modulators of the GABA_A receptors such as benzodiazepines, barbiturates, ethanol, and allopregnanolone can increase aggressive behavior after low acute doses or after tolerance to the sedative doses has developed. By contrast, at moderate and higher doses, the anti-aggressive effects of these substances are accompanied by sedation and motor impairment. The bidirectional effects of allosteric positive modulators of the GABA_A receptors depend not only on the dose, but also on the context and the prior experience with aggressive behavior. When social consequences lower the rate of aggressive behavior, benzodiazepines and ethanol are more likely to increase its occurrence. The current challenge is to understand how an individual's prior experiences with aggressive behavior modify the GABA_A receptor complex so that pro-aggressive effects of GABA_A positive modulators emerge. The prevalent current hypothesis attributes the divergent effects of GABA_A positive modulators on aggressive behavior to differential expression of genes encoding the subunits that form the pentameric GABA_A receptor complexes. Emerging data from gene deletion and pharmacological antagonism studies suggest a structural dissociation between the anxiety-attenuating, sedative

and aggression-heightening effects of GABA_A receptor positive modulation, primarily due to the differential role of alpha subunits. In addition to the GABA_A receptor, the GABA_B receptors are widely distributed throughout the neuroaxis. The population of GABA_B receptors in the dorsal raphe nucleus modulates serotonin cells, and this may be the mechanism via which GABA_B receptor agonists increase aggressive behavior in mice.

Norepinephrine

Reciprocal anatomical links between catecholamine and serotonergic pathways provide the basis for extensive functional interactions. Particularly intense arousal that is associated with salient life events, including certain types of aggressive behavior or just observing a fight, is based on elevated activity in noradrenergic cell bodies in the locus ceruleus and in cortical noradrenergic terminals. Pharmacological blockade of beta receptors may achieve its calming effects in patients with intensely aggressive, hostile outbursts by reducing noradrenergic hyperactivity, although alternatively, beta blockers also act as antagonists at 5-HT_{1A} receptors. Molecular manipulations of the genes encoding for the noradrenergic transporters or metabolic enzymes have so far resulted in inconsistent results.

Dopamine

Specific dopamine (DA) pathways and DA receptor subtypes critically contribute to the neurobiological mechanisms of species-typical and escalated, pathological types of aggressive behavior. Anatomical and pharmacological data provide evidence for serotonergic receptors on soma of DA neurons in the VTA and substantia nigra suggesting modulation of ascending DA pathways by 5-HT.

The most widespread option for pharmacotherapeutic management of aggressive individuals relies on antipsychotic medication that acts via blockade of DA D2 receptors, although the anti-aggressive effects of such agents as haloperidol or chlorpromazine are embedded in sedative and motor incapacitating side effects. At present, so-called atypical antipsychotic drugs with less selective mechanisms appear to be preferred as anti-aggressive medication on account of a more favorable side-effect profile. Clearly, there continues to be a need for more satisfactory medication development. Case studies point to amphetamine intoxication as a potentially triggering event for lethal violence. At intermediate doses, amphetamine disrupts many types of social behavior and at lower doses, it may increase aggressive behavior due to its antifatigue and arousing effects. Increased

corticolimbic DA can be detected via *in vivo* measurement and imaging techniques in individuals who react defensively to an aggressive confrontation and who prepare for such an event. Anatomical and temporal analysis with higher resolution may enable a more precise delineation of DA activity in different phases and types of aggressive behavior.

Disruption of the genes that are critically involved in the inactivation of catecholamines, Catechol-O-methyl transferase (COMT) and monoamine oxidase (MAO)-A can promote aggressive behavior in male mice. It is tempting to relate these preclinical data to the specific polymorphism in the gene for COMT which is associated with increased aggressive behavior in schizophrenic men.

Monoamine Oxidase

Considerable evidence links MAO-A to escalated types of violent behavior. Which of the monoamines is primarily responsible for the effects of mutations or deletions of the gene for this enzyme or for the effects of its pharmacological inhibition requires further analysis. An early study illustrated how acts of violence by the male members of a Dutch family suffering of mental retardation appear to be linked to a missense mutation in the gene for this enzyme on the X chromosome. Mice lacking this gene also initiate injurious aggressive behavior faster. Probably the most significant findings link the allelic variant with low activity of MAO-A to the antisocial and violent behavior only in those adult males who were severely maltreated in childhood, whereas the allelic variant with high MAO-A activity or the absence of maltreatment had no such influence in adults. A variable number tandem repeat polymorphisms of MAO-A may also contribute to the increased probability of a life history of aggressive behavior, particularly aggression involving dysregulated affect. However, there is also evidence that links lower MAO-A activity to aggressive tendencies independent from polymorphisms in MAO-A. While one of the leading candidates, a number of inconsistent findings obscure the causal relationship between the expression of MAO-A gene, its interaction with early life experiences and traits of hostile, antisocial aggressive outbursts.

The differential expression of specific genes for MAO-A in aggressive and nonaggressive individuals is often associated with alterations in the brain serotonin system, based on additional pharmacological studies. A rich array of methodological approaches has implicated the serotonin system in aggressive traits, impulsivity, and also in the initiation and termination of certain types of aggressive behavior. Beginning with the assay data from the hindbrain of isolated aggressive mice and from cerebrospinal fluid (CSF) samples of patients, an inverse correlation between 5-HIAA and trait measures of impulsive aggression was frequently, but not always, found. The

significance of CSF 5-HIAA measures is compromised by the uncertainty as to their precise anatomical origin. Direct challenges of brain 5-HT functions with either an agonist or a tryptophan-depleted diet demonstrated a blunted prolactin response in violent patients with various diagnoses, possibly due to actions on 5-HT_{1A} and 5-HT_{2A} receptors. Instead of relying on a single sample of CSF, a peripheral marker, or an endocrine response to a single pharmaco-challenge, *in vivo* microdialysis reveals no changes in cortical 5-HT during the phase of initiating an attack, but it begins to decline once the fight is progressing and terminating. The termination of an anticipated aggressive confrontation is accompanied by a decrease in accumbal 5-HT suggesting a potentially significant role for 5-HT in the inhibition of aggressive behavior.

Serotonin Transporter

Several receptor families and the serotonin transporter (SERT) have been characterized in terms of their genetic basis and molecular features. Pharmacological and molecular genetics studies have begun to implicate the 5-HT₁ and 5-HT₂ receptor families and SERT in different types of aggressive behavior. Agonists of the 5-HT_{1A} and 5-HT_{1B} receptors reduce aggressive behavior, and the anti-aggressive effects of the 1B receptor subtype are behaviorally specific and especially effective in situations that engender escalated levels of aggressive behavior, although this remains to be clinically verified. Microinjection studies provide evidence that 5-HT_{1A} and 5-HT_{1B} receptor agonists can achieve their anti-aggressive effects via action at either somatodendritic autoreceptors in the dorsal raphe nuclei or the presynaptic terminal autoreceptors or postsynaptic heteroreceptors (Figure 1). If in fact the decrease in extracellular levels of corticolimbic 5-HT after 5-HT_{1A} and 5-HT_{1B} receptor stimulation constitutes a critical mechanism of action for the anti-aggressive effects, a significant revision of the serotonin deficiency hypothesis is required. Genetic deletion studies of 5-HT_{1A} and 5-HT_{1B} receptors generate a more complex pattern of results that appears to be influenced by the genetic background of the mouse or by developmental compensations. Similarly, associations between polymorphisms of 5-HT_{1A} and 5-HT_{1B} receptors and aggressive traits in humans remain inconsistent.

5-HT Receptors

Antagonism of 5-HT_{2A} receptors represents the mechanism through which some atypical antipsychotic compounds achieve their calming effects in patients with diagnoses that range from schizophrenia, dementia, depression, and posttraumatic stress disorders. Yet, the

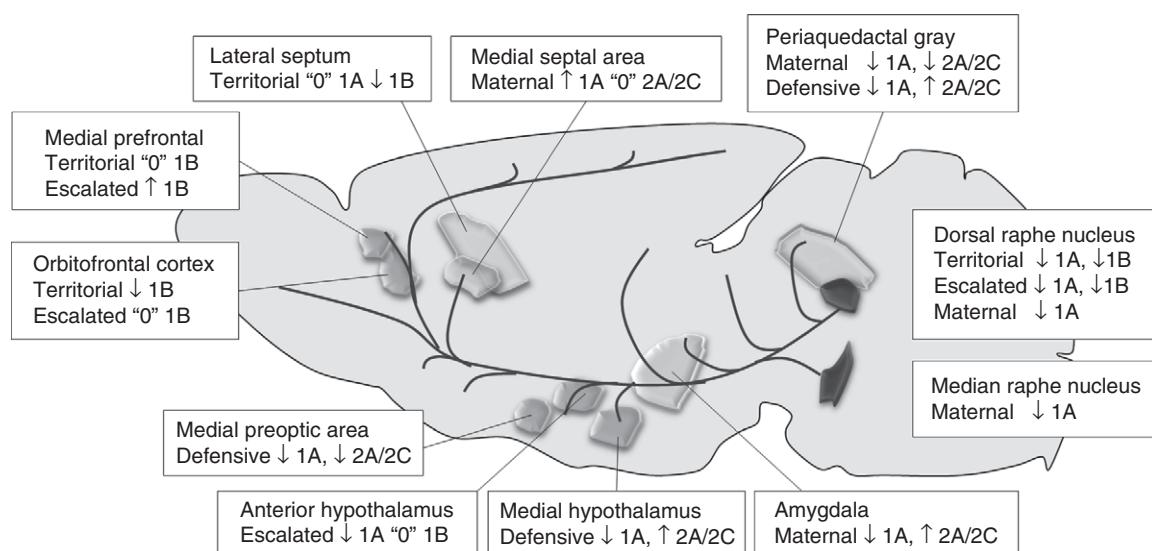

Figure 1 Modulation of aggressive behaviors in rodents by microinjections of 5-HT_{1A}, 5-HT_{1B}, and 5-HT_{2A/2C} receptor agonists. Text boxes show that local injections of 5-HT_{1A} receptor (1A), 5-HT_{1B} receptor (1B), or 5-HT_{2A/2C} receptor (2A/2C) agonist increases (↑), decreases (↓), or has no effect ('0') on territorial, escalated, maternal, and defensive aggressive behaviors. Serotonergic neurons originate from the raphe nuclei and project to several brain areas. Reproduced with permission from Quadros IM, Takahashi A, and Miczek KA (2009) Serotonin and aggression. In: Muller C and Jacobs B (eds.) *Handbook of Behavioral Neurobiology of Serotonin*. Amsterdam: Elsevier.

side-effect profile of these agents highlights the problematic nature of this new class of antipsychotic agents. Preclinical studies of the 5-HT_{2A} and 5-HT_{2C} receptors have to await the development of more selectively acting molecular tools, since at present it is not possible to differentiate between the anti-aggressive effects of agonists and antagonists at these receptors. Similarly, linkage studies between polymorphisms in the 5-HT_{2A} receptor and impulsive-aggressive or antisocial traits require replication.

Blockade of the reuptake mechanism for 5-HT, the SERT, reduces aggressive episodes in most patients, especially when given over extended periods. Large meta-analyses have identified the exceptional nature of the occasional reports of increased aggressivity and suicidal tendencies among those treated with selective serotonin reuptake inhibitors (SSRIs). Preclinical studies have shown that acute and chronic treatment with SSRIs reduces aggressive behavior in species ranging from invertebrates to primates. Chronic SSRI administration can also restore competent agonistic interactions in laboratory species that do not show intact species-typical aggressive behavior.

The short length allele in the serotonin-transporter-gene-linked polymorphic region (5-HTTLPR) leads to lower SERT expression and lower serotonergic activity relative to those with the long length allele. Some evidence supports the association of the short allele with increased hostility, impulsivity, and aggressiveness, primarily in males. The contribution of the 5-HTTLPR to

the variation in aggressive personality traits is relatively small and appears to depend on epistatic influences and on environmental triggers. Early stressful life experiences in monkeys and humans may increase the probability of escalated aggression toward others and themselves in those individuals who carry the short length allele. A more adequate understanding of SERT expression in corticolimbic regions promises to be relevant for the display of aggressive personality traits.

Brain serotonin modulates and is modulated by other amines, amino acids, as well as neuropeptides and neurosteroids. For example, serotonergic projections in specific hypothalamic nuclei may regulate the release and action of vasopressin (VP), a neuropeptide that is associated with high rates of aggressive behavior in several animal species via action at 5-HT_{1A} and 5-HT_{1B} receptors. Similarly, the modulation of serotonergic neurons by corticotrophic releasing factor (CRF) and opioid peptides provides the anatomical basis for functional interactions that are relevant to aggressive behavior. The promising information on CRF, GABA, and glutamate in amygdaloid connections with hypothalamic and brainstem structures during displays of intense emotion should prompt a detailed examination of these mechanisms in escalated types of aggressive behavior.

Glossary

Amphetamines – Sympathomimetic drugs that are stimulators of the central nervous system.

Antidepressants – Drugs used to treat depression; the tricyclic and serotoninergic antidepressants are the most important pharmacological classes.

Basal ganglia – A group of deep nuclei located in the telencephalon and diencephalon; it includes the lenticular nucleus (subdivided into putamen and globus pallidum), the caudate nucleus (which forms the neostriatum with the putamen), the thalamus, and several small nuclei.

Continuous performance task – Task assessing the ability to sustain attention required to detect rare targets appearing among distractors; it usually requires answering to the target by the depressing of a response key.

Controlled processes – These processes involve executive functions and are opposed to automatic processes; they are operating under the direct conscious control of the subject and are especially involved in novel, conflicting, or complex situations.

Executive functions – Control functions mainly subserved by the prefrontal cortex and especially involved in nonroutine situations (novel, conflicting, or complex tasks); deficit of executive functions (labeled ‘dysexecutive disorders’) induces behavioral disorders and impairment of several tests such as Stroop, Go/No-go tests, set shifting, and planning tests.

Frontal lobe – This cerebral lobe, the largest in the human, is located in the anterior part of the brain. It is subdivided into three major parts: mesial regions (belonging to the paralimbic system and including the Brodmann’s areas 32 and 24), basal region, and the lateral region which contains most of the prefrontal cortex (corresponding to supramodal associative cortex involved in higher-order cognitive processes).

Go/no-go – Tasks requiring to answer to one class of stimuli (Go) and to suppress answers to another class (No-go); as ‘No-go’ stimuli are chosen to naturally trigger answers, the erroneous responses to ‘No-go’ stimuli reflect deficit of inhibition of prepotent responses.

Noradrenergic system – It originates in the locus ceruleus (a small nucleus located in the brainstem) and projects to the cortex.

Planning – It reflects the ability to preprogram complex actions prior to execution; it is usually assessed by various tower tasks requiring to move balls to achieve a predetermined spatial configuration. The complexity is assessed by the number of moves required.

Set shifting – The ability to shift from one set of action (e.g., sorting cards using the rule ‘color’) to another one (e.g., sorting cards using the rule ‘number’).

Stroop task – Task assessing the ability to focus attention on the relevant dimension of a stimulus; it is usually assessed using words of color names printed with ink of a different color; subject has to name the ink color (e.g., the word ‘RED’ printed in blue ink requires the answer ‘blue’).

Introduction

The domain of attention has evolved in the last decades. Thus, we first consider the major varieties of attention and its assessment for the nonexpert reader. The second section details criteria and major characteristics of attention-deficit/hyperactivity disorder (AD/HD), including underlying deficits of attention and cognition, which are critical to examine neural basis. Finally, brain regions associated with attentional processes are briefly mentioned before developing the neural basis of AD/HD.

Varieties of Attention

Attention represents a large variety of phenomena (**Table 1**) which are critical for enhancement of efficiency of cognitive processes. Attention is frequently subdivided into two main domains: (1) intensity which includes sustained attention and alertness and (2) selectivity which refers mainly to focused attention and selective preparation. ‘Sustained attention’ (also denoted vigilance) is the ability to maintain an optimal level of performance during a prolonged task (frequently longer than 10 min) which is usually monotonous (such as the detection of rare targets occurring among distractors). Sustained attention is usually examined by performance decline (indexed by reaction time (RT), hits, and false alarm) over time. Such paradigms have been extensively studied in normal

Table 1 Main attentional processes

Attention varieties	Definition	Performance Index	Illustration of key situation
Sustained attention	required to maintain an optimal level of performance during a prolonged task	performance decline over time	Radar monitoring
Alertness	ability to increase response readiness following a warning signal	Increased response speed following a warning signal	'attention!'
Selective attention	efficiency increase related to a cue providing information about the characteristic of target stimulus (e.g., stimulus location)	performance gain conferred by a cue	'Attention on your right!'
Divided attention	involved in situations requiring the performance of two tasks in combination (usually simultaneously)	performance decrement in dual-task condition	to drive and speak to someone

subjects. 'Alertness' (frequently denoted phasic alertness) is the ability to increase response readiness (usually indexed by RT) for a short time-period following a warning signal which indicates the stimulus occurrence. 'Selective attention' is defined by performance improvement following a cue which reduces uncertainties about target stimulus (e.g., stimulus location), task, or response processes. Selective attention is also involved in tasks requiring the inhibition of a prepotent response or process such as in the Stroop task. Selective attention is usually indexed by RT gain conferred by a cue delivering information about signal to be processed. Finally, 'divided attention' is involved in situations requiring the performance of two tasks in combination (usually simultaneously). Divided attention is indexed by performance decrement in the dual-task condition (i.e., when both tasks are performed simultaneously) as compared with the single-task condition (i.e., when performance is measured in each task performed in isolation). These varieties of attention have different neural bases and the present article focuses on attentional processes involved in AD/HD, that is, sustained and selective attention.

Attention-Deficit/Hyperactivity Disorder

General Characteristics of AD/HD

AD/HD is one of the most common childhood disorders. The core symptoms include a severe deficit of attention often associated with impulsivity and motor hyperactivity which interfere with many areas of normal development, learning, and functioning in childhood. In 1902, Still reported the first description of children with hyperkinetic syndrome. The symptoms of AD/HD, as defined by the 4th edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) include inattention and hyperactivity/impulsivity that lead to difficulties in educational, social, and family contexts. Diagnostic criteria require at least six of nine symptoms of each domain in the DSM-IV (AD and hyperactivity-impulsivity) lasting

more than 6 months. These symptoms need to be permanent, that is, present anywhere and independently from environment (at school and at home). The early age of onset is also important: symptoms have to be present before the age of 7 and are usually reported in the first 5 years of life. Motoric hyperactivity most often begins with walking while AD is generally observed when children start school.

DSM-IV provides diagnostic criteria for three subtypes of AD/HD: primarily hyperactive/impulsive (AD/HD-HI), primarily inattentive (AD/HD-IA), and combined type (AD/HD-C). The existence of AD/HD subtypes remains controversial. The hyperactive/impulsive form is relatively rare and is often conceptualized as a precursor of the combined subtype because attentional problems emerge during childhood in many children initially meeting criteria for AD/HD-HI.

Epidemiology

Epidemiological studies in the general population of children and adolescents provide different prevalence rates according to study population and methods, especially diagnostic tools and criteria. Studies using DSM-IV criteria have provided prevalence rates between 3% and 5%. Some studies have shown that the prevalence is higher for the urban than the rural population and increases as a function of lower socioeconomic class. AD/HD is much more common in males both in clinical (9:1) and epidemiological (4:1) samples. A referral bias may contribute to this sex-ratio since girls have primarily inattentive AD/HD and less frequently hyperactive and impulsive symptoms.

Diagnosis and Neuropsychological Assessment

The diagnostic evaluation is based on medical history, parents and teachers questionnaires, the AD/HD Rating Scale, and semi-structured interviews.

Neuropsychological assessment is useful to determine whether difficulties to sustain attention and distractibility are due to true AD. Children with AD/HD have usually a low processing speed index as assessed on the Wechsler Intelligence Scale for Children (WISC-IV). Computerized RT tests provide a more objective index of attention and inhibition, the Conner's Continuous Performance Task being the most widely used.

Attention and Cognitive Deficits Underlying AD/HD

Recent advances in cognitive neuroscience lead to a better understanding of mechanisms underlying AD/HD symptoms and related cerebral networks. Sustained AD is usually thought to be the key deficit in AD/HD. However, studies using computerized Continuous Performance Task showed inconsistent or negative findings supporting that symptoms in AD/HD are not attributable to a true sustained AD *per se*.

Recent studies indicate that AD/HD children suffer from disorders of executive functions and suggest the core deficit concerns inhibition. Studies have documented deficits of various executive processes, including planning, set shifting, and inhibition of prepotent responses. The inhibitory hypothesis of AD/HD provides a good account of clinical symptoms observed in daily life and clinical examination, especially excessive distractibility, as well as deficits on Go/No-go or Continuous Performance Tasks. Although less studied, children suffering from AD/HD show robust slowness and variability of RT in various experimental tasks. This finding could reflect a more diffuse AD than a specific inhibitory deficit. However, convergent data suggest that slowness in AD/HD especially concerns tasks involving controlled processes (i.e., involving executive functions) than those involving automatic processes.

Etiology and Comorbidities

The etiology of AD/HD is unknown and is probably multifactorial. AD/HD is probably the result of the interplay of both psychosocial and biological factors.

Genetic factors have been suggested. Family aggregation studies have shown that AD/HD do run in close family members and adoption studies favor the role of a genetic rather than environmental factor. Consistently, the concordance rate has been estimated between 50% and 66% in monozygotic twins and around 30% in dizygotic twins. Twin studies indicate heritability of 80–90%. A number of chromosomal regions containing potential AD/HD predisposing loci have been identified from family-based linkage studies, including 5p, 6q, 7p, 11q, 12q, and 17p.

Several medical conditions may be associated with AD/HD although AD/HD does not necessarily occur as a result of them. Some prenatal or perinatal factors have been found to be involved, such as fetal alcohol syndrome, severe prematurity, and consumption of caffeine during pregnancy. Genetic condition such as fragile X syndrome, Williams's syndrome, or peripheral resistance to thyroid hormones may also be associated with AD/HD. At least 20% of children with epilepsy have features of AD/HD that begin generally before seizure onset. Finally, postnatal brain injury, lead poisoning, or pediatric autoimmune neuropsychiatric disorder associated with streptococcal infection are often complicated by AD/HD. Comorbid disorders are frequent in AD/HD and include learning disabilities, oppositional defiant disorder, conduct disorder, anxiety, depression, and Tourette's syndrome.

Treatment

The management of AD/HD requires a combination of pharmacological treatment and psychosocial interventions. The psychopharmacological agents are stimulants: amphetamines (mainly dextroamphetamine), pemoline, and methylphenidate, the latter – a stimulant that enhances catecholaminergic systems innervating the fronto-striatal regions – being the most widely used. A minimum of 70% of children with AD/HD have a positive response to psychostimulants. The stimulants bind to dopamine and norepinephrine transporters, blocking reuptake and facilitate release (d-amphetamine only) of dopamine. Efficacy has been clearly demonstrated in reducing AD, improving processing-speed index and inhibitive ability, as well as internalizing symptoms and positively impacting social behavior and academic performance. It is now clear that stimulants are not only 'school time drugs' but should be used throughout the waking day and on weekends. All stimulants share side effects (mainly decreased appetite, sleeping difficulties, headache, stomachache, irritability, and growth reduction related to decreased appetite). There is strong evidence that methylphenidate use does not lead to substance abuse. Second-generation, extended-release, and long-acting stimulants are now available. Other pharmacological nonstimulant agents are sometimes used 'off-label' such as tricyclic antidepressant, α_2 -agonists, or buproprion. More recently, atomoxetine – a specific norepinephrine reuptake inhibitor – has been approved for the treatment of AD/HD.

A recent review of evidence-based psychosocial treatments for children and adolescents with AD/HD indicates that there is adequate evidence to support their efficacy, especially behavioral parent training and behavioral school interventions. The largest and most influential study on the treatment of AD/HD is likely

the Multimodal Treatment Study of children with AD/HD study. This study demonstrates that combined pharmacological and behavioral therapy improves core areas of AD/HD and that families also benefit from this approach. Additionally, the combined approach (pharmacological and behavioral interventions) results in less challenging behaviors and allows prescription of lower doses of medication.

Neural Basis of AD/HD

Anatomy of Sustained and Selective Attention in Adults

Few studies have examined the anatomy of sustained and selective attention, and we only focus on those assessing (1) location of focal brain lesions associated with deficits of these attentional processes and (2) brain regions activated during functional imaging study involving these attentional processes.

Considering 'sustained attention,' the study of patients with focal lesion (especially stroke) has led to controversial results. Excessive fatigability and inability to maintain the ongoing activity are frequently observed clinically in frontal-lobe damaged patients. Although this behavioral disorder suggests a deficit of sustained attention, studies formally assessing performance-decline over time have showed either normal performance or a mild decline in both frontal and posterior lesions. This issue remains largely unresolved because of low test sensitivity or assessment of mixed pathologies, including traumatic brain injury (which induces diffuse lesions and thus prevents determination of the lesion location accounting for the cognitive deficit). The ability to 'sustain alertness' during a task has been found to be impaired in frontal damage, especially when the lesion concerns the superomesial region with a prominence in the right 24 and 32 Brodmann's areas. These regions are usually activated in functional activation studies using the sustained-alertness paradigm as well as other regions including the dorsolateral prefrontal, inferior parietal, thalamic, and pontomesencephalic regions. The role of the noradrenergic system originating in the locus ceruleus and projecting most strongly to frontal areas (at least in rats) has been suggested and is consistent with the finding of pontomesencephalic activation regions. Despite some negative results, most adult studies based on lesion and activational paradigms indicate that the superomesial region is critical for sustained alertness with a hotspot probably centered on the right 24–32 Brodmann's areas, and that a large attentional network is usually involved in activation studies including the lateral frontoparietal cortices and the thalamic and pontomesencephalic regions.

The neural basis of 'selective attention' has been examined in a large number of studies. Patient studies have

mainly used the Stroop and Go/No-go tests and have showed deficit in the frontal focal lesion. Within the frontal lobe, the impairment of selective attention is prominent when the lesion concerns the superomesial region in the Stroop task, and for the Go/No-go task, when it includes the superior part of the premotor–frontal regions with a prominence of the mesial side in some studies, or the lateral side in others. Most functional imaging studies have underlined the activation of the anterior cingulate (frequently with a right hemispheric prominence) usually associated with widespread activation of both right and left dorsolateral prefrontal cortices in the Stroop and Go/No-go tests where the activation of the inferior and middle gyri and medial regions were prominent.

Dysfunction of Brain Circuits Associated with AD/HD

Neuroimaging data suggest that the dysfunction of the cerebello-thalamo-prefrontal circuit may subserve the overactivity and deficits of motor control, inhibition, and executive function encountered in AD/HD.

Structural imaging studies

Structural imaging studies involve four cerebral regions in AD/HD: the prefrontal cortex with a right prominence, basal ganglia (especially the caudate nucleus), the splenium of the corpus callosum, and the cerebellum (vermis lobules VIII–X). These results are consistent both in boys and girls. Children with AD/HD have a reduced volume in the rostrum and rostral body of the corpus callosum, a lack of normal left-right asymmetry in the anterior brain and caudate nuclei, and smaller globus pallidus. These findings are consistent with an alteration of functioning of the prefrontal and anterior cingulated cortices – two regions involved in executive functions. Dysfunctions in the cerebello-thalamo-prefrontal circuitry underlying connections between the cerebellum and prefrontal associative areas may explain subtle neurological signs that are detected in over 50% of children with AD/HD as well as impairment in the cerebellar–vestibular test. The developmental trajectories of these brain-volume abnormalities (except the caudate) remain roughly parallel for children with AD/HD and controls during childhood and adolescence. The lack of asymmetry and reduced volume are fixed, nonprogressive, and unrelated to stimulant treatment. This finding suggests genetic and/or early environmental influences on brain development in AD/HD.

Functional imaging studies

Functional imaging studies also support the role of striato-prefrontal circuitry. Studies using single photonic emission computerized tomography (SPECT) or positron emission tomography (PET) demonstrate decreased

cerebral blood flow and metabolism within anterior frontal regions and striatum in adolescents and adults with AD/HD. Functional magnetic resonance imaging (fMRI) studies have assessed regions activated during various response-inhibition tasks. During the Go/No-go task, AD/HD children demonstrate less activation within a network important for inhibition including the caudate, anterior cingulate, and dorsolateral prefrontal cortex. Methylphenidate restores the normal activation in these regions.

Abnormalities of catecholamine regulation

There is considerable evidence that norepinephrine and dopamine play a critical pathophysiological role although they are certainly not the only neurotransmitters involved in AD/HD. Both agents contribute to maintain alertness, to focus attention, and to control emotions and behavior. Low rates of these monoamines or their metabolites have been observed in children with AD/HD. Increased dopaminergic striatal activity on PET in children with AD/HD suggests that their symptoms result from excessive dopaminergic activity in the striatum and probably the nucleus accumbens. Several studies have reported high levels of dopamine transporters in the striatum of AD/HD subjects. Moreover, high cerebrospinal fluid concentration of metabolites of monoamines is correlated with the severity of AD/HD and with the response to stimulants.

The positive response to psychostimulants and antidepressants also suggests that catecholamines are involved in the pathophysiology of AD/HD. Psychostimulants, such as methylphenidate, inhibit recapture of dopamine and noradrenaline and enhance the postsynaptic effect of dopamine. Stimulants may also reduce hyperactivity by reducing dopaminergic activation of the striatum probably via inhibitory presynaptic autoreceptors. However, adults with AD/HD have lower amounts of dopamine released in the caudate in response to intravenous methylphenidate, and this blunted response to methylphenidate is related to inattention.

Finally, genetic studies also point out the prominent role of dopamine. Polymorphisms in genes have been found for dopamine D4- and D5-receptors, dopamine β -hydroxylase, and the dopamine-transporter gene which is involved in the action of methylphenidate.

Motor and cognitive symptoms in AD/HD are probably mediated differently. The dopamine transporter is expressed in considerably lower amounts in the cortex than the striatum suggesting that transporter inhibitors would have a weaker ability to increase dopamine efflux in the cortex than the striatum. The positive effects of methylphenidate on cognitive function seem to be due to the facilitation of dopaminergic activity while behavioral improvement (hyperactivity and impulsivity) may be mediated by reduction in dopaminergic stimulation.

Hyperactivity may result from striatal dysfunction whereas AD may be related to prefrontal dysfunction. Indeed, decrease of dopamine concentration has been observed in prefrontal synapses and this may account for the deficit of inhibition. The increase of dopaminergic postsynaptic activity obtained with methylphenidate may enhance the integration of relevant signals from other cortical regions and the efficiency of executive functions.

Implication for General Management and Directions for the Future

AD/HD is a descriptive syndrome whose developmental pathways and causal mechanisms are not fully understood. The most scientific investigations to date focused on mechanisms involved in behavioral and cognitive dysfunctions that lead to a better understanding of the neural basis of AD/HD. The question about the causes and particularly the part of endogenous versus exogenous contributions is not resolved. The role of genetic factors, developmental pathways, and experiential factors needs further research. A better understanding of the pathophysiology of AD/HD would help for delineation of diagnostic tools and may contribute to finding alternative pharmacological and multimodal approaches for the treatment of AD/HD. The wide variability of response to medications and the heterogeneity of this syndrome need the development of personalized treatment.

Glossary

Amygdala – An almond-shaped mass of nuclei that are located deep within the temporal lobes of the brain, adjacent to the hippocampus and medial to the hypothalamus. The structure has been implicated in emotional learning and memory.

Discrimination/reversal conditioning – A conditioning procedure that involves the presentation of two conditioned stimuli (CSs), one that is followed by an unconditioned stimulus (US; the CS+) and one that is not (the CS−). The task is for the subject to learn to respond with a conditioned response (CR) to the CS+ while not responding to the CS−. During the reversal stage, the CS+ and CS− are switched.

Hippocampus – A horseshoe-shaped area of cells buried deep in the forebrain. The structure has been implicated in learning and memory as well as in contextual and spatial processing.

Inferior olive – A large nucleus located deep in the medulla oblongata that has connections with the thalamus, cerebellum, and spinal cord.

Instrumental conditioning – A type of associative learning in which there is a contingency established between an observed behavior and the presentation of a biologically significant event.

Interpositus nucleus – The middle of three pairs of nuclei located in the brainstem that receives input from other brainstem nuclei, including the pontine nuclei and inferior olive as well as input from Purkinje cells in cerebellar cortex.

Latent inhibition – A conditioning procedure that involves presenting the CS alone several times before starting paired CS-US presentations. The pre-exposure to the CS slows down the rate of conditioning.

Long-term depression (LTD) – The weakening of a neuronal response at a synapse that could last from hours to days. LTD in the cerebellum is produced at the synapse between parallel fibers and Purkinje cells by the coactivation of climbing fibers from the inferior olive and mossy fibers from structures such as the pontine nuclei.

Long-term potentiation (LTP) – The strengthening of a neuronal response at a synapse that could last from hours to days. LTP has been demonstrated in the hippocampus and is produced by relatively high-frequency stimulation.

Medial prefrontal cortex – An anterior region of the frontal cortex that lies in front of the motor cortex. It has often been implicated in cognitive function.

Pontine nuclei – A large grouping of nuclei located in the pons. The brain region receives much input from virtually all areas of neocortex and, in turn, projects to many areas of the brain including the cerebellum.

Introduction

A very fertile area of research for experimental psychologists and behavioral neuroscientists for well over a century has been how the brain changes as a result of experience with the environment – that is, the neural substrates of learning and memory. For much of the twentieth century, research in this area focused on the involvement of neocortex and higher brain areas in learning and memory as exemplified by the classic experiments of Karl Lashley. Lashley used what on the surface seemed to be a very simple behavior – the learning and memory of mazes – to explore regions of neocortex involved in learning and memory. After many years of experiments he concluded that relatively large lesions of neocortex did not abolish learning and memory of this simple behavior.

Later studies involving amnesics suggested that at least one region of the brain, the hippocampus and associated temporal cortex, was involved in learning and memory processing. Subjects with damage to this brain area were found to be incapable of forming new memories for facts and events (i.e., declarative memories) even though they seemed to be able to form memories for skills and associative conditioning and able to demonstrate priming effects (i.e., procedural memories). The intact procedural memories suggested that learning and memory for these nondeclarative tasks might involve subcortical brain areas, a possibility that has subsequently been investigated by a number of researchers.

One approach that has been enormously successful in exploring how subcortical and cortical brain areas are engaged and changed during simple procedural learning and memory has involved the use of eyeblink classical conditioning. Indeed, use of this paradigm has arguably generated more data about the neural substrates of

learning and memory than any other approach. Eyeblink classical conditioning involves the presentation of two stimuli, a conditioned stimulus (CS) and an unconditioned stimulus (US), which are presented closely together in time. The CS is typically a discrete tone, light, or tactile stimulus while the US is typically an air puff directed onto the cornea of the eye or a very mild shock delivered to the skin overlying the musculature that surrounds the eye. The intensity of the US is normally set to elicit a robust eyeblink when presented, which is called the unconditioned response (UR). The intensity of the CS is normally set so that no behavioral response is elicited although in some species a small orienting or startle response that normally habituates after several presentations can be seen. Training consists of presenting the CS before the US on several discrete trials with onsets separated by 150–1500 ms (i.e., with a 150–1500-ms inter-stimulus interval, ISI). After several paired presentations, eyeblinks appear with onsets that begin before presentation of the US. These learned, anticipatory responses are called conditioned responses (CRs). Presentations of the US before the CS or unpaired presentations of the CS and US do not produce CRs.

The earliest eyeblink-conditioning studies were conducted using humans as subjects. However, as interest shifted to more cognitive phenomenon, humans were less frequently used as subjects and animal models of learning became more popular. In the late 1950s and early 1960s, Isadore Gormezano and his colleagues began using rabbits in eyeblink-conditioning experiments and developed an extensive data base on parametric and behavioral features of this basic form of associative learning. Recently, eyeblink-conditioning procedures for rats and mice have been perfected and these species have been used more frequently as subjects. In addition, the increased interest in translational research has resulted in a renewed interest in human eyeblink conditioning. Indeed, behavioral features as well as the neural substrates of eyeblink classical conditioning seem to be highly conserved across species, making this paradigm ideal for translational behavioral and neural research.

Much is known about the basic behavioral properties of eyeblink classical conditioning. For example, rates of conditioning increase when the intensities of the CS and/or US are raised. There is a well-defined ISI function that has been delineated by training subjects at various CS-US intervals and noting rates of conditioning. In rabbits, for example, the rate of conditioning is highest when the ISI is around 250 ms. Intervals less than 100 ms and greater than 2000 ms produce little learning. In general, two conditioning procedures have been employed – delay conditioning, in which the CS and US overlap in time to some extent, and trace conditioning, in which the CS is presented, a period of time is allowed to elapse, and then the US is presented.

Finally, an interesting feature of eyeblink conditioning is that in addition to the establishment of the CR to the tone, the acquired response is exquisitely timed. After learning, the peak of the CR occurs around the time that the air-puff delivery is anticipated, even on CS-alone trials. If the ISI is shifted during the experiment, the CR will move in time so that its peak corresponds to the new time when the air puff is expected. Thus, in studying behavioral features of eyeblink conditioning as well as the neural substrates of its learning and memory, two features of the learning have been explored – the acquisition and retention of the basic CR and the timing of its execution. This behavioral procedure has proven to be a powerful tool for studying how the brain changes during learning and memory.

Early Studies of the Neural Basis of Eyeblink Conditioning

In the late 1960s and early 1970s, a great deal of attention was focused on the involvement of the hippocampus and other higher brain areas in learning and memory due to a large extent on data from amnesics demonstrating severe memory impairments associated with hippocampal and temporal cortex damage. Of particular note were a series of studies that explored the learning-related activity of neurons in the hippocampus and related structures during eyeblink conditioning. In general, these studies showed that paired training, but not unpaired training, recruited populations of hippocampal neurons that discharged in close relation to the acquisition and execution of the learned response. Interestingly, the summed unit activity formed a rather precise amplitude-time course model of the CR, thus indicating that the hippocampus (and some related cortical areas) encodes the conditioning process. This recording work has been extended in several directions using variations of the basic conditioning procedure including studies of unit activity during (1) unimodal and multimodal discrimination and reversal training, (2) latent inhibition training, and (3) trace conditioning. Taken together, these studies indicate an engagement of the hippocampus and related cortical structures that occurs early in training. It also appears that the hippocampus is activated when features of the conditioning procedure are altered, such as when new CSs are introduced during training, the training context is changed, and perhaps when training is switched from one eye to the other.

The recording data provided strong evidence that the hippocampus was robustly engaged during eyeblink conditioning. However, even prior to when these recording studies were complete it was known that delay conditioning could be obtained in animals given complete removal of the neocortex and the hippocampus. The lesion data

suggested that while the hippocampal neurons were engaged during delay eyeblink conditioning, the structure was not necessary for CR learning and memory to occur; however, the same is not true for trace conditioning. There is solid evidence that hippocampal lesions given before training prevent learning of trace eyeblink conditioning and abolish CRs in animals trained before removal of the hippocampus. More recent data, however, suggest that this effect might be dependent to some extent on the relative lengths of the CS and the trace interval. From these data, the idea has emerged over the years that the hippocampus and related cortical areas are critically involved in trace conditioning and other relatively complex eyeblink-conditioning procedures (such as discrimination/reversal training and latent inhibition training). However, what is also clear is that while higher structures, such as the hippocampus, are engaged during the basic delay procedure, these structures are not necessary for conditioning to occur. This observation suggests that critical plasticity associated with the acquisition and performance of classically conditioned eyeblink responses occurs somewhere in the subcortical areas of the brain.

Later Studies of the Neural Basis of Eyeblink Conditioning

Around 1980, Richard Thompson and his colleagues at Stanford University reported a remarkable finding concerning the neural substrates of eyeblink conditioning that has defined the direction of research for the last 30 years. The Thompson group reported that lesions of the cerebellum, which included the interpositus nucleus, permanently abolished eyeblink CRs that had been established before the lesion. Lesions given before training prevented acquisition from occurring. These initial lesion studies have been followed up by several other experiments which have refined the location and extent of damage necessary to affect eyeblink conditioning. It appears that for rabbits, the critical area of the interpositus nucleus for eyeblink conditioning is about 1 mm³ of tissue located in the dorsomedial region of the anterior division of the nucleus; and the lesion effect is permanent – CRs do not reemerge with daily training sessions delivered for at least a year after the lesion. Perhaps the most compelling evidence for the critical involvement of the interpositus nucleus in eyeblink conditioning came from an infusion study conducted by Thompson and his colleagues, who infused the γ -aminobutyric acid (GABA) agonist muscimol into the interpositus nucleus during several days of paired CS and US training (which, in essence, produces a reversible lesion). During the training sessions with muscimol no CRs were seen. More interesting was the behavior of rabbits on subsequent training sessions when saline was infused instead of muscimol: the

rabbits behaved as if they were naive and had received no previous training (i.e., their rate of CR acquisition was identical to naive rabbits). These data provide irrefutable evidence that eyeblink conditioning is dependent on critical neuronal plasticity involving interpositus neurons. If plasticity, capable of supporting conditioning, occurred in one or more other brain areas one would expect CRs to emerge either immediately or relatively quickly after the training with muscimol was stopped. These data provide strong evidence that critical plasticity associated with basic delay conditioning is relatively localized within the cerebellum.

Lesions studies have also been conducted to explore the involvement of the cerebellar cortex in eyeblink conditioning. The results of these experiments have not been as definitive as the interpositus nucleus lesion studies. Two cortical regions have been studied: lobule HVI and a region located in hemispheric portions of the anterior lobe. A variety of effects have been reported for lobule HVI lesions that range from complete abolition of CRs to partial effects on the rate of conditioning and the size of the CR to little or no effect. Differences in results might be accounted for by factors such as lesion size and amount of postlesion training. What is clear is that it has been difficult to establish a precise role for lobule HVI in eyeblink conditioning using the lesion data. With regard to the anterior lobe cortical site, Mauk and colleagues have shown that anterior lobe lesions affect the timing and sometimes the execution of CRs, thus suggesting a role for the anterior lobe in conditioning. In addition to these ablation or electrolytic cortical lesion experiments, other manipulations have been used to study cortical function. For example, greatly impaired learning is seen in Purkinje cell-degeneration (pcd) mutant mice given eyeblink conditioning. Infusions of 6-cyano-7-nitroquinoxaline-2, 3-dione (CNQX) into lobule HVI, which reversibly blocks α -amino-3-hydroxy-5-methyl-4-isoxazole-propionate (AMPA)-kainate receptors, disrupts the expression of eyeblink CRs. It appears that picrotoxin infusions into the deep cerebellar nuclei, which disrupt cortical input to the deep nuclei by antagonizing GABA receptors, impair the acquisition of CRs when relatively long ISIs are used but not when shorter optimal ISIs. All of these lesion and inactivation studies suggest a role for cerebellar cortex in conditioning although the precise nature of that role is not as of yet well understood.

Neural recording studies have been used to strengthen the argument that the cerebellum is critically involved in eyeblink classical conditioning. Recordings taken from the anterior interpositus nucleus have revealed populations of neurons that alter the firing rates as a result of training. The predominant pattern of neuronal firing recorded from this population of cells was a significant increase in activity that preceded the onset of the behavioral response by 30–50 ms. Similar to what was seen in the hippocampus, the summed unit activity formed a

precise amplitude–time course model of the CR. The fact that activity precedes the behavioral response is extremely important – this is precisely what is expected if activity in that structure is responsible for generation of the behavioral response. The 30–50-ms lag time between interpositus activation and onset of the CR can be accounted for by synaptic delays between the cerebellum and brainstem nuclei responsible for CR generation. These recording data, coupled with the lesion data described above, argue strongly that the interpositus nucleus is a critical site for neuronal plasticity that underlies acquisition and performance of the classically conditioned eyeblink response.

Recordings from Purkinje cells in cerebellar cortex have revealed neurons that discharge in close relationship to the execution of the behavioral response. Two patterns of activation have been seen in lobule HVI: Purkinje cell inhibition, where the neuron slows or stops its spiking in relation to the CR, and Purkinje cell excitation, where the neuron increases its spiking in relation to the CR. Because Purkinje cells inhibit deep nuclear cells when they are activated, it is expected that inhibition of the cortical cells is involved in CR acquisition and performance. In fact, a cellular plasticity process known as ‘long-term depression’ (LTD) has been demonstrated in cerebellar cortex when populations of cerebellar projection fibers are conjunctively activated. The recording studies from lobule HVI, however, have consistently demonstrated a larger number of excitatory Purkinje cells than inhibitory Purkinje cells, which at this point in time begs an explanation.

Recordings from lateral regions of the anterior lobe of the cerebellum, however, have revealed Purkinje cell spiking patterns that are predominantly inhibitory in nature. An ISI discrimination procedure has been used to train rabbits to respond with appropriately timed CRs to two different ISIs signaled by two different CSs (i.e., low- and high-pitched tones). Recordings for individual Purkinje cells showed interesting patterns of CR-related responding. Some Purkinje cells discharged exclusively to one of the ISIs with a CR-related spiking train. Some Purkinje cells, however, responded to both ISIs with appropriately timed learning-related discharge patterns. Together, results of the lobule HVI and anterior lobe recording experiments provide strong evidence that discrete regions of cerebellar cortex are involved in eyeblink conditioning.

At about the same time, the critical involvement of the cerebellum in eyeblink conditioning was being established, the major neural pathways involved in getting the CS and US from the periphery to the cerebellum were delineated along with the output pathways from the cerebellum to motor nuclei responsible for recruiting eyeblink musculature involved in CR and UR production.

The crucial pathway for an auditory CS appears to involve projections from the cochlear nuclei to discrete

regions of the dorsolateral pontine nuclei, which, in turn, send mossy fibers axons to the interpositus nucleus and to granule cells in cerebellar cortex. Granular cell axons, known as parallel fibers, make synapses on Purkinje cells that, in turn, send axons to the same interpositus nuclear cells that receive direct mossy fiber input. This pathway was established through a series of stimulation, lesion, recording, and anatomical tract-tracing experiments. Direct electrical microstimulation of neurons in the dorsolateral pontine nuclei can be used instead of a tone CS for conditioning, and recordings from the region have shown auditory CS-related activity during tone conditioning. Discrete lesions placed in various areas of the pontine nuclei can selectively abolish learning to CSs of specific modalities and cutting the middle cerebellar peduncle, which is the source of pontine input to the cerebellum, results in loss of CRs. It appears that other CSs may engage other regions of the nuclei and relatively recent studies in rats have shown that there may be an important portion of the auditory CS pathway that engages the medial geniculate nucleus of the thalamus.

The major pathway for projecting US information to the cerebellum involves the dorsal accessory inferior olive. It appears that an air-puff US activates neurons in the trigeminal nucleus. The trigeminal nucleus, in turn, sends US input in two directions. First, some axons project to a region of the reticular formation, which then projects input to brainstem nuclei involved in eye-blinking – the reflexive UR pathway. Second, trigeminal axons course to the dorsal accessory olive where they make contact. The activated inferior olfactory neurons then send input to Purkinje cells along with collateral input to interpositus neurons that receive output from those Purkinje cells. A variety of experiments established this US pathway: lesions of the dorsal accessory olive produce either extinction or abolition of the eyeblink CR. Microstimulation of the dorsal accessory olive produced a variety of discrete movements (including eyeblinking if the stimulating electrode is positioned appropriately) that can be conditioned when paired with a peripheral or pontine-stimulation CS. In addition, a number of anatomical tract-tracing studies have established direct connections between critical regions of cerebellar cortex and the interpositus nucleus.

The output pathway for the CR from the interpositus nucleus has been delineated. Excitation of neurons in the interpositus nucleus activates neurons in the magnocellular division of the red nucleus. The red nucleus, in turn, sends axons to several brainstem nuclei that, dependent on the species being conditioned, are involved in generating the eyeblink CR, including the abducens nucleus, accessory abducens nucleus, and the facial nucleus. It appears that the interpositus nucleus also projects to the precerebellar regions involved in projecting the CS and US to the cerebellum. The projection from the

interpositus nucleus to the pontine nucleus appears to be excitatory in nature while the projection from the interpositus to the dorsal accessory inferior olive seems to be inhibitory in nature. It has been proposed that both of these projection systems may be important for regulating the activation of the CS and US systems during conditioning.

A Cerebellar-Brainstem System Critical for Eyeblink Classical Conditioning

Based on the relatively large volume of data described above, a number of formal and informal models have been developed to describe the neural substrates of eyeblink classical conditioning. These models differ from each other in the specifics as to exact locations where critical plasticity occurs during CS-US pairing (i.e., solely in cerebellar cortex, solely in the interpositus nucleus, or in both), but all agree that the cerebellum and associated brainstem structures contain the essential circuitry for this simple type of associative learning and memory.

It is clear that at least three regions of the cerebellum, the interpositus nucleus, lobule HVI, and the anterior lobe, are involved in eyeblink conditioning. This author has proposed that neurons in all these regions alter their firing patterns because of convergent CS and US input. Specifically, CS information is transmitted to the cerebellum through the basilar pontine nuclei via mossy fibers that terminate in cerebellar cortex and the deep nuclei. Information about the US is transmitted to the cerebellum through the inferior olivary complex via climbing fibers that terminate in cerebellar cortex and the deep nuclei. The firing patterns of neurons in the cerebellar cortex and deep nuclei are thought to be altered due to the convergent mossy fiber and climbing fiber input, presumably through LTD and long-term potentiation (LTP) mechanisms involving cortical Purkinje cells and likely through LTP-like processes in the interpositus nucleus (although scant data are available to support this conjecture). Because Purkinje cells only inhibit deep nuclear cells, it is assumed that LTD induced in the Purkinje cells phasically release nuclear cells from inhibition, thus encouraging or increasing their excitability. A powerful release-from-inhibition phenomenon has been reported for Purkinje cell input onto deep nuclear neurons and this may also play a role in establishment of the CR. The net effect of plasticity in the cerebellar cortex and interpositus nucleus is to increase firing of interpositus nucleus neurons, which in turn activates cells in the red nucleus, which then drive behavioral responses by activating neurons in brainstem nuclei known to be involved in generating eyeblinks. In other words, the changes in firing patterns in the interpositus nucleus neurons are critically involved in generating the

behavioral response – the interpositus nucleus is a critical location of learning and memory for this simple associative learning task.

In addition, as excitability changes occur in the interpositus nucleus there is evidence that these changes affect the CS and US pathways. For example, as neurons in the interpositus nucleus increase their firing rates after paired training, there is excellent evidence that output from the nucleus inhibits neurons in the inferior olivary complex that are known to transmit critical information about the US to the cerebellum. Thus, after CRs have been acquired it appears that further US input on subsequent trials is inhibited. Some elegant computational models have been forwarded that propose that the regulation of inhibition in the inferior olive by the interpositus nucleus may play a central role in the definition and regulation of the very precise timing of the CR that is observed. Ongoing work continues to refine this basic cerebellar model of eyeblink classical conditioning, especially in areas such as better defining the role of cerebellar cortex in the acquisition and retention of CRs.

The Involvement of Noncerebellar Brain Areas in Eyeblink Conditioning

As described above, the study of the neural substrates of eyeblink conditioning actually began with studies that examined the role of neocortex and the limbic system in conditioning. A focus on the cerebellum and brainstem emerged only after it was clear that the basic delay conditioning task could be learned with all tissue above the level of the thalamus removed. Does this mean that eyeblink conditioning does not engage or involve these higher brain regions? The answer to this question is an unequivocal no: while it is true that the cerebellum is necessary for all variations of eyeblink classical conditioning, it is clear that many brain regions are engaged during the learning and that these areas contribute in many ways to the learning and memory that takes place.

The involvement of the hippocampus and limbic system remains a central area of study. From data that has been collected, it appears that the hippocampus becomes increasingly engaged and important for conditioning as the procedure becomes more complex. For example, under some circumstances, trace conditioning is highly dependent on an intact hippocampus, perhaps especially so when the CS is of short duration and the gap between CS offset and US onset is relatively long (i.e., the demand for maintaining the CS in memory before US presentation is relatively great). It appears that the hippocampus is important for discrimination/reversal learning and perhaps for processing contextual information during conditioning. These data are consistent with a large

body of literature suggesting a central role for the hippocampus in memory processing.

Eyeblink classical conditioning, similar to many forms of learning, has an emotional component because it is an aversive conditioning procedure. During eyeblink conditioning as well as other Pavlovian procedures, changes in autonomic responding can be seen after the first few CS-US pairings, including changes in heart rate and respiration. A number of studies have shown that the medial prefrontal cortex and associated thalamic areas are involved in eyeblink conditioning. It appears that prefrontal lesions have little or no effect on simple delay learning. While the lesion studies did not support a role for the medial prefrontal cortex in the acquisition process or as a storage site for memory, it has been suggested that the cortical area is involved in promoting the persistence of the memory trace for the CS during the trace period, hence its critical role in this kind of conditioning.

There has been a lot of recent interest in exploring the involvement of the amygdala in simple associative learning, especially its role in encoding fear and emotional aspects of learning. For example, stimulation of the central nucleus of the amygdala causes an increase in the UR amplitude during conditioning. Amygdala lesions disrupt maintenance of facilitation of the eyeblink UR and slow down the rate of eyeblink conditioning, thus further suggesting that the amygdala may be involved in processing aspects of the US and UR. Recording data seems to support this idea. For example, the activity of amygdala neurons has been monitored during a variety of learning tasks, including eyeblink classical conditioning, classical fear conditioning, and aversive instrumental conditioning. Robust learning-related activation of the central nucleus of the amygdala was seen during acquisition of all of these tasks. The basolateral nucleus of the amygdala, however, showed little activation during the eyeblink-conditioning task but significant activation during the fear-conditioning and instrumental tasks. In general, the amount of learning-related activity appeared to be related to the relative intensity of the US presented during the task as well as the somatic requirements of the task.

Neural Substrates Appetitive Classical Conditioning

A number of years ago, an appetitive classical conditioning task in rabbits, known as ‘classical jaw-movement conditioning,’ was developed to parallel the aversive eyeblink classical conditioning task. During jaw-movement conditioning, a tone or light CS is presented before a rewarding intraoral water or saccharin US. The UR in this procedure is a rhythmic jaw movement that precedes consumption of the liquid. With CS-US pairings, presentation of the CS elicits the jaw-movement response in the absence of the

US. While initial studies used this procedure to study motivational influences on learning, later studies explored the neural bases of the appetitive learning. An important observation was that jaw-movement conditioning was not critically dependent on the interpositus nucleus of the cerebellum. While lesions of the interpositus nucleus completely abolished conditioned eyeblink responses, they had no effect on the performance of jaw-movement CRs recorded from the same rabbit. A central role for the hippocampus in jaw-movement conditioning has been demonstrated. For example, jaw-movement conditioning produces robust CR-related activity in the hippocampus, but the within-trial pattern of activity recorded during jaw-movement conditioning differed from activity recorded during eyeblink conditioning when both types of training were given to the same rabbit. These data suggest that higher brain areas are critically involved in encoding jaw-movement conditioning, and importantly, the cerebellum does not seem to play a critical role in encoding this appetitive conditioning task.

Classical Eyeblink Conditioning and Translational Research Approaches

Around 50 years ago, a shift was made away from using humans in eyeblink-conditioning studies and toward the development of animal models. As detailed above, the use of animal models have produced a wealth of data concerning how the brain encodes simple associative learning and memory. Interestingly, given the advancements recently made in our understanding of the brain correlates of eyeblink conditioning, there has been a recent renewed interest in the use of this procedure to study brain-behavioral correlates of clinical disorders – that is, eyeblink conditioning is being used in translational research programs interested in advancing our understanding of brain pathologies that accompany clinical disorders. The list of these translational efforts is indeed long and includes Alzheimer’s disease, Parkinson’s disease, fetal alcohol syndrome, obsessive-compulsive and anxiety disorders, schizophrenia, autism, and posttraumatic stress disorder, to name some.

The study of fetal alcohol syndrome provides a good example of this translational approach. This disorder is caused by excessive consumption of alcohol by pregnant mothers, which produces a variety of neural and behavioral deficits that depend on the timing and amount of alcohol that is consumed during pregnancy. One brain area that appears to be particularly susceptible to the alcohol-induced developmental insult is the cerebellum. Given the critical involvement of the cerebellum, eyeblink conditioning seemed to be an ideal behavioral paradigm to use concomitantly with experimental brain techniques to study brain-behavioral relations associated

with the disorder. A rat neonatal (i.e., third-trimester) model of the disorder was developed and it was shown that binge level exposures produced severe learning deficit in both juvenile and adult rats. Further, the neonatal alcohol exposure produced significant neuronal losses in regions of the cerebellum and brainstem known to be involved in eyeblink conditioning – lobule HVI of cerebellar cortex, the anterior lobe of cortex, the interpositus nucleus, and the inferior olivary complex. Unit recordings taken from the interpositus nucleus showed decreased CR-related activity that precisely predicted the observed learning impairment. In a recent study, children with fetal alcohol syndrome and related impairments were tested using the eyeblink-conditioning task. They showed severe deficits in conditioning as predicted by the animal model data and the large literature showing the involvement of the cerebellum in eyeblink conditioning. These data suggest there may be great value in working back and forth between the animal model and human clinical populations in describing the brain pathology and the behavioral phenotype associated with clinical disorders such as fetal alcohol syndrome.

Conclusion

The simplicity of the eyeblink classical conditioning procedure and the great experimental control that it affords have undoubtedly been key reasons that its use has advanced our understanding of the neural basis of conditioning more than any other behavioral procedure that is available. Indeed, the amount of neural and behavioral data generated through the use of eyeblink conditioning is perhaps rivaled only by the impressive amount of data on brain function that has been generated through the use of fear conditioning, another task that holds great promise for studying the neural substrates of learning. Future eyeblink-conditioning studies will undoubtedly further refine the nuances of the critical brain circuitries that have been described to date as well as explore molecular and cellular processes that underlie the neuronal plasticities that have been observed. In addition, the use of eyeblink conditioning in translational research aimed at uncovering the correlates of clinical disorders holds great promise for providing the keys to the mysteries of brain function and dysfunction that continue to be of interest to researchers from many fields.

Glossary

Activational effects – Effects of sex hormones that cause transient changes in brain and behavior. Examples are the effects of fluctuations of estradiol and progesterone levels during the estrous cycle on female sexual behavior.

Amygdala – Telencephalic area embedded in the temporal lobe that controls cognitive, behavioral, and autonomic responses to emotionally charged stimuli. In rats, the posteromedial nucleus is larger in males than in females, a difference that depends largely on activational effects of gonadal steroids. In humans, the amygdala shows sex differences in activation related to emotional stimuli.

Bed nucleus of the stria terminalis (BNST) – Telencephalic area located near the rostral pole of the lateral ventricle that controls behavioral and autonomic responses to emotionally charged stimuli. It shares architectonic and neurochemical characteristics with the central and medial divisions of the amygdala but differs in connectivity. In humans, its central subdivision is larger and contains more cells in males than in females except for male-to-female transsexuals, who show a female-typical anatomy. This suggests a role for the BNST in gender identity.

Kisspeptin – A recently discovered peptide that plays a role in the initiation of puberty as well as in the release of gonadotrophic hormone releasing hormone (GnRH). Kisspeptin neurons have been found in the arcuate nucleus and the anteroventral periventricular nucleus (AVPV). In rodents, the latter area is much larger and contains more cells in females than in males. The sex difference in the number of its kisspeptin neurons goes in the same direction, but is much more extreme. For example, male rats show virtually no kisspeptin cells in the AVPV.

Organizational effects – Effects of sex hormones exerted early in development that cause permanent changes in brain and behavior. Higher levels of testosterone during development, for example, make male mammals more likely to show male sexual behavior (masculinization) and less likely to show female sexual behavior (defeminization). If levels are low, a female pattern of behavior develops.

Random X inactivation – An epigenetic process by which one of the two copies of the X chromosome in female mammalian cells is inactivated.

Sexually dimorphic nucleus of the preoptic area (SDN)

(SDN) – Nucleus in the medial preoptic area that was first described in rats, where it is about 5 times larger in males than in females. Similar sex differences have been found in the preoptic area of other species, including humans. Currently, the most plausible function of the SDN is partner preference in males. There is no known function for this nucleus in females.

Sry – Gene on the Y chromosome that codes for sex determining factor, the protein that causes the primordial gonad to develop into a testis. Sry stands for sex determining region Y (chromosome). Sry is also expressed in the adult male brain and may thus influence neuron function in a sex-dependent fashion.

Vasopressin – Neuropeptide that was initially identified as a hormone synthesized by hypothalamic neurosecretory cells and released into the blood in the posterior pituitary (antidiuretic hormone). Vasopressin is also made by nonneurosecretory neurons and released in areas throughout the brain but especially in the limbic system, where it modulates autonomic process, social behaviors, and cognitive functions. In most vertebrates studied, vasopressin, or its nonmammalian homolog vasotocin, is expressed at higher levels in males than in females.

Practically, all reproductively active animals show sex differences in behavior. Sex differences in sexual behaviors are literally a fact of life. Likewise, sex differences in aggression and parenting were known long before there was any scientific interest in finding the cause of these differences. Our understanding of sex differences in cognitive behaviors has evolved from negative stereotyping and innuendo, usually intended to establish mental superiority of men, to a much more sophisticated understanding of the different ways in which humans and animals approach various cognitive tasks. Because behavior is generated by brains, they form a logical starting place for studying the physiological basis of behavioral differences. Sex differences have, in fact, been found throughout the brain, in almost any parameter imaginable. How these differences develop and what is their function forms the topic of this article.

Why Care about Sex Differences in the Brain?

There are sound medical reasons to study sex differences in the brain. Being born male or female influences the chances of developing specific neurological and psychiatric illnesses, the age at which symptoms develop, the course of illness, and perhaps even responsiveness to treatment. For example, women are twice as likely as men to become depressed, suffer from Alzheimer's disease, or develop multiple sclerosis, and at least 10 times more likely to develop eating disorders such as bulimia and anorexia nervosa. Boys are more than twice as likely to be dyslexic, suffer from Gilles de la Tourette syndrome, and 4 times more likely to be autistic or have an attention deficit and hyperactivity disorder than are girls. Men develop schizophrenia on average at an earlier age and the disease typically follows a more serious course than it does in women. Although societal factors may contribute to some of these differences, biology probably explains most of the variance. In some cases, the cause of the sex difference is clear. For example, Rett syndrome is a serious form of autism that is found almost exclusively in girls. It is caused by a spontaneous mutation of the MeCP2 gene. As this gene is found on the X chromosome, girls with Rett syndrome typically have one healthy and one mutated form of the MeCP2 gene. Having only one X chromosome per cell, male fetuses with this mutation typically do not make it to term. It has also been argued that the mutation occurs preferentially on the X chromosome derived from the father, which is found in girls only. The higher incidence of multiple sclerosis in women is another example that conforms to the higher incidence of autoimmune diseases in general. In this case, the cause of the sex difference appears to reside in the immune system rather than the brain. Rett syndrome and multiple sclerosis are exceptions, however. In most cases, we do not understand the cause of sex differences. As differences in the physiology and anatomy of the brain may contribute to differences in behavioral and neurological disorders, understanding the development and function of sex differences in normal brains is crucial.

There are solid basic scientific reasons to study sex differences as well. Sex differences present a unique perspective in figuring out how brains work. They allow us to compare sex differences in brain structure with those in brain function. The same is true for studying how brains develop the circuitry for stereotypical behaviors, in this case masculine and feminine behaviors. As sexual differentiation of brain and behavior can be manipulated hormonally or genetically, sex differences provide an alternative way of studying brain development in general. Although we are making inroads in understanding the cellular and molecular processes underlying sexual

differentiation, nature is not readily giving up its secrets as to how structural sex differences contribute to function, as is clear later in this article.

Sexual Differentiation

Central Role for Hormones in Sex Differences in Brain and Behavior

Hormonal effects on brain physiology and behavior

Alfred Jost's proposal in the 1940s that testes are crucial for the development of the mammalian male phenotype, and that without them bodies develop in a female direction, has driven research in the field of sexual differentiation for more than half a century, especially that of brains and behavior. The more recent discoveries of genes that direct the differentiation of the primordial gonad into a testis require minor reformulating of the theory on the mechanisms of sexual differentiation: sex chromosomal genes determine the differentiation of the gonads into testes or ovaries; the resulting differences in gonadal secretions cause all other differences.

For the following decades, differences in brain and behavior seemed to fall in line with Jost's principle. Initial research focused on processes linked with reproduction. For example, in the early 1950s, Harris and Jacobsohn demonstrated that male pituitary transplants placed directly under the hypothalamus sustained ovarian cycles in female rats, thereby disproving earlier claims that the pituitary was responsible for sex differences in gonadotrophic hormone release. Barracough and his collaborators then showed that single injections of testosterone propionate given shortly after birth caused permanent infertility in female rats. After identifying the anterior preoptic area as the site responsible for cyclicity in gonadotrophic hormone release, they concluded that the anterior preoptic area is undifferentiated at birth with regard to its subsequent control of gonadotropin secretion. They also concluded that in the absence of androgen the anterior preoptic area differentiates to sustain cyclicity whereas in the presence of androgen this area becomes refractory to both intrinsic and extrinsic activation, resulting in the tonic type of gonadotropin secretion observed in males.

At about the same time, William Young and colleagues demonstrated that administering testosterone propionate to pregnant guinea pigs increased the chances that their female offspring displayed male sexual behavior as adults while having the opposite effect on female sexual behavior. This work led to the important realization that gonadal hormones influence sexually dimorphic behaviors in two fundamentally different ways. Early in life, they direct the development of neural circuitry that will generate male- or female-typical functions and behaviors

in a male or female direction. These developmental effects are permanent and called organizational. For example, testosterone exposure during development increases the likelihood that animals will show male sexual behavior as adults. However, to show male sexual behavior, animals have to be exposed to testosterone in adulthood as well. This latter effect is transient and therefore called activational.

Sex differences in brain structure

Young and colleagues suggested that early androgen exposure causes a more subtle change in the brain than in genital morphology, one that is reflected in function rather than in visible structure. The first reports of sex differences hinted that differences were indeed subtle, but at least they were detectable. For example, in 1960, Kato reported higher serotonin levels in female than in male rat brains. A little while later, Pfaff showed that neonatal castration of rats permanently changed the size of nucleoli in hypothalamic neurons. In 1970, McEwen and colleagues showed that neonatal steroid treatment changed testosterone and estradiol uptake in rat brains. A year later, Raisman and Field reported the first sex difference in neural connectivity: male rats showed more synapses from nonstriatal origin on dendritic shafts and fewer on dendritic spines than did females. Although the functional significance of this finding is still unclear, it was a milestone because it showed that neonatal manipulations of gonadal hormone levels could reverse morphological sex differences. It mapped well, therefore, onto the concept of organizational effects of steroids.

After these admittedly subtle findings, Nottebohm and Arnold reported much more conspicuous differences in the size of song control nuclei in the brain of zebra finches and canaries. Males, which sing, had much larger song control nuclei than did females, which do not sing. This striking correlation between structure and function reinforced the notion that studying sex differences would allow one to link brain structure to function. Soon thereafter, equally impressive differences were found in the gross anatomy of mammalian brains. Arguably, the most famous of these was found in 1978 by Gorski and his colleagues in the sexually dimorphic nucleus (SDN) of the medial preoptic area of rats. This nucleus is 5 times larger in males than in females, which is remarkable considering that for years researchers must have overlooked this difference, which can be seen in Nissl-stained sections by the naked eye. Currently, hundreds, if not thousands, of sex differences have been reported, in almost any parameter imaginable. Remarkably, however, in most cases, we do not know the functional consequences of these differences for behavior.

Molecular mechanisms underlying hormonal effects

Gonadal hormones often have similar organizational effects on brain structure as they do on behavior. For example, the SDN attains a male size in females treated around birth with testosterone, and a female size in males castrated neonatally. Activational effects play no role, or at most, a minor role, as hormonal treatments of adult rats cannot reverse this sex difference. Other sex differences are caused in different ways. For example, the medial nucleus of the amygdala contains more cells that express the neuropeptide cholecystokinin in males than in females. This sex difference can be eliminated by treating males and females with similar levels of hormones. The same is true for sex differences in the size of subnuclei of the medial amygdala. Yet, other sex differences can be attributed to a combination of organizational and activational effects. For example, male rats have denser vasopressin projections from the bed nucleus of the stria terminalis (BNST) and amygdala than do females (**Figure 1**). This innervation is exquisitely sensitive to circulating gonadal hormones. Without these hormones, BNST and amygdala cells do not express vasopressin. Treating males and females with similar levels of gonadal steroids, however, does not equalize vasopressin content, unless males and females were exposed to similar levels of gonadal hormones during development. Clearly, sex differences in the brain can be caused by organizational or activational effects of gonadal hormones, or both.

A current focus is the cellular and molecular processes underlying organizational effects on the brain. Research at the molecular level, for example, indicates that masculinization, the process by which testosterone promotes the development of neural circuitry underlying male-typical behaviors, and defeminization, the process by which testosterone suppresses the development of neural circuitry needed to generate female-typical behaviors, can occur independently. For example, testosterone's effect on the development of male sexual behavior is mediated by prostaglandin E₂. Treating male rats with inhibitors of prostaglandin synthesis around birth blocks masculinization but not defeminization. On the other hand, blocking N-methyl-D-aspartic acid (NMDA) receptors during development inhibits defeminization, but not masculinization. These findings will help delineate the processes involved in the control of sexual behavior and may provide insight in the mechanism underlying sexual differentiation of other behaviors as well.

The use of genetically engineered mice is also helpful in this regard. For example, sex differences in the volume and cell number of distinct brain areas can be caused by differential cell birth, cell migration, cell differentiation, or programmed cell death. Of these four, cell death has been best documented. Areas such as the SDN, which are larger in males than in females, show higher levels of

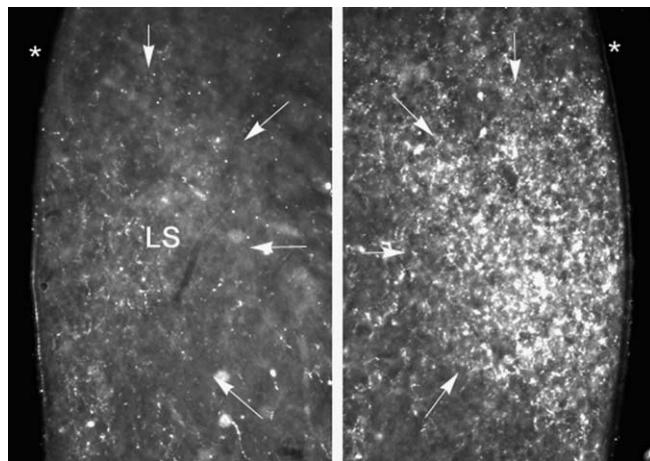

Figure 1 Sex difference in vasopressin innervation (arrows) of the lateral septum (LS). Females (left panel) show a much sparser innervation than males. Asterisks are placed in lateral ventricles. Modified from De Vries GJ and Panzica GC (2006) Sexual differentiation of central vasopressin and vasotocin systems in vertebrates: Different mechanisms, similar endpoints. *Neuroscience* 138: 947–955.

apoptosis, an orderly process of programmed cell death, in females around birth. The opposite is true for areas that are larger in females than in males. Mutant mice with abnormal apoptosis allowed a direct test of the hypothesis that this differential cell death contributes to sex differences in brain areas. For example, the principal nucleus of the BNST is larger and contains more cells in males than in females. This sex difference, however, is completely eliminated in mice unable to produce Bax, an obligate protein in the molecular cascade leading to neuronal cell death. The Bax mutation, however, leaves the sex difference in vasopressin expression intact, suggesting that in this case testosterone influences the capacity of individual cells to synthesize vasopressin. A change like that is likely caused by epigenetic changes, which is rapidly becoming a focus in research on sexual differentiation.

Direct Role for Sex Chromosomes

Model system to distinguish between chromosomal and hormonal contributions

The Jost doctrine that all sex differences in nongonadal tissues can be traced back to differences in gonadal secretions may not be as generally applicable as first thought. Several sex differences (e.g., those in songbird plumage, and in the development of pouch versus scrotum in wallabies (a marsupial)) likely depend directly on sex chromosomal composition in those tissues rather than on differences in gonadal hormone levels. Research on bird song had hinted that this might be true for brains as well. Sex differences in bird song or song control areas are not readily, or at all, reversed by hormonal manipulations. To test whether sex chromosomes may have direct effects in mammals as well, a mouse model system has been developed that differentiates between direct actions of sex

chromosomal composition (XX vs. XY) and gonadal hormones. In this model, female mice with the familiar XX genotype are crossed with males with an XY⁻ *Sry* genotype. The Y chromosome of these mice lacks the *Sry* gene on the Y chromosome, which normally directs the growth of the testis. XY⁻ *Sry* mice, nevertheless, develop a male phenotype because they have an *Sry* transgene inserted on an autosomal chromosome. The offspring of XX and XY⁻ *Sry* mice consist of XX and XY⁻ mice of either sex, depending on whether they inherit the *Sry* transgene.

Comparing XX and XY⁻ mice within sex (defined on basis of gonad) has revealed a number of traits that are influenced by sex chromosomal composition, for example, aggressive and maternal behavior. In addition, the vasopressin projections of the BNST show a modest but significant direct effect of sex chromosomes. XY animals of either sex have slightly denser projections than XX animals. In each of these cases, however, gonadal hormones seem to be the most important factors in sexual differentiation. Yet in some cases, sex chromosomes do seem to be the main cause of sex differences in neural structure or function. For example, gonadectomized XX mice are less sensitive to painful stimuli than XY⁻ mice, and express more of the neuropeptide precursors prodynorphin and preprotachikin in the striatum, irrespective of their gonadal sex. Similarly, fetal midbrain cell cultures from XX mice yielded more cells that express tyrosine hydroxylase (TH), the rate-limiting enzyme in dopamine production, than cultures from XY⁻ mice.

These findings suggest that sex chromosomes cause sex differences in brain and behavior indirectly as well as directly. The presence or absence of a Y chromosome determines whether an individual will develop testes or ovaries. Resulting differences in gonadal hormone levels then cause differentiation of the brain. In parallel,

differential expression of X and Y chromosomal genes in the brain causes additional differences. Currently, only a few traits are known to be directly influenced by sex chromosomes. However, as research on direct sex chromosomal effects on brain traits is relatively new, we may have seen only the tip of the iceberg.

Mechanisms underlying direct sex chromosomal effects

Seeking the molecular mechanisms underlying direct chromosomal effects may prove easier than identifying genes that mediate steroid action on the brain. Whereas gonadal hormones may target genes on any of the chromosomes, the genes primarily responsible for direct sex chromosomal effects are restricted to the sex chromosomes. The most obvious candidates are genes found exclusively on the Y chromosome, such as *Sry*. In fact, *Sry* is expressed in brain tissue of adult rats as well as mice, most notably in the substantia nigra. Treating animals with *Sry* mRNA antisense reduces TH production and causes motor defects in males but not in females, presumably by compromising dopamine neurotransmission. Therefore, the dopamine system, which on the surface is not strikingly dimorphic, harbors significant differences in biochemistry. Perhaps this difference contributes to the 50% higher incidence of Parkinson's in men than in women.

Other factors underlying direct chromosomal effects may be differences in the dosage of X chromosomal gene products. Although such dosage differences are in most cases prevented by random X inactivation, during the process by which the expression of most genes on one of the two X chromosomes is blocked, some genes escape inactivation, and they may therefore be expressed at different levels in male and female brains. Differential imprinting of X chromosomal genes may also cause sex differences. In male brains, all X chromosomes are inherited from the mother, and thus they carry maternal imprints that either block or alter the expression of select X chromosomal genes. In female brains, X chromosomes are derived from both parents and therefore they carry maternal as well as paternal imprints. As paternal and maternal imprints differ, this may lead to differential expression of X chromosomal genes. An interesting case is found in Turner's syndrome, where one of the two X chromosomes is lost early in development, leading to an XO genotype. Girls with Turner's syndrome who retained the paternal X chromosome have better social skills and a slightly higher verbal IQ than girls who retained the maternal X chromosome. It is tempting to correlate this difference with sex differences in social skills and verbal IQ, which tend to favor girls. Perhaps girls outperform boys in part because approximately half of their brain cells express paternal X chromosomal genes. Males will have to do with the maternally imprinted X chromosome.

Function of Sex Differences in the Brain

Our understanding of sexual differentiation stands in remarkable juxtaposition to our understanding of the function of sex differences, which is extremely limited. Research on the SDN illustrates how difficult it is to relate sex differences in brain structure to those in function. Because the medial preoptic area is essential for male sexual behavior, it has been attractive to link sex differences in this area to differences in male sexual behavior. However, lesions centered in the SDN produce little-to-no decrements in male sexual behavior. Discrepancies in the effects of perinatal endocrine manipulations on SDN morphology and male sexual behavior further weaken the link. For example, prenatal testosterone treatment increases SDN volume in female rats but not their propensity to show masculine behavior as adults.

Inconsistencies between sex differences in male sexual behavior and sexual dimorphism have also been reported for the male nucleus of the preoptic area (MN) in ferrets. This nucleus depends on the presence of testosterone before birth. If levels are low, as is true for females, no MN develops. If testosterone is given to females immediately after birth, females develop a masculine pattern of sexual behavior but not an MN. Interestingly, however, the MN may be important for partner preference as lesions centered in the MN cause male ferrets to prefer male over female conspecifics. Homologous sexually dimorphic structures may play a similar role in other mammals. Lesions of the SDN, for example, disrupt partner preference in rats as lesions of MN do in ferrets. Natural variation in male versus female preference also correlates with the size of sexually dimorphic nuclei in the MPOA. For example, about 8% of rams prefer mounting male rather than female sheep. These male-oriented rams have an ovine SDN only half the size of that of female-oriented rams. Interestingly, humans have an area in about same region, the third interstitial nucleus of the anterior hypothalamus (INAH3), which is larger in men than in women. In homosexual men, however, the size of INAH3 is intermediate to that of heterosexual men and women.

Even if a structural sex difference in the brain correlates well with a sex difference in behavior, such as appears to be the case with sexual preference, it remains still unclear what, for example, a difference in cell number buys one sex over the other in terms of function. To answer this, one has to identify the connections and functions of the components that make up a sexually dimorphic system. In the spinal cord, this is relatively easy. For example, the ventral horn in the lumbar region of the spinal cord contains a nucleus that is much larger in males than in females, the spinal nucleus of the bulbocavernosus in rodents such as rats and mice, and Onuf's

nucleus in dogs, hyenas, and humans. This nucleus contains motoneurons that innervate muscles at the base of the penis. Homologous muscles in females are much smaller or even vestigial. In this case, the function is obvious. Males need more motoneurons because the muscles that they target contain more muscle fibers. These muscle fibers are involved in genital responses that are clearly dimorphic. Similarly, sex differences in medullary motoneurons that innervate the muscles of the larynx in clawed frogs or muscles of the dewlap in green anoles have been linked to more frequent and intense use of these structures during courtship in males. In the brain, it is much harder to link structure to function, in large part because connections are far more numerous and complex.

Using Neurochemical Markers to Study the Function of Sex Differences

Studying neurochemical markers in sexually dimorphic systems has proven very helpful in this regard. Focusing on neurotransmitter systems, for example, helps trace the anatomical connections of subsets of cells within sexually dimorphic areas. It also allows more specific manipulations than lesioning entire cell groups or transecting projections. For example, injecting receptor agonists and antagonists or making conditional knock-outs or knock-ins have proven useful in delineating systems engaged in food intake and energy balance and may yield similar success in research on sex differences.

A recent success story concerns the anteroventral periventricular nucleus (AVPV) of mice and rats. In rodents, the AVPV is larger and contains more neurons in females than in males. This area is important for generating the surge in luteinizing hormone (LH) in response to rising levels of estradiol. This surge is found in females but not in males. A subset of AVPV neurons expresses Kiss1-mRNA and its gene product, kisspeptin. In mice, females have 10 times more AVPV kisspeptin neurons than males; in rats, males express almost no kisspeptin, making the sex difference nearly absolute. These kisspeptin neurons appear to contact neurons that synthesize gonadotropin-releasing hormone (GnRH). As kisspeptin triggers a surge of LH by stimulating these neurons, the higher number of kisspeptin neurons in females may explain the sex difference in the LH surge and thereby at least in part the sex difference in cyclicity of gonadal hormone release. The key to the success of the kisspeptin story may be similar to that of the sexually dimorphic nuclei in the spinal cord. Kisspeptin neurons form part of a final common pathway, in this case, of the sexually dimorphic control of the LH surge. The quest for the function of sexually dimorphic neural systems with no clear links to peripheral structures has turned out to be much more difficult.

Dual Function of Sex Differences in the Brain

One reason for this may be that the function of structural differences is too narrowly interpreted. We like to think that sex differences in brain structure beget sex differences in behavior. We typically overlook the possibility that sex differences in brain structure may allow males and females to reach similar behavioral endpoints even though their bodies and physiology differ. The need for such compensation is clear in behaviors that are shown by both sexes but depend on specific hormonal conditions in one sex that never occur in the other, for example, parental behavior in prairie voles.

Prairie voles form stable pairbonds, in which both parents take care of the pups. Once pups are born, males and females show similar parental behavior with the exception of nursing. Female voles have to experience the hormonal changes related to pregnancy as well as give birth naturally to become fully parental. Obviously, males need a different strategy. Part of this strategy appears to be engaging the sexually dimorphic vasopressin innervation, as blocking the vasopressin projections from the BNST inhibits parental behavior in males.

In rats, the same innervation can cause as well as prevent sex differences in brain function. For example, the higher levels in males probably make males more aggressive than females, as vasopressin stimulates aggressive behavior. On the other hand, the same higher levels appear to prevent sex differences in social recognition memory. Blocking vasopressin neurotransmission blocks vasopressin recognition memory in males, but not in females, thereby inducing a sex difference in performance that was not present before. In relation to this, in mice, a null mutation of vasopressin's V1a receptor reduces anxiety-related behaviors in males, but not in females. These differential effects are exactly what one would predict for a sex difference that may cause as well as prevent sex differences in behavioral output. Sex differences in vasopressin transmission may also influence human behavior. For example, a specific variation in DNA sequence upstream of the V1a gene has been linked to differences in pairbonding in men but not in women. Men with that variation are less likely to be married and, if they are, more likely to have had serious marital discord. Because the same variation has also been linked to disorders such as autism, it could potentially contribute to sex differences in these disorders.

Cause of Sex Differences in Behavioral and Neurological Disorders Revisited

Just as gonadal hormones and sex chromosomes can direct normal brain development in male or female direction, they may also increase the vulnerability for, and course of,

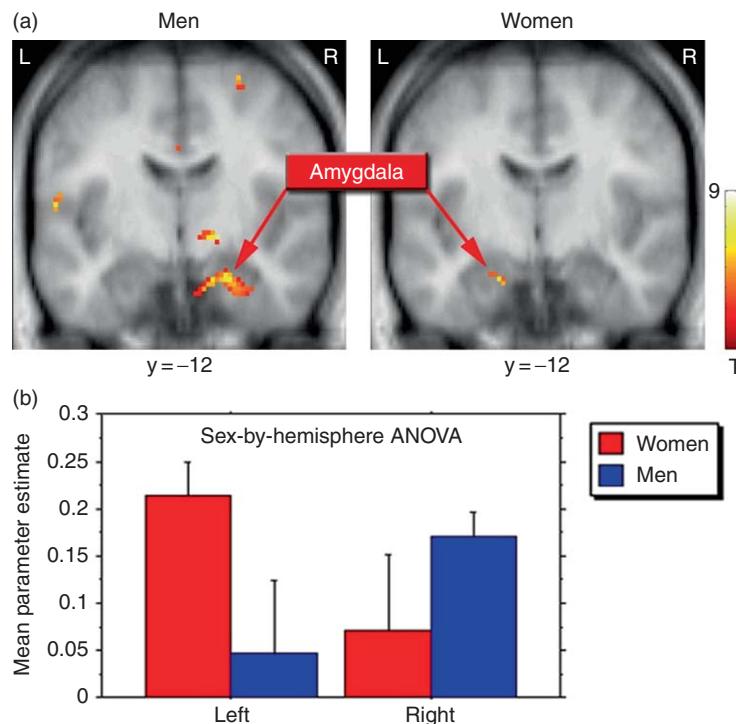

Figure 2 Functional magnetic resonance imaging study showing higher activation of the left and lower activation of the right amygdala in women than in men during a recall test for pictures with a negative emotional content ($F(1,13) = 7.99$, $P = 0.022$). From Cahill L, Uncapher M, Kilpatrick L, Alkire MT, and Turner J (2004) Sex-related hemispheric lateralization of amygdala function in emotionally influenced memory: An fMRI investigation. *Learning and Memory* 11: 261–266.

behavioral and neurological disorders. Although in most cases the nature of differences in these disorders is not well understood, there are many possible factors. For example, higher levels of circulating estrogen in women may offer greater levels of neuroprotection. Other factors may depend on sex differences in the brain. One possibility, for example, is directly related to males and females using different neurochemistry and neural circuitry to reach similar behavioral endpoints. This is probably not just vasopressin's prerogative. Strokes centered in similar areas in the brain can have different outcomes for men and women in, for example, language and visuospatial abilities. In addition, functional imaging studies show that male and female brains activate different areas during specific cognitive tasks even if there are no clear differences in performance. This is true, for example, for specific language tasks that show a more lateralized activation pattern in males than in females. It is also true for remembering images that evoke negative emotions, which activate the right amygdala more in males and the left amygdala more in females (Figure 2). All these studies suggest that men and women employ different neural circuitry for similar tasks, which almost by definition leads to different vulnerabilities to behavioral and psychiatric disorders.

Glossary

Familiarity – The mere judgment of knowing a stimulus that is currently present.

Recognition memory – When something previously experienced is identified as familiar when encountered again.

Recollection – The full recall of an event elicited by a stimulus that is currently present.

Setting the Stage: Recall versus Recognition, Familiarity versus Recollection

Recognition and recall are memory processes allowing conscious access to information previously encoded and stored in long-term memory. Recall is the self-organized retrieval of an event from long-term memory without any help (free recall) or based on partial information (cued recall). The tip-of-the-tongue phenomenon is a typical recall failure. Recognition, by contrast, is the mere decision that a currently present person, object, place, or event has been encountered or experienced before; hence, it is often, though not always, more efficient than recall.

Recall and recognition are the retrieval processes of a specific memory system – termed declarative, explicit, or cognitive – which include episodic memory for personal events in time and semantic memory for facts about the world. This system is distinct – functionally and anatomically – from the procedural, implicit, habit memory system, which simply expresses previously acquired skills through performance. Unlike procedural learning, which entails a lengthy acquisition phase, new information is rapidly committed to declarative memory. Accordingly, a characteristic common to all recognition-memory tasks is the use of a single exposure to the stimuli to be memorized.

Declarative memory is the system that is selectively disrupted in human amnesia. In most patients this syndrome leads to dense impairments in both recall and recognition, but relative sparing of recognition over recall has nevertheless been observed in a few amnesic patients. Recognition tasks are therefore markers of declarative

memory – crucial for understanding human amnesia – with the reserve that they cannot provide insights into all forms of declarative memory, but only into a subset of declarative memory processes.

Recognition itself is not a single process as it can yield two different outcomes: either a pure familiarity/novelty judgment or a full-event recollection akin to recall. The former is epitomized by what is known as the ‘butcher-on-the-bus phenomenon’: someone seen in an atypical context that we feel is familiar while failing to remember any information whatsoever about him or her. The latter consists, like recall, in remembering the information plus the spatiotemporal context of the latest episode in which it was encountered, for example, in remembering the butcher as well as his tiny shop down the block and the fantastic T-bone steaks he sold you last Saturday.

Determining whether familiarity and recollection form a unitary process depending on a single neural substrate or a dual process subserved by different brain structures is a challenge to current research. In the human, several protocols have been designed to distinguish recollective recognition from novelty/familiarity detection. They include the ‘remember/know’ procedure, which asks subjects whether the stimulus simply feels familiar (‘know’) or if they can recollect its context (‘remember’) and the ‘receiver operating characteristic’ (ROC) procedure, in which the relationship between the subjects’ confidence ratings of their recognition judgments and their accuracy is used to signal recollective recognition.

The above parsing of memory systems and recognition processes has a clear intuitive appeal and heuristic value when applied to the human with fully developed language skills. It is less helpful for nonverbal primates. Prelanguage human infants, as well as infant and adult monkeys, do possess recognition capabilities that can only be inferred from their changes in behavior. Which kind of ‘declarative’ memory do recognition tasks measure in these instances? Are familiarity/novelty judgments the only recognition tools available to nonverbal primates, or do they have access to some precursor form of recollection? In our current understanding of recognition, these questions remain open issues. Remarkable progress has, nevertheless, taken place with regard to the recognition memory of primates in the last five decades. The present article aims at emphasizing this progress.

A 50-Year-Old Plot: Amnesia, the Medial Temporal Lobe, and Recognition Memory

Brain regions other than the medial temporal lobe (MTL), in particular diencephalic structures, play a role in declarative memory and recognition processes – as long known from human Korsakoff patients (whose alcoholism-induced damage to this brain region yields global amnesia) and from numerous animal studies. However, the discovery of the crucial role of the MTL in human declarative memory, and the numerous subsequent monkey studies that this discovery prompted, has been the main driving force of research on recognition memory in primates. Hence, we chose to keep the present article focused on this brain region.

In 1950, Karl Lashley published the results of 30 years of lesions studies in rats spent “In Search of the Engram” only to conclude that, “It is not possible to demonstrate the isolated localization of a memory trace anywhere within the nervous system.” Thus, the theory of centralized memory storage in the brain had been laid to rest. At about this same time, however, quite different results emerged from Wilder Penfield’s investigations in epileptic patients about to undergo surgical removal of their epileptic foci. Presurgery stimulation of some cortical areas would repeatedly elicit detailed memories in the awake patient and subsequent unilateral temporal lobe resections could result in mild memory impairments. It is thus not surprising that we owe to one of Penfield’s collaborator, Brenda Milner, the description of the landmark case H. M. which, for more than 50 years now, has driven the study of memory and its neural underpinnings.

In 1953, Henry Molaison (26 February 1926–2 December 2008) – the now “Unforgettable Amnesiac” (*The New York Times* published on 4 December 2008 an obituary entitled “H. M. an Unforgettable Amnesiac, Dies at 82”) – was treated for intractable epilepsy by the bilateral removal of the MTLs. The result of this surgery was a devastating global (nonmodality specific) anterograde amnesia that persisted through his entire life, with a milder retrograde amnesia disrupting events close to the time of his operation without affecting his childhood memories. This profound deficit made the skill-learning capabilities that were later proved to be retained by H. M. all the more remarkable. H. M.’s case thus established three important points: (1) the MTL is required to encode some new memories, but some memory functions remain intact after MTL damage, (2) because some past memories survived, the MTL is not the permanent storage site of long-term memory, and (3) to the extent it is involved in retrieval, this role must be time limited as well. The now prevailing concept of multiple memory systems comes directly from H. M. and other patients suffering like him from global anterograde amnesia.

The MTL is a large region including two deep structures – the amygdala and hippocampus – which are wrapped rostrally by the rhinal (entorhinal and perirhinal) cortices, and caudally by the parahippocampal cortex (Figure 1). As estimated by William Scoville at the time of surgery, bilateral removal of the MTL in H. M. involved most of these structures. Why then was H. M.’s memory deficit attributed to the sole hippocampal damage? The original study by Scoville and Milner, in 1957, concerned 30 patients with bilateral temporal lobectomy. The three patients, who developed the amnesic syndrome, including H. M., had estimated excisions that extended sufficiently posterior to include a large portion of the hippocampus in addition to the amygdala. A subsequent study by Penfield and Milner, in 1958, involved 90 patients with temporal lobectomies that, although posterior enough to damage a large portion of the hippocampus, were only unilateral. Two patients, nevertheless, developed the amnesic syndrome.

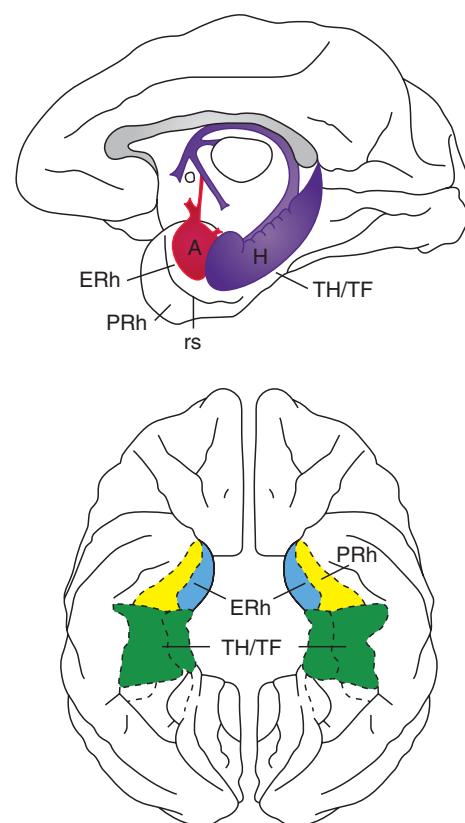

Figure 1 View of the medial surface (top) and of the ventral surface (below) of the brain of a rhesus monkey depicting the approximate location of the amygdala and the hippocampus – which lie deep in the temporal lobe and are shown in red and purple – and the extent of cortical areas, such as the entorhinal cortex (ERh, shown in blue), the perirhinal cortex (PRh, shown in yellow), and areas TH/TF on the parahippocampal gyrus (shown in green). These brain structures have a high degree of homology between rodents, monkeys, and the human.

Autopsy findings from one of this patient revealed a shrunken and necrotic hippocampus in the unoperated temporal lobe without any obvious damage to neighboring structures. A moderate amnesic syndrome was later described in a patient who suffered an ischemic event yielding a medial temporal damage seemingly restricted to a bilateral cell loss in the CA1 field of the hippocampus. These are the main findings that imposed the idea of the hippocampus as the structure whose bilateral damage was responsible for human amnesia.

What was not immediately forthcoming was similar evidence from the animal literature. Contrasting with the devastating effect of MTL damage on human memory, damage to the hippocampus in monkeys initially appeared to have very limited and somewhat specific effects on monkey memory. For some time it appeared that there was no comparison between the human and the monkey in spite of the high degree of anatomical homology between the two species with respect to the MTL structures.

In 1975, Mishkin and Delacour modified the matching-to-sample memory task developed by Gaffan in 1974 so that it could readily be learned by monkeys, while being closer to tests of human recognition memory, known as trial unique. They use a nonmatching rather than a matching rule to take advantage of monkeys' natural attraction to novelty. To better approximate the recognition tasks used in the human, they opted for a large pool of stimuli, creating a version of the task with 'trial-unique' stimuli; that is, rather than requiring the monkey to remember which stimulus had been seen most recently (recency memory), the new version simply required the monkey to indicate which stimulus was novel, while avoiding the previously seen other stimulus (recognition memory). An other crucial change was to combine this new task with extensive MTL ablations similar to that sustained by H. M., that is, encompassing both the amygdala and the hippocampal regions. Mishkin demonstrated for the first time in 1978 that, whereas amygdalectomy or hippocampectomy alone produce mild impairments at best, combined lesions, effectively replicating H. M.'s damage, produce a severe impairment.

Continued work in human amnesic patients further characterized the nature of the deficit as being limited to particular long-term memory processes, termed 'declarative,' 'episodic/semantic,' or 'explicit' memory, and those processes that are spared in human amnesics termed 'nondeclarative' or 'implicit' memory were also shown to be spared in the operated monkeys. This research has vastly increased our knowledge about the neural bases of memory and generated models in monkeys and rodents, and at the cellular level in invertebrates.

The Leading Actor: Delayed Nonmatching-To-Sample

As delayed nonmatching-to-sample with trial-unique stimuli (DNMS) was the first task to successfully demonstrate a recognition-memory deficit in monkeys accurately modeling that produced by human amnesia, it became the benchmark task in monkey research for about 15 years.

Delayed nonmatching-to-sample with trial-unique stimuli (**Figure 2(a)**) is simple in that monkeys learn to displace junk objects to obtain a hidden food reward. However, food is only located under objects that have not been seen recently; that is, animals are trained to associate novelty with reward. In the basic paradigm, the monkey is seated in a sound-attenuated chamber (Wisconsin General Testing Apparatus (WGTA)) behind an opaque screen. When the screen is raised, the monkey views a testing tray containing three equidistant food-wells, which can be covered with junk objects, hiding either a baited or empty well. Training takes place in two phases for each trial: sample and choice (**Figure 2**). During the sample phase, a single object covers the central food-well and when displaced, a food reward can be retrieved. The screen is then lowered and the now-familiar sample object is moved to cover a lateral well (empty) while a novel object covers the opposite lateral well (baited). After a brief period, typically ranging from 5–10 s, the screen is raised and the monkey must choose one of the objects. If the animal remembers the sample object, and correctly applies the nonmatching rule 'choose the unfamiliar item,' then the novel item is chosen and the food reward can be retrieved. When the animal reliably masters the rule governing the task, memory can be further manipulated (1) by introducing variable delays between the sample and choice phases (generally from 30 s to 40 min), occupied or not with interfering tasks, (2) by increasing the number of items to be remembered (list learning, generally from three to 10), and (3) by changing the nature of the information to be remembered (i.e., stimulus location, or nonvisual, e.g., tactile, features).

The early work by Mishkin and others on this task confirmed that large lesions to the MTL dramatically impaired performance while sparing performance on tasks such as visual discrimination learning in which monkeys learn a set of 20 concurrent discrimination problems that are presented only once per day, thus with 24-h delays. These results seemed to match the impaired and spared performance capabilities of amnesic patients, such as H. M., who could not retain new information for more than a few seconds without active rehearsal, but could improve over many trials to perform tasks such as mirror drawing, or the incomplete figures task. However, as a measure of combined amygdalo-hippocampal

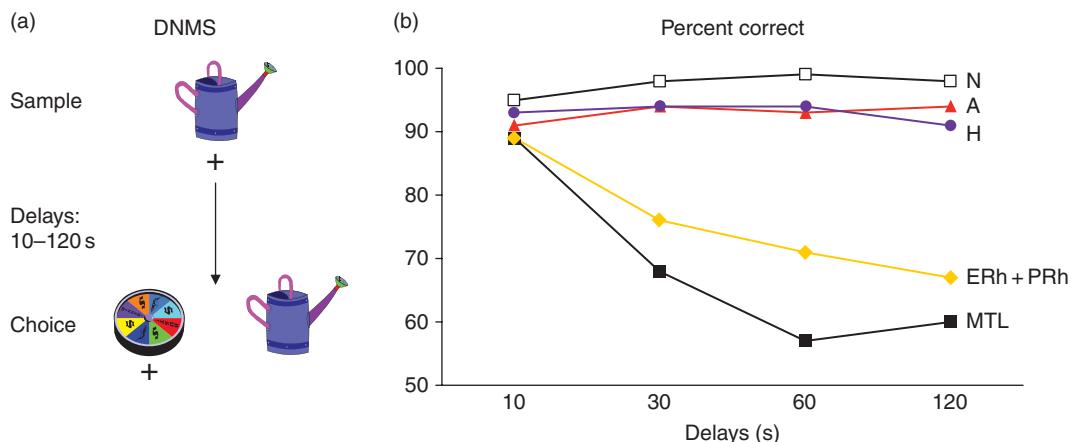

Figure 2 (a) The delayed nonmatching-to-sample (DNMS) task. During the sample presentation, central well of a 3-well tray is baited with a reward (+) and covered by an object that the subject displaces to retrieve the reward. After a delay varying from 10 to 120 s, the two lateral wells are now covered with two objects, one is the familiar positioned above an empty well and the other is a new object positioned above a baited well. Subject must displace the new object to retrieve the reward. The number of correct choice over 100 trials is used to assess visual recognition performance. (b) Performance scores obtained at each delay by normal monkeys (N) and monkeys with either amygdalectomy (A), hippocampectomy (H), combined amygdala and hippocampal lesions (MTL), or combined entorhinal and perirhinal lesions (ERh + PRh). Note that animals with the combined cortical lesions (ERh + PRh) are almost as severely impaired and those with the MTL lesions, whereas those with either amygdalar or hippocampal lesions alone are only mildly impaired. Adapted from Mishkin (1978) and Meunier *et al.* (1993).

memory function, the results from DNMS task were soon called into question.

More selective lesion techniques made it possible to parse out the individual contributions of MTL structures to recognition memory. In 1989, Zola-Morgan, Squire, and Amaral showed that the addition of cortical-sparing radiofrequency amygdala lesions to animals with hippocampal damage did not exacerbate their memory impairment. This raised for the first time the possibility that the hitherto overlooked cortical damage included in Mishkin's combined lesions contributed to the observed severe DNMS impairment. Subsequent studies, indeed, demonstrated that damage to the subjacent perirhinal and entorhinal cortices, removed along with the hippocampus and amygdala in the initial Mishkin studies (collectively referred to as rhinal cortex), devastates DNMS performance in monkeys (Figure 2(b)), producing as large an impairment as the combined hippocampo-amygda lesion.

The rhinal cortex is now unanimously viewed as a key substrate of recognition memory in primates. However, even the use of cell-selective neurotoxic lesions has not entirely solved the question of the hippocampal contribution. In 1998, Murray and Mishkin showed that monkeys with such neurotoxic, fiber-sparing damage to the hippocampus and amygdala showed normal DNMS performance out to 2-min delays. Nor were they impaired on lists of 40 items tested in reverse order and resulting in delays ranging from 30 s to 40 min. By contrast, Zola and colleagues, in 2000, found that irrespective of lesion method, hippocampal damage impaired DNMS performance at delays of 10 min and beyond. A meta-analysis of the results across several laboratories suggested that there

was a negative correlation, across and within studies, with the amount of damage on performance of the task. One possibility is that the lack of impairment in monkeys with selective hippocampal damage is due to the use of alternate strategies that allow the animal to bridge the longest delays. Indeed, when a distraction is inserted into the delay period (opening the screen at short delays, having the animal perform a motor task at longer delays, or removing it from the apparatus during 10-min delays), an impairment does emerge at the longest '10-min' delay that correlates 'positively' with the amount of hippocampal cell loss. In any case, in this study as in the earlier one by Meunier and colleagues in 1993, damage to the perirhinal cortex clearly produces a greater impairment on DNMS performance, with or without distraction and even at short delays.

Taken in context with what we now know of the anatomy of the region, it is clear that the perirhinal cortex is important for object memory, in particular for object identity, and that damage limited to this region produces a severe impairment in visual recognition memory. Indeed, it is currently being argued that the perirhinal cortex may be important for visual perception as well as memory. Hippocampal damage, by contrast, leaves short-term memory intact on this task, which is maintained both by the temporal cortical region, but also by active mechanisms when necessary, possibly controlled by the prefrontal cortex.

Likewise, the memory deficit produced by the selective hippocampal damage, resulting from forebrain ischemia, has been called into question. As mentioned above, ischemic events produce moderately severe memory

deficits in the human. Whereas ischemia was thought to damage only a single hippocampal cell field (CA1) in human patients, there is now evidence that the damage is more widespread. Furthermore, although ischemic damage in human amnesic patients impaired performance on a DNMS-like task, thus seemingly providing a direct link between the hippocampus and recognition memory, recent work by Mumby and colleagues, in 1996, showed that ischemia-related memory impairments were likely due to either extrahippocampal damage or dysfunction, as removing the entire hippocampus immediately after ischemia actually spared DNMS performance in rats. Thus, at best, the effect of hippocampal damage on DNMS for objects is mild and restricted to long delays and lists.

The Supporting Actor: Visual Paired Comparison

Similar to DNMS, the visual paired comparison task (VPC) utilizes a familiarization phase and a choice phase, but the task demands are quite different (Figure 3(a)). This task also takes advantage of the monkey's natural preference for looking at novel things in its environment but, contrary to DNMS, it requires neither rule learning, nor forced-choices between two objects to obtain a reward. For VPC, monkeys passively view a visual stimulus, typically a black/white image, and are allowed to look at it for a sufficient period to show habituation (i.e., they cease visual exploration). This familiarization period may range from 15 to 30 s of looking time. At this point, the image disappears and after a variable delay period (as brief as 1 s) the image reappears on the

screen, side-by-side with a novel image. Monkeys and the human naturally prefer to look at (explore) the stimulus they have not yet seen (novelty preference); thus, we infer that they remember the familiar stimulus. Given that the subject is not actively performing a task, it should not be surprising that performance levels on VPC are much lower than on DNMS, in which animals are trained to a 90%-correct criterion. With VPC, typical novelty preference is in the range of 65–70% preference for novelty, but this effect is reliable. Unlike the DNMS task, VPC has proven to be very sensitive to hippocampal damage at delays as short as 1 min. Similar to DNMS, however, damage to the medial temporal cortical areas produces impairments at shorter delays (~30 s for the parahippocampal gyrus and ~10 s for the perirhinal cortex). Thus, though the sensitivity may be greater in detecting recognition-memory deficits in the VPC task, the contributions of at least three regions of the MTL maintain a similar relationship to each other; that is, perirhinal contributes in the initial encoding and short-term retention of visual stimuli, whereas parahippocampal areas TH/TF and the hippocampus are required for longer retention (Figure 3(b)).

Similar to the DNMS task, the role of the hippocampus and parahippocampal areas in the VPC becomes more prominent when arrays or locations of objects are used as stimuli, making the task more spatial in nature, but the role of the perirhinal cortex is evident in all object conditions, irrespective of their spatial relations.

In sum, the two main measures of recognition memory show very different sensitivity to selective damage to hippocampus or temporal cortex. As noted above, however, in both tasks, each region contributes to recognition

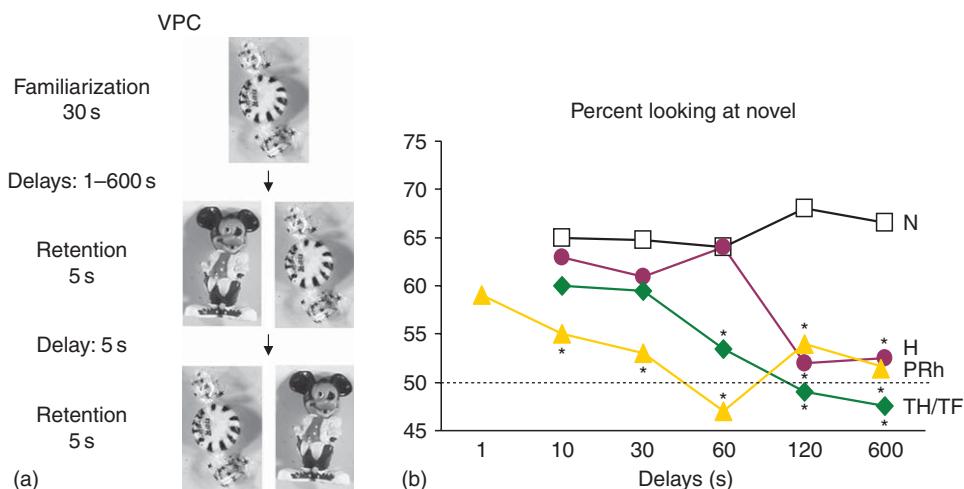

Figure 3 (a) The Visual Paired Comparison (VPC) task. The animal is familiarized with a picture of an object for a cumulative 30 s. After delays varying from 1 to 600 s, the familiar object reappears side by side with a new object for two short retention tests of 5 s each. Longer looking time at one of the two objects (generally the new one) during the two retention tests serves as a measure of recognition memory. (b) Percent looking at the novel images for normal monkeys (N) and those with neurotoxic lesions of the hippocampal formation (H) and aspiration lesions of the perirhinal cortex (PRh) or parahippocampal areas TH/TF. Dashed line indicates chance performance and asterisks defines scores that did not differ from chance. Adapted from Nemanic S, Alvarado M, Bachevalier J (2004) The hippocampal/parahippocampal regions and recognition memory: insights from visual paired-comparison versus object delayed nonmatching in monkeys. *Journal of Neuroscience* 24: 2013–2026.

memory in the same relative manner, but the absolute delay for which impairment occurred differs for each region damaged.

The Denouement: Performance of Human Amnesics on Animal Tests of Recognition

Human amnesia has, by and large, been tested with numerous tasks that are quite different from those used with animals. Thus, differences in the nature or extent of impairments between animal models and the human impairment may be due to task differences, to lesion differences, to evolutionary forces, in addition to the lack of language capabilities. This makes it important to test the human on animal memory tasks both to validate the behavioral assays, and better understand specific impairments in human patients. With regard to the lesion differences, the recent reports of patients with selective damage to individual components of the MTL provides an opportunity to test specific memory functions in the human with similarly selective damage, to compare the results with those from other species, and eventually, may inform the assessment of human patients.

Tests of human amnesic patients on animal tests of recognition, while relatively few, are largely in agreement with the animal findings when large temporal lobe lesions were used. For example, Squire and colleagues, in 1988, reported that a group of patients whose presumed damage was either diencephalic (Korsakoff's patients) or hippocampal (ischemic/anoxic patients) were severely impaired on the DNMS task, similar to the initial monkey studies. Similarly, Reed and Squire, in 1997, reported marked impairments on DNMS in patients with damage to the hippocampal formation. Unlike the monkey studies, however, they were also impaired on a concurrent discrimination task that is routinely spared in monkey studies and that presumably is a model of procedural memory. Based on the finding that performance levels on the task were directly related to declarative knowledge of the solution, Squire *et al.*, in 1988, suggested that, unlike monkeys, the human normally learns this task declaratively. By contrast, patients with damage restricted to the hippocampus have shown spared performance even on DNMS at delays up to 30 s, which follows more closely the results in monkeys and rodents and suggests that the impairment seen in the early studies of Squire might have resulted from damage to the adjacent MTL structures.

Similarly, recognition-memory impairments have been demonstrated on the VPC task, and, as in animals, these impairments are often larger than those obtained from matching or nonmatching tasks. For example, McKee and Squire, in 1993, reported novelty preference

in human amnesic patients when the delays were short (0.5 s) but not when delays were extended to 2 min or 2 h. Direct comparisons of the VPC and delayed matching-to-sample (DMS) performance have been investigated in the human amnesic patient Y. R. by Holdstock and colleagues in 2000. Patient Y. R. became amnesic after a possible ischemic infarct, resulting in reduced hippocampal volume and no other obvious pathology as measured by magnetic resonance imaging (MRI). This patient had previously shown impaired recall, but intact recognition on standard human memory tests. She also demonstrated severe impairments in memory on VPC demonstrating preference for novelty at the 0-s delay only. At the longer delays of 5 and 10 s, her performance fell to chance. By contrast, as described above, her performance was as good as that of controls on the DMS task with delays up to 30 s. Unfortunately, she was not tested at longer delays on DMS, but the reported results map onto those reported in monkeys in that hippocampal damage impairs VPC performance at much shorter delays than on DNMS. As for the animal studies, it is possible that the difference between VPC and DMS/DNMS performance is related to the forced choice required by the matching tasks that may encourage the subjects to rely on familiarity in the absence of recall to support good performance.

Importantly, the extensive knowledge accumulated in monkeys over the last decades combining the nonverbal tasks with selective lesions is now helping patients suffering from memory deficits. A human version of the monkey DNMS task developed by Barbeau and colleagues in 2005, and called the DMS48 has proved efficient to distinguish two subpopulations among patients suffering from mild cognitive impairment. Those who failed on the DMS48 were found to have grey matter loss predominantly in the MTL. As one hallmark of Alzheimer's disease is to initially develop in the perirhinal cortex, these patients seem at risk to develop the disease. By contrast, the patients who succeeded had damage elsewhere, making other etiologies such as Lewy body disease more likely. DMS48 could thus become a valuable clinical tool for early and accurate differential diagnosis of the different forms of dementia which plagues the world aging population.

Glossary

Delayed-response task – A task that involves the presentation of a set of stimuli with the instruction that it be held in memory across an interval of a few seconds (the ‘delay’) after which the subject must make a response to a query designed to assess the accuracy of the subject’s memory.

Domain-specific – Pertaining to a particular cognitive domain, such as verbal, visuospatial, visual-object, motoric, olfactory, etc. The domain may cut across sensory modalities, so that, for instance, auditory-spatial and visuospatial information might belong to the same processing domain.

Memory maintenance – A strategy for keeping memories ‘active’ that involves repeatedly and iteratively focusing internal attention on a set of items currently held in working memory.

Prefrontal cortex – A region of the frontal lobe that is located anterior to the motor cortices and constitutes, in the human, nearly one-third of the entire neocortex. The capacity for many higher-order functions, including reasoning, planning, and memory, is largely subserved by the prefrontal cortex.

Short-term memory – Memory for sensory/perceptual information that has been encountered only a few seconds ago. Unlike working memory, the concept of short-term memory is specifically related to time and, moreover, does not necessarily refer to cognitive processes associated with information maintenance and manipulation.

Working memory – A cognitive system for the maintenance and manipulation of information that is currently within the focus of attention.

for resurrecting a past experience at the precise moment when we need it. To some extent this idea of memory as a passive phenomenon – consisting of certain properties and governed by certain rules, but not terribly amenable to strategic control or manipulation – was assumed in much of the early research on the psychology of human memory.

In the last 30 years or so, however, the study of memory in the human and other species has focused a great deal more on how ‘executive control’ – the ability of an animal to organize and regulate its own internal cognitive milieu – allows for memory to take on a dynamic and interactive quality, whereby its contents are hardly accidental or desultory, but rather are under the direct control of the conscious animal. A typical example of this sort of ‘top-down’ memory is when one has to keep a telephone number in mind during the interval that may intervene between hearing the number and actually having to dial the digits. If memory were always passive, we would not be able to keep the telephone book more than an arm’s distance away from the telephone – memory decay and interference would always ensure that by the time we were ready to dial the numbers they would have vanished from our mind. As everyone knows, however, the best way to succeed at this basic task is to mentally ‘rehearse’ the numbers – to say them over and over again to ourselves (overtly or covertly) – until the time comes to dial them into the telephone. Of course, all this rehearsing is a lot of ‘work,’ and it takes discipline, effort, and cognitive agility to keep the numbers mentally aloft, but in the end this kind of memory – this ‘working memory’ – is essential to the efficient and effective performance of the task at hand.

Defining Working Memory

A basic definition of the term ‘working memory’ – as it has come to be used in the neuroscience and psychological literature – is the online maintenance and manipulation of information that is not directly available in the current environment. Most of the time, in the context of behavioral paradigms testing some aspect of working memory, the information retained in mind has only recently arrived to the senses. This is also the case in our phone-book example in which the telephone numbers are perceived and then immediately transferred to a working memory rehearsal loop. It is important to emphasize, however, that this need not be the case. Information ‘in’ working memory may have been recently received from

Introduction

In everyday life we often complain of memory ‘coming and going,’ or ‘not being there when you need it,’ as ‘fading away with time,’ or as occasionally ‘escaping’ us. The ways we talk about memory often suggests that it is a passive phenomenon, something that more or less has a ‘mind of its own’ and is not to be summoned at will. Indeed, this characterization of memory is often accurate: there is not always a tried and true method, a strategy, or secret recipe

the environment but it may also have been retrieved from long-term memory. For instance, if a person were asked to retrieve his or her own telephone number from memory and then to covertly rehearse that number for some period, then the contents of memory would consist of an informational sequence whose proximal source is not the immediate sensory environment, but rather, a stored trace in long-term memory. This is an important aspect of working memory that distinguishes it from ‘short-term’ or ‘immediate’ memory in that both of the latter terms refer to the retention of information that has only just arrived to the senses. Thus, although working memory is often thought of as a special case or more detailed conceptualization of short-term memory, in fact, it refers to a broader class of memory phenomena involving the maintenance or manipulation of ‘active’ representations, without respect to their proximal source (i.e., long-term memory or recent sensory experience). Nevertheless, because recently received information very often lacks a preexisting representation in long-term memory (for instance, when the information is novel), many tasks designed to tap working memory are generally also considered short-term memory paradigms. As a result, there is a great deal of overlap between short-term memory and working memory research and the terms are sometimes used interchangeably despite the above-mentioned differences between the concepts.

The next section introduces the working memory model of Alan Baddeley and colleagues, provides a description of its main principles and underlying logic, and then describes its functional architecture. The remaining sections will be devoted to the neural organization of working memory as it has been established in neurobiological research in the human and other animals in the last 30 years.

The Working Memory Model

The central tenets of the Working Memory model of Baddeley and colleagues are as follows: (1) it is a limited-capacity system; at any moment in time, there is only a finite amount of information directly available for processing in memory; (2) the specialized subsystems devoted to the representation of information of a particular type, for instance, verbal or visuospatial, are structurally independent of one another; the integrity of information represented in one domain is protected from the interfering effects of information that may be arriving to another domain; and (3) storage of information in memory is distinct from the processes that underlie stimulus perception; rather, there is a two-stage process whereby sensory information is first analyzed by perceptual modules and then transferred into

specialized storage buffers that have no other role but to temporarily ‘hold’ preprocessed units of information. Moreover, the pieces of information that reside in such specialized buffers are subject to passive, time-based decay as well as inter-item interference (e.g., similar sounding words like ‘man,’ ‘mad,’ ‘map,’ ‘cap,’ ‘mad’ can lead to interference within a specialized phonological storage structure); finally, such storage buffers have no built-in or internal mechanism for maintaining or otherwise refreshing their contents – rather, this must occur from without – through the process of rehearsal, which might be a motor or top-down control mechanism that can sequentially access and refresh the contents that remain active within the store.

The initial working memory model proposed by Baddeley and Hitch argued for the existence of three functional components of working memory (**Figure 1**). The ‘central executive’ was envisioned as a control system of limited attentional capacity responsible for coordinating and controlling two subsidiary slave systems, a ‘phonological loop’ and a ‘visuospatial sketchpad.’ The phonological loop was responsible for the storage and maintenance of information in a verbal form, and the visuospatial sketchpad was dedicated to the storage maintenance of visuospatial information. These two slave-systems are thought to be independent in the sense they do not rely on the same storage resources – phonological and visuospatial codes are, as it were, implemented atop different mental hardware – but, nevertheless, they must be coordinated by a unitary central executive, and thus there can be a competitive relation between the two systems.

In the last 20 years, the concept of working memory as a system for the active maintenance and manipulation of information has been embraced by researchers studying the brain basis of memory and cognition, and the following sections trace the progress that has been made in uncovering the neural basis of just such a system. As a result of this effort to resituate working memory in the brain, the concept has not merely been dressed up in neural garb, but rather has been enriched and expanded in the process, and what has emerged is a better and more nuanced understanding of working memory.

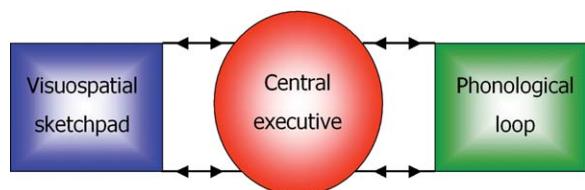

Figure 1 The Working Memory model comprises a control system, the central executive, and two storage systems – the visuospatial sketchpad and the phonological loop.

The Emergence of Working Memory as a Neuroscientific Concept

The first insights into the neurobiological underpinnings of a memory whose purpose is to bridge an interval of time comes from the work of Jacobsen, who studied nonhuman primate behavior after ablation to the prefrontal cortices (PFCs). Jacobsen showed that damage to the PFC of the monkey produces selective deficits in a task requiring a delayed response to the presentation of a sensory stimulus. The delayed-response tasks were initially devised by Hunter in 1913 as a way of differentiating between animals on the basis of their ability to use information not currently available in the sensory environment to guide an imminent response.

In the classic version of the delayed-response task (**Figure 2**), a monkey is shown the location of a food morsel that is then hidden from view and placed in one of two wells. After a delay period of a few seconds, the monkey chooses one of the two locations and is rewarded if his choice corresponds to the location of the food. Delayed response tasks measure a complex cognitive ability that requires at least three clearly identifiable subprocesses: to recognize and properly encode the to-be-remembered item, to hold an internal representation of the item ‘online’ across an interval of time, and, finally, to initiate the appropriate motor command when a response is prompted. Jacobsen showed that lesions to the PFC impair only the second of the above three functions, suggesting a fundamental role for the region in immediate or short-term memory. Thus, monkeys with lesions to PFC perform in the normal range on a variety of tests requiring sensorimotor behavior such as visual pattern discrimination and motor learning and control – that is, tasks without a short-term mnemonic component. Although the impairments in the performance of delayed-response tasks in Jacobsen’s studies were caused by large prefrontal lesions that often extended into the frontal pole and orbital surface, later studies showed that lesions

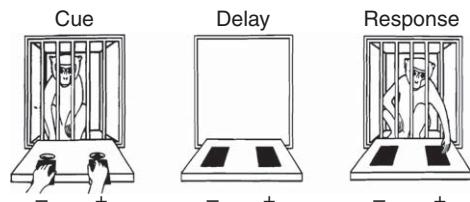

Figure 2 Three components of a spatial delayed-response trial. Left, the monkey observes the experiment place a morsel of food in a well (cue) before both wells are covered. Middle, an opaque screen is lowered for several seconds (delay). Right, the screen is raised and the monkey chooses one well by removing its cover. Adapted from Goldman-Rakic PS (1987) Circuitry of primate prefrontal cortex and regulation of behavior by representational memory. In: Plum F (ed.) *Handbook of Physiology – The Nervous System*, vol. 5, pp. 373–417. Bethesda, MD: American Physiological Society.

confined to the region of the principal sulcus produced deficits equally as severe.

In 1971, Fuster and Alexander reported the first direct physiological measures of PFC involvement in short-term memory. With microelectrodes placed in the PFC, they measured the firing patterns of neurons during a spatial delayed-response task and showed that many cells showed increased firing, relative to an inter-trial baseline period, during both cue presentation and the later retention period. Importantly, some cells fired exclusively during the delay period, and therefore could be considered pure ‘memory cells.’ The results were interpreted as providing evidence for PFC involvement in the focusing of attention on information that is being or that has been placed in temporary memory storage for prospective use.

Many subsequent electrophysiological studies have demonstrated memory-related activity in the PFC of the monkey during delayed-response tasks of various kinds, although it was Patricia Goldman-Rakic who first drew a parallel and then firmly linked the phenomenon of persistent activity in PFC to the cognitive psychological concept of ‘working memory.’ In a 1987 monograph, Goldman-Rakic – citing lesion and electrophysiological studies in the monkey, human neuropsychology, and the cytoarchitectonics and cortico-cortical connections of the PFC – argued that the dorsolateral PFC (the principal sulcus of the monkey) plays an essential role in holding visuospatial information in memory before the initiation of a response and in the absence of guiding sensory stimulation. In this and later work, Goldman-Rakic and colleagues developed a model of PFC in which visuospatial and (visual) object working memory were topographically segregated, with the former localized to the principal sulcus and the latter localized to a more ventral region along the inferior convexity of the lateral PFC (**Figure 3**). This domain-specific view of the prefrontal organization, which was supported by observed dissociations in the responsiveness of neurons in dorsal and ventral areas of the PFC during delayed-response tasks, could be viewed as an anterior expansion of the dorsal (where) and ventral (what) streams that had been discovered in the visual system in the posterior neocortex by Ungerleider and Mishkin. In addition, the parallel and modular nature of the proposed functional and neuroanatomical architecture of the PFC was in keeping with the tenet of domain independence in the Working Memory model of Baddeley and colleagues.

The Neural Organization of Working Memory

The early evidence from the animal literature emphasized the profound importance of the PFC in the performance of working memory tasks. Indeed, one

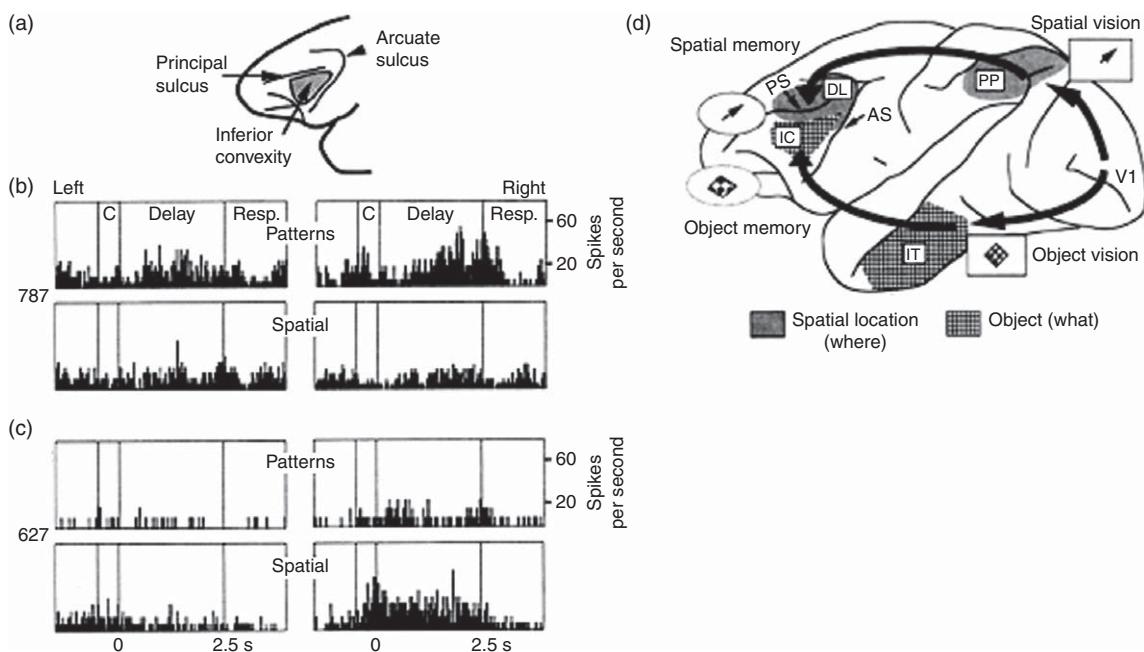

Figure 3 (a) Diagram of the frontal lobe and location of the principal sulcus and inferior convexity. (b) Responses of inferior convexity neuron with visual object-specific activity in the delayed-response task. The upper panels show delay-period activity for object-memory trials; the lower panels show lack of response on spatial memory trials. (c) Responses of the dorsolateral prefrontal neuron with spatial memory selectivity. The upper panels show lack of responsivity on object-memory trials; the lower panels show delay-period activity on spatial memory trials. (d) Schematic diagram illustrating the dorsal and ventral streams in the visual system and their connections with PFC; PS, principal sulcus; AS, arcuate sulcus; The posterior parietal (PP) is concerned with spatial perception, and the inferior temporal (IT) cortex with object recognition. These regions are connected with the dorsolateral (DL) and inferior convexity (IC) prefrontal cortices where, according to the Goldman-Rakic model, memory for spatial location and object identity are encoded in working memory. Adapted from Wilson FA, Scalaidhe SP, and Goldman-Rakic PS (1993) Dissociation of object and spatial processing domains in primate prefrontal cortex. *Science* 260: 1955–1958.

might conclude on the basis of these initial studies that an animal's ability to maintain information in an active state over a delay – a primary function of working memory – is the exclusive province of the operations of the PFC. One might have also concluded, based on the influential work of Goldman-Rakic and colleagues, that information stored within the PFC is segregated according to the processing domain, for instance, that certain subregions (i.e., dorsolateral portion) of the PFC store spatial information and other regions (i.e., ventrolateral portion) store information pertaining to object identity. Recent research on the neural basis of working memory has clarified and tempered these initial conclusions about the neural basis of working memory and the specific role of the PFC.

Working Memory and Domain Specificity in the PFC

As already mentioned, evidence for the neuroanatomical segregation of the what and where processing domains into dorsal and ventral pathways, suggested that a similar functional-anatomical organization might also hold for memory processes. Funahashi and colleagues – using a

memory-guided saccade task in the macaque and recording from neurons in the posterior part of the principal sulcus in the dorsolateral PFC (DLPFC) – showed that cells in this region code for the location of spatial cues (**Figure 4**). Moreover, lesions of the same region in the principal sulcus of the macaque impair performance on the spatial memory task, indicating the importance of the area for spatial working memory. In addition, Wilson and colleagues showed a double dissociation between object and spatial working memory in the macaque in which the DLPFC coded for spatial location memory in the delayed-response task and the ventrolateral PFC (VLPFC) coded for the identity of objects in memory (**Figure 3**).

Evidence for this neuroanatomical dissociation between spatial and object working memory was further bolstered by some human functional neuroimaging studies that revealed similar dissociations in the PFC between spatial and object domains. For instance, an early event-related functional magnetic resonance imaging (fMRI) study by Courtney and colleagues showed a neuroanatomical dissociation between delay-period activity during working memory maintenance for either the identity (object memory) or location (spatial memory)

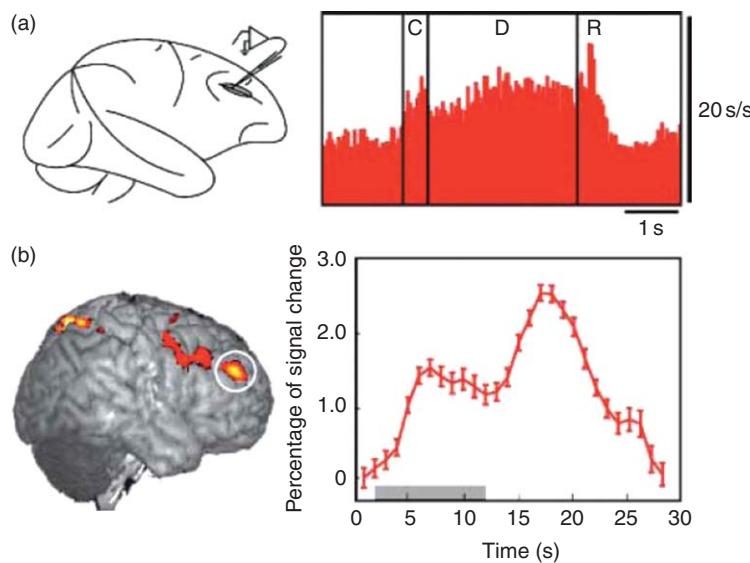

Figure 4 Neural activity in the monkey and the human lateral PFC during the retention interval of a spatial oculomotor delayed-response task. (a) average of single-unit recordings from 46 neurons with delay-period activity from the monkey principle sulcus; C = cue, D = delay period, and R = response. Adapted from Funahashi et al. (1989). (b) Human: significant delay-period activity (left) and average (right) fMRI signal from the right lateral PFC in human subject performing oculomotor delayed-response task (unpublished data from laboratory of M. D'Esposito). The gray bar represents the delay interval.

of a set of three face stimuli. Greater activity during the delay period on face-identity trials was observed in the left inferior frontal gyrus, while greater activity during the delay period of the location task was observed in the dorsal frontal cortex – a finding consistent with the spatial/object domain-segregation thesis of Goldman-Rakic. This dorsal–ventral dissociation has been observed in a number of human neuroimaging studies, using a variety of visual paradigms, and has been extended to the auditory modality – where Rama and colleagues observed a similar dorsal ventral dissociation for a task requiring working memory maintenance for either voice location or voice identity in separate trials.

The Integration of Information in the PFC

The domain-specificity hypothesis has not, however, received unequivocal support either from monkey electrophysiological investigations or from studies in the human. For instance, Miller and colleagues trained monkeys to perform a delayed object-matching task (what) and a delayed spatial-response task (where) within the same trial – a design that allowed a direct comparison of a neuron's response properties across the two domains. The results indicated that most of the neurons showing delay-period activity were equally responsive during the object and spatial memory tasks. This finding was essentially replicated in a human functional neuroimaging study by Postle and

D'Esposito who found that no region in the PFC was differentially active across the delay periods of the object and spatial working memory-trial phases. Other data from monkey physiological and human functional imaging studies also seem to be inconsistent with the domain-specific hypothesis because they provide evidence that certain dorsal and ventral PFC regions do not appear to be specific to one domain of information. For example, cooling of PFC and dorsal PFC lesions causes impairments on nonspatial working memory task and ventral PFC lesions cause spatial impairments. In addition, ventral PFC lesions in monkeys did not lead to delay-dependent defects on a visual pattern-association task and color-matching task. There are also numerous human functional imaging studies that have failed to find different patterns of PFC activation during spatial versus nonspatial working memory tasks. Postle has argued, moreover, that even if one accepts that some human neuroimaging studies have shown differences in delay-period activity across spatial and object domains, the magnitude of these effects is relatively small, and that the most salient aspect in the neural patterns observed in these studies is the extraordinary degree of overlap in the distribution of brain activity in the frontal cortex in an assortment of working memory tasks. Thus, there is good evidence that the role of the PFC in working memory, for the most part, cuts across stimulus domain, and this evidence argues for a role that is rather more integrative and flexible than is indicated by the strict domain-segregation view of Goldman-Rakic and colleagues.

Working Memory Processes and the PFC

Another possible axis along which the human lateral PFC may be organized is according to the type of operation that is performed on the contents of memory, rather than the type of information that is being maintained. For example, Petrides proposed that there are two processing systems – one dorsal and the other ventral – within lateral PFC. He proposed that the ventral PFC (Brodmann areas 45 and 47) is the site where information is initially received from posterior association areas and where active comparisons of maintained information are made. In contrast, the dorsal PFC (areas 9, 46, and 9/46) is recruited only when monitoring and manipulation of this information is required.

This model received initial support from an empirical positron emission tomography (PET) study performed by Owen and colleagues in which dorsal PFC activation was found during three spatial working memory tasks thought to require greater monitoring of remembered information than two other memory tasks that activated only the ventral PFC. For instance, in a study by D'Esposito, subjects were presented two types of trials in random order in which they were required to either (1) maintain a sequence of letters across a delay period or (2) manipulate (alphabetize) this sequence during the delay in order to respond correctly to a probe. In every subject, delay-period activity was found in both dorsal and ventral PFC in both types of trials. However, dorsal PFC activity was greater in trials during which actively maintained information was manipulated. These findings suggest that the dorsal PFC may exhibit greater recruitment during conditions that require additional processing of actively maintained information, supporting a process-specific PFC organization.

One resolution to the issue of domain specificity and working memory in the PFC comes from a close examination of the particular PFC regions that do or do not exhibit persistent activity that is specific to a particular type of information. For instance, domain specificity may exist within the superior frontal sulcus (Brodmann area 6/8) and portions of the inferior frontal gyrus (areas 44, 45, and 47), but other lateral PFC regions such as the middle frontal gyrus (areas 9, 46, and 9/46) may not show domain specificity. A coarse subdivision of the PFC into dorsal and ventral regions fails to account for the possibility that both domain-specific and process-specific organization may exist. A hybrid model of PFC organization could accommodate the empirical findings but may not be able to capture the specific types of processes that are carried out by the middle frontal gyrus (Brodmann areas 9, 46, and 9/46). Are the processes attributed to this region, for example, ‘monitoring’ and ‘manipulation’, distinct from active maintenance processes? For example, one possibility is that ‘monitoring’ and ‘manipulation’

tasks recruit the middle frontal gyrus because they require active maintenance of more abstract relations (e.g., semantic, temporal, etc.) between items. In this view, the PFC is not organized by different types of processing modules, but by the abstractness of the representations being actively maintained. This organization could be hierarchical, ranging from features of an object (e.g., red), to more abstract dimensions (e.g., color), to superordinate representations such as goals or task context (e.g., color-naming task). Evidence from functional neuroimaging studies has begun to provide support for this idea, although other explanations of the division of labor of the domain general portion of the PFC are also viable and this is an active area of research.

Working Memory Storage in the Posterior Neocortex

Although much of the focus of working memory research in the neurosciences has been on the PFC, it is now clear that regions in the parietal, temporal, and occipital cortices in the posterior part of the brain play at least a large role as the PFC in working memory. Indeed, there is good evidence to suggest that the informational content of working memory – that is, the constellation of sensory and perceptual features that comprise a memory representation – are primarily stored in the posterior neocortex. In contrast to the PFC, where evidence for functional neuroanatomical dissociation across stimulus domain has been equivocal, delay-period activity for a large number of stimulus and feature classes have been identified in sensory cortices. Single-unit recording studies have shown, for instance, that inferior temporal neurons show persistent delay-period activity as monkeys retain objects in memory across a short delay. Moreover, disruption to areas in the inferior temporal cortex of the monkey via cooling or lesions leads to severe impairments in working memory maintenance for visual object features. Similarly, application of repetitive transcranial magnetic stimulation (TMS) to the posterior temporoparietal cortex – a region known to be important for verbal memory storage in the human has been shown to disrupt verbal working memory maintenance.

As a general principle, it appears that regions that are preferentially involved during the perceptual processing of a given stimulus feature – that is, color, shape, spatial location, pitch, motion, and so on – also show reliable delay-period activation during tasks requiring working memory maintenance. For instance, the fusiform face area in the human inferotemporal region – a region that has repeatedly been shown to activate most strongly when subjects passively view pictures of human faces – also shows robust delay-period activation when subjects are required to retain face stimuli in memory across a

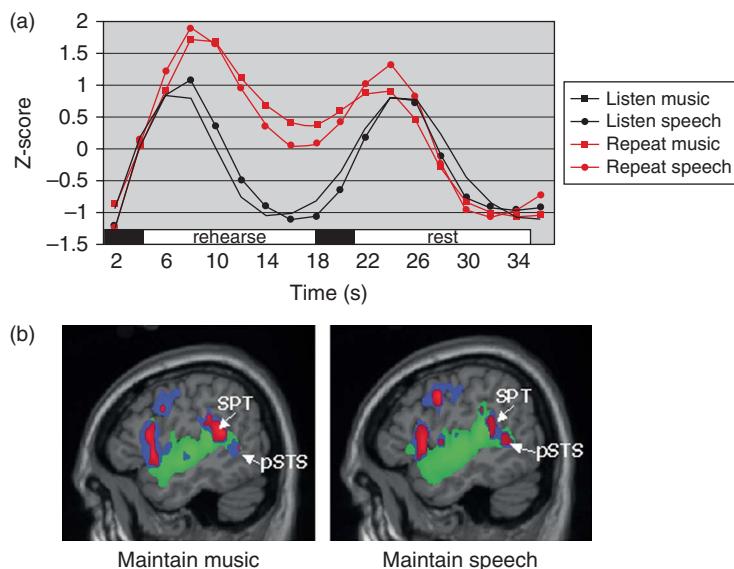

Figure 5 Main results from Hickok *et al.* (2003) study of verbal and musical working memory maintenance. (a) Averaged time course of activation over the course of a trial in the planum temporale for speech and music conditions. Timeline at bottom shows structure of each trial; black bars indicate auditory stimulus presentation. Red traces indicate activation during rehearsal trials and black traces indicate activity during listen-only trials in which subjects did not rehearse stimuli at all. (b) Activation maps of in the left hemisphere (sagittal slices) showing three response patterns for both music-rehearsal (left) and speech-rehearsal trials (right): auditory-only responses shown in green; delay-period responses shown in blue; and auditory + rehearsal responses shown in red.

short retention interval. Similarly, fMRI studies of the perception of human voices has been shown to preferentially recruit the anterior portion of the superior temporal sulcus and this same area shows delay-period activity during working memory for voice-specific information; in contrast, a more dorsal temporal region at the posterior end of the Sylvian fissure is active during the rehearsals of verbal and tonal sequences (see Figure 5).

Similar correspondences across perception and memory have been demonstrated for motion stimuli, for manipulable versus nonmanipulable objects, visual-verbal versus auditory-verbal word stimuli, olfactory stimuli, and even memory for line orientations in the primary visual cortex to name but a few examples. The evidence, therefore, is now overwhelming that domain-, stimulus-, and feature-specific memory codes are represented in the very posterior cortical centers that are known to be crucial for the sensory and perceptual encoding.

The important conclusion to be drawn from the numerous demonstrations of functional-anatomical congruence between perception and working memory storage – especially considering the relative lack of such fine-grained differentiation in the PFC – is that the maintenance of information in working memory is an interactive process in which general attentional control mechanisms in the PFC serve to modulate and bias sites in the posterior neocortex wherein specific patterns of activation that represent specific perceptual memories are stored. According to this guided activation view, the

delay-period activation observed in the PFC may actually correspond to the maintenance of task goals, abstract rules, or the maintenance of attention that is required to stave off irrelevant or distracting information. Thus, working memory requires the concerted collaboration of prefrontal and posterior areas – where the former operates as a kind of central executive whose role is to sustain attention on the currently relevant stimulus representations, even in the face of competing demands and possibly irrelevant and distracting sensory information.

Summary and Conclusions

The emergence of the concept of working memory, with its emphasis on the utilization of the objects stored of memory in the service of behavioral goals, has enlarged our understanding and broadened the scope of neuroscience research concerning working memory. It appears that the PFC has functional subdivisions that are organized according to the domain (verbal, spatial, object, etc.) of the topographical inputs arriving from posterior cortices. On the other hand, a level of representational abstractness is achieved through the integration of information converging in the more anterior and dorsal portions of the PFC. Finally, working memory function is not localized to a single brain region but is rather an emergent property of the functional interactions between the PFC and other posterior neocortical regions. Many questions remain about the neural basis of this complex

cognitive system, but studies such as those reviewed in this article should continue to provide converging evidence that may provide answers to the many residual questions.

Neural Representations of Direction (Head Direction Cells)

P E Sharp, Bowling Green State University, Bowling Green, OH, USA

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Attractor states – In the context of neural networks, this term refers to a stable state of ongoing neural activity within a set of interconnected neurons. In any such state, each neuron has its own stable activity level (typically, for many of the cells, this level would be zero). It is assumed that these stable firing patterns are enabled by strong, mutually excitatory connections between the active cells, with strong inhibitory projections from these active cells onto those cells which are silent (or less active).

Beacon following – A navigational strategy in which the goal (or an intermediary goal) is immediately observable from the current position. In this case, it is necessary only to directly approach that goal.

Dead reckoning – A navigational strategy in which information about one's own direction and speed of movement through space is integrated over time to provide a constantly updated representation of current position. Note that this term is the less formal term for path integration.

Grid cell – A recently discovered type of navigation-related cell which resides in a portion of the entorhinal cortex. As an animal travels through a region of space, each of these grid cells will fire only in certain circumscribed hot spots. Remarkably, these spots form a hexagonal grid pattern across the two-dimensional floor of the environment.

Hippocampal formation – A set of cortical regions thought to be involved in learning and memory, perhaps especially spatial learning and memory. The hippocampal formation includes the dentate gyrus, the hippocampus proper, the subiculum complex, and the entorhinal cortex.

Path integration – A navigational strategy in which information about one's own direction and speed of movement through space is integrated over time to provide a constantly updated representation of current position. See also 'Dead reckoning.'

Place cell – A type of navigation-related cell originally discovered in the hippocampus. As an animal travels through a region of space, each of these cells will fire in only one (or, rarely, two or three) hot spot within the area. Unlike the entorhinal grid cells, these place cell firing fields do not form any regular pattern, even when they have more than one hot spot.

Postsubiculum – Sometimes also referred to as dorsal presubiculum. This is a cortical region which is one of the subregions of the subiculum complex. The subiculum complex is, in turn, part of the hippocampal formation. The postsubiculum is characterized by distinctive cell islands in layer 2. In addition, it has a somewhat different set of connections with other limbic and sensory regions, when compared to the other parts of the subiculum complex. Head direction cells were first discovered in the postsubiculum.

Subiculum complex – A set of interconnected cortical regions which form a border along much of the longitudinal extent of the hippocampus. This subiculum complex has been divided into a set of subregions based on anatomical and connectional characteristics. Depending on the species and the exact criteria used, these subregions can include the postsubiculum, prosubiculum, parasubiculum, presubiculum, and the subiculum proper. Each of these subregions contains cells which appear to signal navigation-related information.

Animals and Humans Depend on Sophisticated Navigational Abilities for Survival

The ability to navigate over extended terrain is an essential skill for many animals, including humans. Thus, it is often necessary to leave the safety of the home in order to search for food, water, mates, warmer climate, and so on. Typically, it is also then necessary to make the return trip back to the starting location. This extended travel requires that the individual, in some manner, keeps track of the relative distance and direction of travel during the outward journey, so that an accurate calculation can be made for the trajectory needed to return home.

Behavioral scientists have discovered that this ability depends on a variety of interwoven capabilities, including calculations based on the relative positions of environmental landmarks, beacon following, route following, and inertial guidance.

One component of this complex navigational capacity is a sense of direction. Thus, for example, when one is sitting in the office at work, it is typically possible to point

toward the approximate relative direction of various other familiar locations, such as home, the grocery store, the library, and so on. This ability can be demonstrated behaviorally in animals as well by testing their ability to head out in the correct direction toward a goal.

Head Direction Cells: The Basic Phenomenon

An insight into how this sense of direction is generated in the nervous system was provided by James Ranck in 1984, with the discovery of head direction (HD) cells. Ranck recorded the activity of the cells in a cortical region known as the 'hippocampal formation,' which had already been identified as being critical for navigation (see below). In particular, he had placed the electrodes in a subregion of the hippocampal formation known as the 'postsubiculum.' There, he observed cells which had the remarkable property that any one cell fired only when the animal faced one particular direction, relative to the surrounding environmental cues.

Figure 1 shows a diagram of the recording system used to document these cells in the seminal work of Taube and colleagues. Rats were trained to constantly locomote within a 76-cm-diameter recording chamber while they foraged for tiny food pellets which were continually dropped onto random locations on the cylinder floor. The rat carried with it two small lights which were rigidly attached to its head. These lights enabled an overhead tracking system to continually record the rat's momentary

directional heading. At the same time, action potentials from cells in the postsubiculum were recorded.

Figure 2 provides an illustration of three different, prototypical HD cells. **Figure 2(a)** shows an overhead view of the cylindrical recording chamber, along with the radially organized numeric scale used to indicate directional heading. The left side of each row in **Figure 2(b)** shows the average firing rate for one HD cell over the entire 30-min recording session, plotted as a function of directional heading. The right panel in each row shows a pictorial diagram of the cell's directional firing pattern. As can be seen, each cell was active only over an approximately 90° portion of the 360° range of possible headings. Within this 90° preferred directional range, each cell showed a pronounced peak rate located at the center of this range, and the average rate for each cell falls off symmetrically for directions on either side of this peak. Thus, each cell provides a signal that the rat is currently facing one particular direction within the cylinder. Since different cells have different preferred directions, this indicates that for any direction the rat can face, there will be a unique pattern of cell activity across the HD cell population.

Note that it does not matter where the animal is within the chamber or what behavior it is engaged in. As long as the animal obtains a directional heading within the range of a given HD cell, that cell will fire.

It should be noted that these HD cells have also been observed in the subiculum complex of the monkey, *Macaca mulatta*, by Edmond Rolls and colleagues. In addition, those brain regions in which the HD cells have been

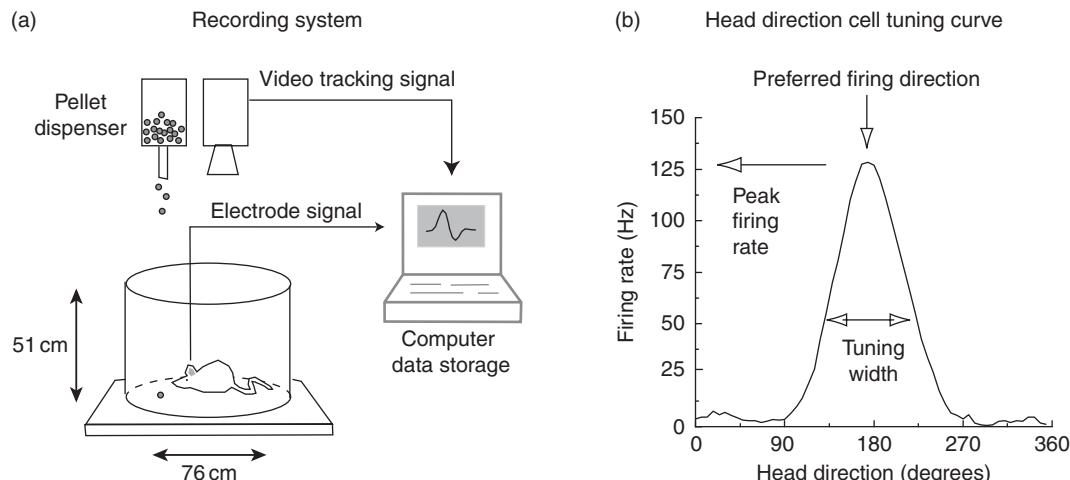

Figure 1 (a) A schematic diagram of the recording setup used for many studies of the head direction (HD) cell system. The rat is first trained to search for tiny food pellets which are continually dropped to random locations within the chamber floor. This training results in a behavioral pattern in which the rat constantly zigzags over the chamber floor, continually circling through all possible directional headings over the course of recording sessions which can last up to an hour. Throughout the recording sessions, the rat's location and directional heading are constantly monitored. In addition, microelectrodes implanted in the navigation-related brain regions constantly record the action potentials of single neurons. (b) An illustration of a typical directional tuning curve from a HD cell. Here, the average firing rate of the cell over the course of the recording session is shown as a function of the rat's momentary directional heading.

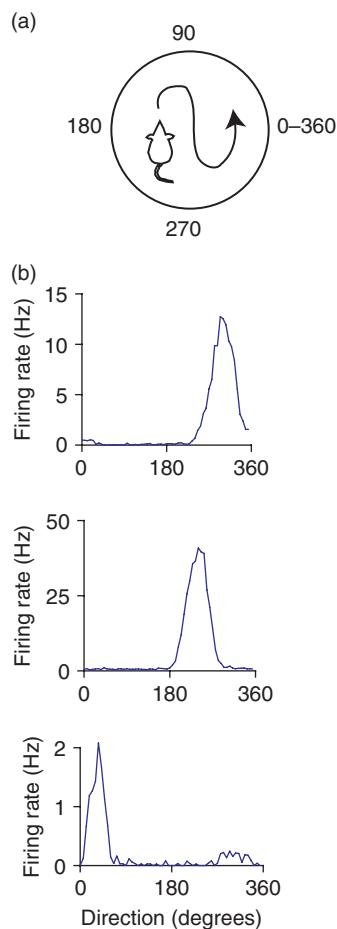

Figure 2 (a) Here, an overhead view of the recording chamber from **Figure 1** is shown. The numbers placed around the outside of the chamber indicate the angular scale used to calculate the directional tuning curves for the head direction (HD) cells. (b) Each row illustrates one typical HD cell. The left panel of each row shows the directional tuning curve for the cell, while the right panel shows an illustration of the directional heading at which that cell fired maximally.

documented in animals are also known to be important for navigation in humans. Thus, it appears that the HD cell system may be a highly conserved component of the vertebrate neural circuitry for navigation.

HD Cells Are Guided by Both Environmental Landmarks and Path Integration

Since the initial discovery of HD cells, follow-up studies have investigated how these cells work; that is, how can a neuron buried deep within the cortex manage to somehow track which direction the rat is facing at each moment?

HD Cells Are Partly Controlled by Familiar Landmarks

One possibility would be that the cells somehow receive information about the local geomagnetic field. Thus, they could possibly sense the directional relationship between the head and actual geocentric coordinates.

Work conducted in laboratory settings has indicated that if such an influence is present, its influence is minimal. **Figure 3** provides a diagrammatic illustration of one of the early findings by Taube and colleagues. For this work, the gray, cylindrical recording chamber was typically equipped with a salient white cue card which served as an orienting stimulus. The top row in **Figure 3** shows this card in the standard position, which was used on a daily basis for the routine screening and recording of these cells. The second row illustrates what happened during occasional probe sessions in which the card position was rotated prior to the rat's entry into the chamber. Here, it can be seen that this angular rotation of the position of the card caused an equal rotation of the angle of the preferred direction of the HD cell. Thus, it appeared that this familiar, salient landmark controlled the directional preference of the cells, rather than (or at least more strongly than) any geomagnetic cues which were available.

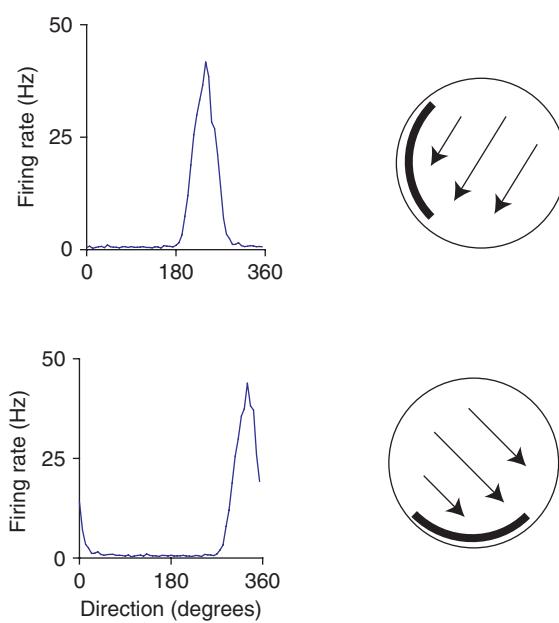

Figure 3 An illustration of the landmark control of head direction (HD) cells. The upper row shows the directional firing properties for a typical HD cell recorded in the cylindrical chamber equipped with a cue card in the standard position, on the west portion of the wall. The second row shows the data from that same cell during a probe session in which the cue card position was rotated by 90°. As can be seen, in this familiar chamber, the position of the cue card exerted control over the directional preference of the HD cell.

This finding is compatible with everyday experience, in that we often use available landmarks, such as mountains or tall buildings, to help us get our bearings. The above finding also suggests the possibility that, indeed, the only explanation necessary for the behavior of these cells is that they are tuned to respond to particular stimuli, when those stimuli are positioned within a certain limited region of the visual field. Thus, it is possible that the cell portrayed in **Figure 3** responds to any large, white stimulus whenever it is in the right portion of the visual field. Within the cylindrical chamber used here, this would only happen when the rat was facing the direction indicated by the arrows.

HD Cells Are Also Guided by Path Integration (Dead Reckoning)

Additional work, however, has clearly shown that the explanation for direction-specific firing in these cells is not as simple as this. Indeed, it seems that the HD cells have a remarkable ability to keep track of directional heading even when the animal travels into a novel environment, so that there are no familiar landmarks, and even if it is in a situation in which the salient landmarks are ambiguous.

Figure 4 illustrates findings from an experiment conducted by Taube and Burton. Here, HD cells were first recorded in the standard cylinder used for training and recording. Thereafter, during probe sessions, the rat was

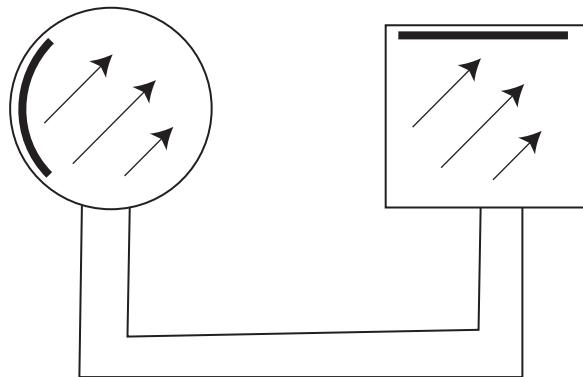

Figure 4 An illustration of path integration in a head direction (HD) cell. During training and standard recording sessions, the rats were confined to the cylindrical chamber which forms the left compartment of this apparatus. Note that this cylinder is equipped with a single, white cue card on the west portion of the wall. Then, during a probe session, the rat was allowed, for the first time, to travel down the corridor to locate the novel square chamber on the right. As illustrated, HD cells in this experiment retained the same directional preference in this new chamber. Note that a white cue card is also present in the square, but placed in a different angular position here. This suggests that the HD cell system tracked the animals as they traveled heading into the new terrain, and was not controlled by the cue card in this unfamiliar context.

allowed to travel along a novel route provided by the opening up of a hallway which led to a novel chamber. Note that this new chamber was also equipped with a single white cue card, but then it was placed in a different angular position. In this case, the cells retained the same directional preference (relative to earth) as for the original standard cylinder. Thus, even when the rat traveled into a chamber it had never previously visited, it retained a single, fixed, directional preference for each of its HD cells. In this novel setting, the familiar relationship to the cue card was broken.

These findings are also compatible with everyday experience. Thus, if one heads north, out of town, and drives into novel terrain, it is possible to retain some ongoing sense of which way one is headed, even if there are no available directional indicators, such as the sun (i.e., the sky being overcast) or distant mountains. For example, if the road is straight, and one has not turned onto any other road, then one must still be headed north. Similarly, if one then makes a 90° right turn onto another road, then one must now be heading east.

Note that in this new environment, one is likely to see examples of familiar stimuli, such as gas stations and fast-food restaurants. When we see these stimuli in our familiar home territory, they can often help us get our bearings. Thus, for example, if the Exxon station is on the north end of Main and we are able to view this station from the center of town, it must be the case that we are currently facing north. In novel terrain, however, the same sort of Exxon station may be in any arbitrary position relative to nearby towns. Thus, this new Exxon station is not initially a useful directional landmark. The experiment illustrated in **Figure 4** suggests that the HD cell system recognizes that familiar landmarks do not retain a constant relation to directional heading when in a novel terrain, since the HD cells do not snap into line with the cue card in the novel setting, even though they did so in the familiar environment (**Figure 3**).

This ability to keep track of directional heading even in the absence of learned environmental landmarks is thought to depend on a process known as ‘path integration,’ or, less formally, ‘dead reckoning.’ According to this idea, directional heading can be tracked by a process in which any angular motion of the head is constantly integrated to calculate the current directional heading. Thus, in the example above, a 90° right turn taken from a start position heading north would result in a position in which the head faces east. In relation to the HD cells, this implies that the right turn somehow turns off the north HD cells and turns on the east ones.

Another example of evidence for the path integration process for these cells is illustrated in **Figure 5**. This study used a chamber equipped with eight alternating, vertical, black and white stripes. These stripes were all identical in width and designed to provide an

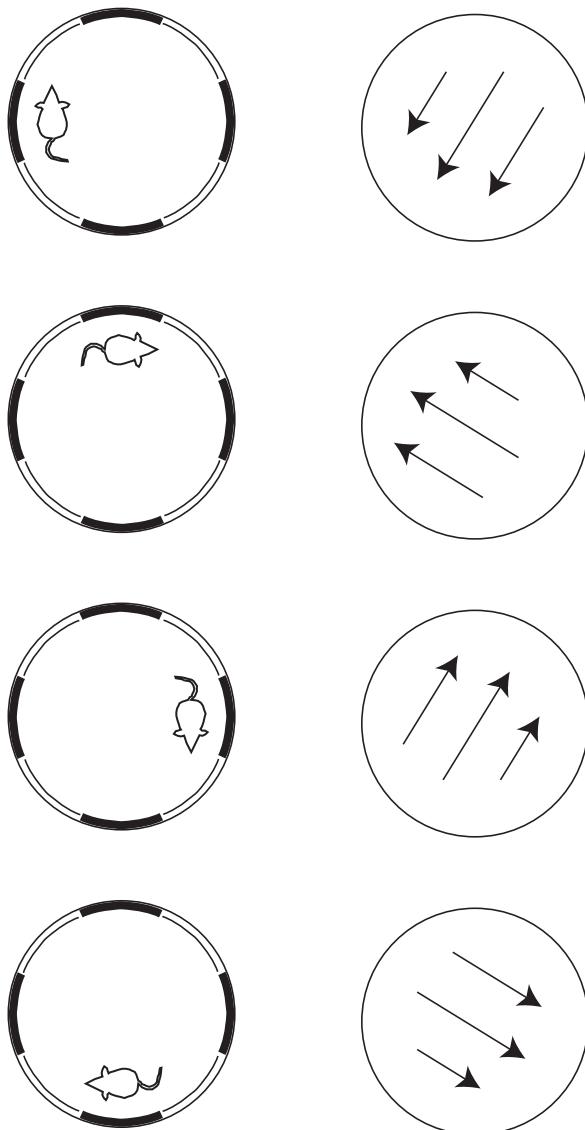

Figure 5 An additional example of path integration in the head direction (HD) cell system. Here, the cylindrical recording chamber has been equipped with a set of alternating black and white stripes, meant to provide an ambiguous stimulus situation. Each row illustrates a different session for the same HD cell. The only variable which was manipulated from one session to the next was the rat's start position. As indicated by the drawn rat figure, each session began by initially placing the rat down next to a different black stripe. As shown, this initial placement determined the preferred direction of that HD cell for the duration of that session.

environment in which all salient visual cues were ambiguous in terms of their relationship to directional heading. Thus, for example, if the rat stood in the middle of the chamber and faced due north, its view would include a black stripe surrounded by two white stripes. This same view would also be available when facing each of the directions east, south, and west.

Note that if the HD cells were controlled just by the immediate input from environmental landmarks, then this environment might be expected to cause directional firing patterns with four, equally spaced peaks along the directional range. However, in keeping with the path integration idea presented above, this is not what happened. Indeed, during any given recording session, each HD cell showed only one preferred direction. This preferred direction was robust and stable throughout the 15-min session.

Interestingly, however, this preferred direction could be changed from one session to another simply by changing the position at which the rat was initially placed down into the chamber. Specifically, each 90° rotation of the start position caused a corresponding 90° rotation of the cell's directional peak. This suggests that the initial placement of the rat into the chamber served to initialize the HD cell system to some constant value (such as north). From that initial setting, the rat's subsequent movements served to constantly update the firing pattern in the HD cell system, so that all cell activity was stable relative to the start position in that particular session.

HD Cells Appear to be Wired Together to Form a Single, Internally Consistent Set of Direction-Signaling Cells

One additional general finding is relevant here that serves to capture the flavor of these cells. This finding comes from cases in which two or more HD cells were recorded at once. Imagine, for example, that in the standard cylinder there is one cell which fires when the rat faces north, and another which fires when the rat faces south. Next, imagine that the rat is placed into a covered carrying cage and is spun around, one way and then the next, many times, so that there is no way the HD cell system could track so many different turns and twists. During this spinning process, the animal is also transported and placed down into a completely novel chamber in a new laboratory room. In this case, there is no way to predict which direction will be selected by either of the two cells; that is, in keeping with common experience, if they have no way of keeping track of their ongoing position, and if there are no familiar cues available, then the system simply has no way to tell which direction is which, relative to earth.

What can be predicted, however, is that each of the cells will show a single preferred direction in the new environment; that is, they will be well-formed HD cells. In addition, these two cells will, once again, have a 180° difference between their two preferred directions. Thus, if cell 1 chooses east (in earth-centered coordinates), then cell 2 will choose west.

There have been numerous additional studies conducted to examine the relative influences of

environmental landmarks and path integration on the firing rates of the HD cells. All of these data are compatible with the idea that the HD cells are somehow connected together to provide a single, internally consistent set of direction-specific cells. This cell population receives input about the animal's angular head motion from vestibular, motor, and other sources of movement information, and uses this input to update the population firing vector. In addition, however, the cells can become attached to familiar landmarks, so that these can sometimes reset the directional firing pattern. This attachment to landmarks is thought to result from Hebbian increases in synaptic strength, which result when signals from environmental inputs are paired with activity in certain HD cells.

Neural Network Models for the HD Cells

Investigators in several laboratories have worked to encapsulate the above ideas into a neural network model of the HD cell system. All the models incorporate the same general set of principles, and these are illustrated in **Figures 6 and 7**.

All the models begin with the idea that the HD cells are linked together in a ring-like architecture in which

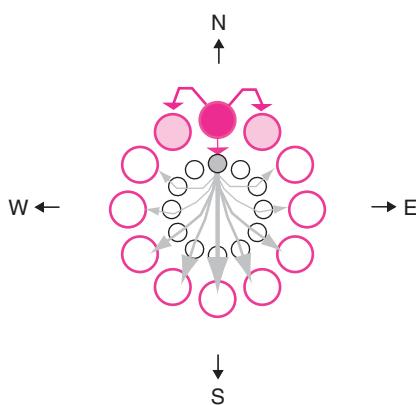

Figure 6 The basic ring architecture is shown here which forms the core of most neural network models of head direction (HD) cells. The to-be-modeled HD cells themselves are drawn in pink. For illustrative purposes, these cells are drawn in a circular formation, with each cell occupying a radial position corresponding to its preferred firing direction. Each HD cell has a companion inhibitory cell (drawn in black), to which it sends an excitatory projection. Each inhibitory neuron, in turn, sends inhibitory projections to the remaining HD cells. In addition, there are excitatory connections between neighboring HD cells. This architecture enforces a winner-takes-all behavior in which, at any one time, activity is allowed only for a small subset of adjacent cells located within a small range of the circle. Note that cell activity here is indicated by coloring in the cell bodies. In addition, the excitatory and inhibitory connections are shown here only for the north HD cell and its inhibitory companion. However, each of the cells is assumed to have a corresponding set of connections.

cells meant to represent similar (nearby) directions are linked through a combination of excitatory and inhibitory connections, while those meant to represent different directions (such as north vs. south) are linked through strong inhibitory connections. This basic ring structure is illustrated in **Figure 6**.

This architecture ensures that the HD cell population can never represent two different directions (such as east and north) at the same time, and thus matches the real-world fact that it is not possible to face two different directions at once. Indeed, these structures form a ring attractor in which a single, localized packet of activity can come to rest at any position along the ring.

The models also incorporate cells which provide information about angular head velocity, as shown in **Figure 7**. These angular velocity cells fire tonically, so that they are active even when the rat is at rest. This rate is modulated by the angular motion of the head, however, so that the head turns to one side (e.g., to the right or clockwise) cause increases in the rate which are linearly related to the speed of the turn. In contrast, turns to the opposite side (e.g., left or counterclockwise) result in firing-rate decreases which are linearly related to the turning speed.

Cells like this have, in fact, been discovered in many of the same brain regions in which HD cells are located (see discussion of the 'anatomical location of HD cells' below). These angular velocity cells are thought to receive information from a variety of sources. These include the vestibular system, which contains cells that code the angular acceleration of the head, as well as optic flow induced by head rotation, and also motor commands which produce head motion.

These angular velocity cells are incorporated into the models in such a way that when the animal turns its head, this angular motion will cause the firing pattern in the HD cell population to be updated. For example, if the animal starts out heading north and then makes a 90° clockwise turn, this motion will result in turning off the north HD cells and turning on the east ones.

An example of this idea is provided in **Figure 7**. Here, the angular velocity cells described above are attached to a set of intermediate cells (angular velocity by HD cells), which also receive input from the HD cells themselves. Specifically, each of these angular velocity by HD cells receives input from just one HD cell. In addition, they receive input from only one of the two possible kinds of angular velocity cells (clockwise vs. counterclockwise). This means that any one angular velocity by HD cell will fire only when the rat is facing one particular direction and turning one particular way (clockwise or counterclockwise). Thus, each of these cells detects one particular conjunction of current heading direction and current angular motion. The solid blue cell in the lower panel of **Figure 7**

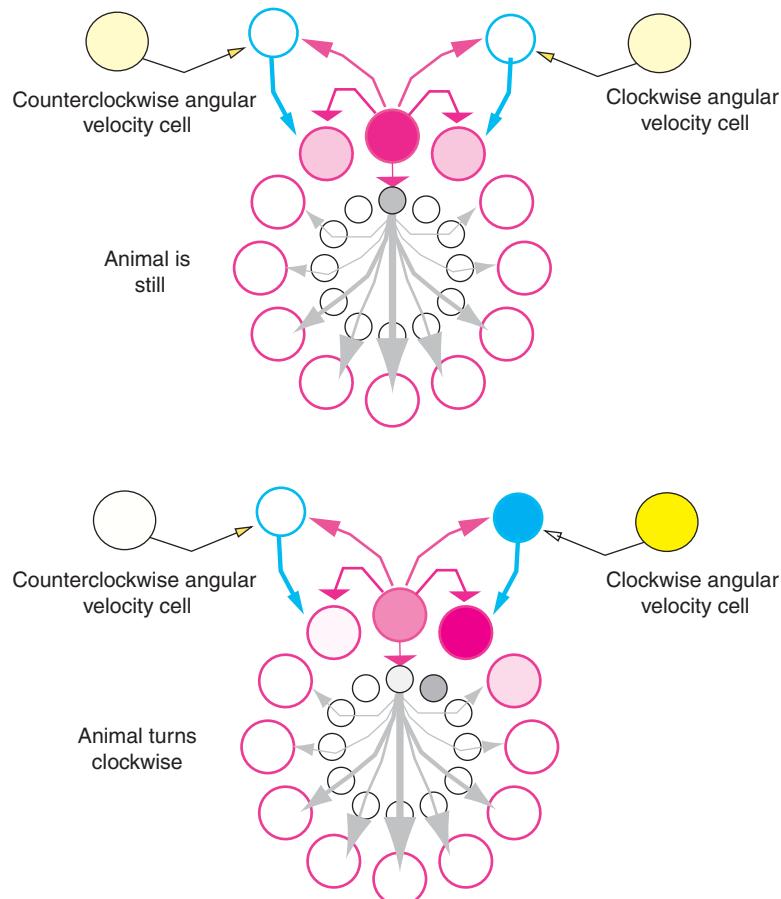

Figure 7 Here, angular velocity cells (yellow) and angular velocity by head direction cells (blue) have been added to the ring structure shown in **Figure 6**. When the rat is still (upper panel), the two angular velocity cells fire at the same low, tonic rate. This is not sufficient to activate the angular velocity by HD cells. When the rat turns to the right (lower panel), the angular velocity by HD cell on the right is activated. This cell, in turn, provides excitation to the next HD cell in the ring. Thus, as described in the text, the activity pattern in the HD cells is updated to reflect the rat's angular head turns.

represents a cell which requires joint activity in the north-preferring HD (pink) cell and the clockwise angular velocity (yellow) cell. Note that each of these angular velocity by HD cells, in turn, sends an excitatory projection onto the appropriate adjacent HD cell. In this case, activation of this blue cell causes activation of the HD cell one step clockwise from the north cell. As this next HD cell begins to increase its firing rate, it activates its own companion inhibitory cell, which then begins to inhibit the other HD cells. In this way, the overall pattern of cell activity is shifted clockwise by one step. Continued movement will cause continued shifting.

Anatomical Location of HD Cells

Since the initial discovery of HD cells in the postsubiculum region of the hippocampal formation, these cells have been discovered in numerous additional brain

regions. Indeed, much of the rat limbic system seems to contain HD cells. **Figure 8** shows a diagram of the portions of the rat limbic system in which HD cells have so far been documented. These areas include a set of interconnected regions which form a loop from the hippocampal formation down to the mammillary bodies, continue up to the anterior thalamus, and then back up to the hippocampal formation. Within each of these limbic regions, the HD cells usually constitute only a small subset of all the cells.

Interestingly, many of the cortical regions which contain HD cells also contain additional cell types thought to be critically involved in navigation-related cognition. These other types include the well-known hippocampal place cells and the recently discovered entorhinal grid cells.

It is thought that the place cells, grid cells, and HD cells all work together to form a spatial tracking system which constitutes the basis of navigational tracking abilities at the behavioral level.

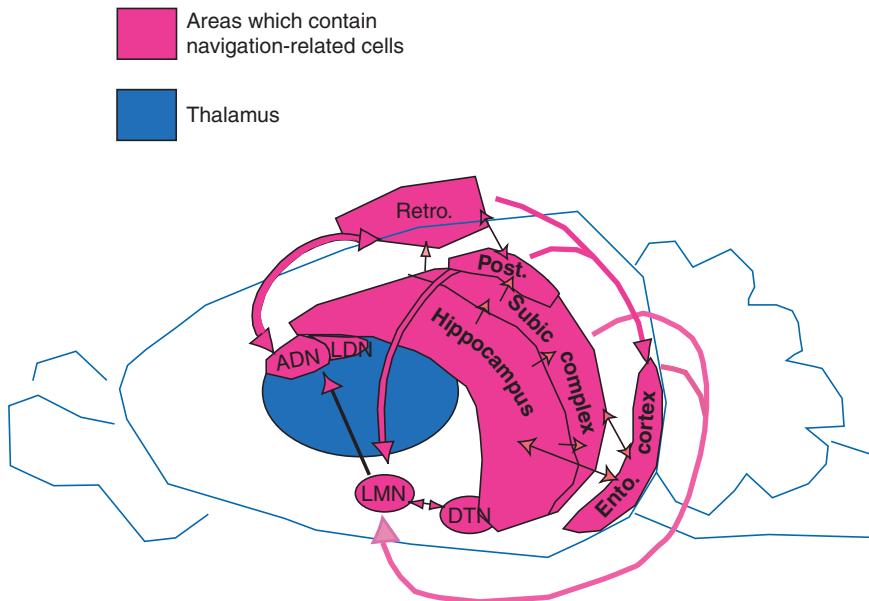

Figure 8 A schematic diagram of the rat limbic system areas in which head direction cells, as well as additional navigation-related cell types have been discovered (see text). ADN, anterodorsal nucleus of anterior thalamus; DTN, dorsal tegmental nucleus; Ento. cortex, entorhinal cortex; LDN, lateral dorsal nucleus of thalamus; LMN, lateral mammillary nucleus; Post., postsubiculum; and Retro., retrosplenial cortex.

Glossary

- Coordinate transformation** – A computation that converts the position of an object in one reference frame into its corresponding position in another reference frame.
- Efference copy** – A copy of the brain's motor command that could, in principle, be shared among brain areas.
- Intention** – The goal or purpose behind a particular action or set of actions.
- Proprioception** – The sense of position and orientation of the parts of the body. This sense is derived from receptors in the skin, joints and muscles.
- Reference frame** – A coordinate system or set of axes used to describe the position or movement of an object.
- State estimation** – The process of computing the position and velocity of a time-varying system from online measurements.

Intentions represent early plans for movement. Rather than specifying the endpoint forces, joint torques, or muscle activations required for movement execution, intentions represent 'earlier' aspects of movement planning. Intentions specify the goal of a movement as well as the effectors (eyes, limbs, etc.) that will be used to accomplish that goal. Thus, the formation of intentions depends upon a host of cortical functions, including spatial perception, action planning, and decision making.

Where are intentions encoded in the brain? In humans, neurological deficits following injury to the frontal and parietal cortices are consistent with these regions playing an important role in early aspects of eye and arm movement planning and spatial perception and thus in the formation of intentions. For example, injury to the superior parietal lobule (SPL) of the posterior parietal cortex (PPC) can lead to disturbances of planning such as optic ataxia, which is characterized by an inability to accurately reach objects under visual guidance. In contrast, injury to the inferior parietal lobule (IPL) and premotor cortex leads to disorders that have traditionally been thought to be more perceptual or cognitive in nature: (1) neglect, characterized by a failure to perceive space (extrapersonal or intrapersonal) on the side contralateral to the injured half of the brain, and (2) apraxia, defined as an inability to perform complex gestures that is not caused by weakness, loss of sensation, or other obvious motor-related deficits. Importantly, these deficits do not reflect difficulties in

movement execution but rather in the planning and preparation of movement.

As in humans, the frontal and parietal cortices of non-human primates have also been implicated in the formation of intentions. For example, effector-specific areas responsible for the planning of saccades and limb movements have been identified in both cortices. In addition, activity related to movement goals can easily be elicited in these areas. In many instances however, this intention-related activity is combined at the single cell level with activity that encodes the state of the animal, that is, the position and configuration of the eyes, limbs, and/or other body parts. Thus, borrowing terminology from engineering, these areas can be thought of as being involved in 'state estimation' as well as in the formation of intentions. The discussion here focuses on how state- and intention-related activity are encoded and interact in limb movement-related areas of the brain, with special attention given to the dorsal premotor cortex (PMd) of the frontal lobe and parietal area 5 and the parietal reach region (PRR) of the SPL ([Figure 1](#)). It will be argued that the particular form of this interaction allows for maximum flexibility in planning and executing movements of the eyes and limbs under constantly changing environmental conditions.

State Estimation in the PPC

State estimation refers to the process of computing the current state (i.e., position and velocity) of a time-varying system from online measurements. In the context of limb motor control, optimal state estimators monitor incoming sensory information as well as outgoing motor commands in order to reduce uncertainty in the estimate of limb position and velocity. Estimating limb position on the basis of motor commands is facilitated by a forward model, a system that uses efference copy and an internal model of the dynamics of the limb to predict the limb's state in response to these commands. A recent study of nonhuman primates trained to control a computer cursor by moving a joystick has shown that many PPC neurons encode the future position and velocity of this cursor, suggesting that this area may also play an important role in estimating the state of the limb.

Psychophysical experiments in humans also implicate the PPC in this important function. For example, in humans damage to the SPL has been shown to result in

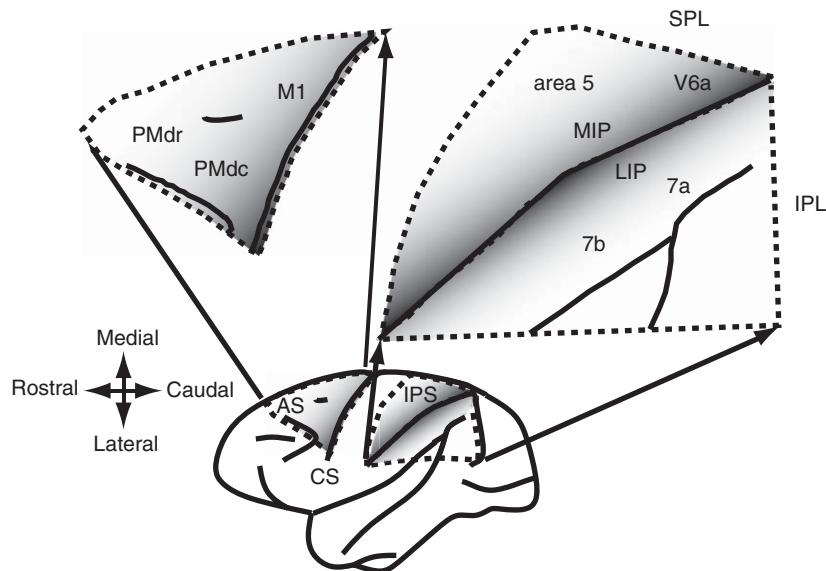

Figure 1 Lateral view of the rhesus macaque monkey brain with the PPC and parts of the frontal lobe highlighted and expanded. Shaded regions indicate the banks of sulci. In the PPC, PRR corresponds to what is labeled MIP (medial intraparietal area) and V6A. AS: arcuate sulcus. CS: central sulcus. IPS: intraparietal sulcus.

a profound difficulty in maintaining limb position and grip force in the absence of vision, supporting a role for this structure in integrating sensory and motor information to estimate limb state. Studies of patients with known optic ataxia exhibit marked difficulty in making corrections to their ongoing arm movements in response to a sudden change in target location, suggesting impairment in the system responsible for rapidly updating movements. Importantly, these patients can correct their ongoing movements; they just do so in a slower and more deliberate fashion than their neurologically intact counterparts. These observations have led to the proposition that there are two distinct brain systems subserving the online control of visually guided arm movements: a fast-acting automatic system, based largely in the SPL, and a slower more voluntary one, based in the IPL and inferotemporal cortex, that augments the automatic system. The ability to rapidly update ongoing movements requires accurate information about the current position and velocity of the moving limb; thus, it is possible that the automatic and voluntary systems, and their constituent brain areas, may be distinguished from each other by their relative contributions to online state estimation.

Sources of Limb-State Information

What signals contribute to the encoding of limb state in the PPC? In nonhuman primates, both the SPL and IPL have been shown to receive visual and somatosensory inputs. Within the IPL, sensory inputs appear to be largely segregated, with 7a receiving input primarily from visual areas and 7b receiving input from areas considered

to be involved in somatosensory processing. Although it has been known for some time that neurons in area 7a respond during arm movements, these responses have not been nearly as well characterized as those in the SPL. Recent studies indicate that 7a neurons are strongly modulated at the time of, or slightly after, movement onset. These observations, in addition to anatomical data showing a lack of direct projections from the motor cortex (M1) or PMd to 7a, suggest that area 7a responses during movement are related largely to sensory processes. However, it should be noted that 7b receives input from area 5 and projects in turn to 7a, providing a possible neural substrate for an efference copy of limb movement commands to 'leak into' the IPL reach areas (see below). In addition, probably the strongest neural evidence to date of the existence of an efference copy signal, though in the context of oculomotor control, comes from studies of a part of the IPL immediately adjacent to 7a, that is, the lateral intraparietal area (LIP). Subsets of neurons in this area begin to increase their firing rate in anticipation of a visual target falling within their receptive field at the completion of a planned saccade. This suggests that LIP neurons have access to an estimate of the future position of the eyes that is derived from efference copy and a forward model of the eye plant. In a similar way, it is conceivable that arm movement-related areas of the IPL could receive an estimate of the future position of the limb based on efference copy and an internal model of the arm.

In nonhuman primates much more is known about the anatomy and physiology of arm movement-related areas of the SPL, particularly area 5. Neurophysiological

studies have consistently reported that area 5 neurons encode information about static limb position as well as limb position and velocity information during movement, both strongly suggestive of a role for this area in state estimation. However, the relative roles of efference copy and sensory signals in this process remain unclear. Historically, activity in area 5 has been assumed to reflect high-level somatosensory processing though recent studies have provided evidence that static limb position signals in this area are based, in part, on visual input. Regarding efference copy, lesion studies suggest that the SPL receives a copy of ongoing arm movement commands. This finding is supported by anatomical studies, which report direct projections from PMd and M1 to area 5 of the SPL. Lastly, neurophysiological studies have shown that many cells in area 5 often respond before movement onset in reaction time tasks and continue to respond even following deafferentation of the arm by dorsal rhizotomy. It is unlikely that activity preceding movement in area 5 reflects a descending motor command, as direct projections from area 5 to the spinal cord synapse on cells in the dorsal, rather than ventral, horn. Instead, this activity may represent an efference copy of a command generated elsewhere.

Thus, evidence obtained from nonhuman primates suggests that limb movement-related areas of the SPL and IPL can be distinguished not only by the type of sensory signals (visual, proprioceptive) that they process during movement, but also by the extent to which they integrate sensory inflow with ongoing movement commands. Even within each subdivision of the PPC, the relative contribution of these signals varies anatomically. For example, in the most dorsal parts of area 5, somatosensation (i.e., proprioceptive and tactile sense) seems to dominate the representation of limb position; neurons here respond strongly to passive manipulation of the joints and have large tactile receptive fields that are sometimes bilateral. In addition, reach-related neurons in dorsal area 5 appear to encode information about the configuration of the limb and not simply its endpoint, further supporting a strong role for proprioception in this area. However, as one moves caudally in the PPC, that is, toward the crown and bank of the intraparietal sulcus, the relative contribution of vision gets stronger, as discussed below.

Interaction of State and Intention Related Activity in the PPC

Coding of Intention

Areas located with the banks of the intraparietal and parieto-occipital sulcus, such as the medial intraparietal area (MIP) and V6A, are generally more responsive to visual stimuli than adjacent areas on the cortical surface.

These anatomically defined areas appear to correspond to what has been termed, on functional grounds, as the PRR. Cells in PRR respond briskly to briefly flashed visual stimuli and continue to respond even after these stimuli have been extinguished, that is, during the delay periods of instructed delay tasks. Despite being strongly visually driven, it appears that this area is involved in the early planning of limb movements rather than simply being involved in sensory and/or attentional processes. For example, cells in this area have been shown to be much more active during the planning of reaches than during the planning of saccades. In addition, PRR neurons are preferentially activated with movements of the contralateral limb and their activity during delay periods is correlated with reach but not saccadic reaction times, findings that might be expected of areas fairly far along in the computations involved in specifying limb movements. Interestingly however, goal locations in this area are encoded with respect to the current point of visual fixation, that is, in eye-centered, rather than limb- or body-centered coordinates. Even more surprising is the observation that the responses of some PRR neurons are further modulated in amplitude (i.e., gain modulated) by the position of the limb, an effect which also appears to be best described in eye coordinates. This hand-in-eye coding appears to persist even in the absence of concurrent visual input about hand position, suggesting the representation of limb position in this area is constructed, at least in part, by transforming somatic signals (proprioception/efference copy) into a reference frame that is more aligned with the visual one.

Coordinate Transformations for Reaching

The benefits of such an encoding scheme are now clear. If both the goal location and current hand location are encoded in eye coordinates, a representation of the desired arm movement vector can be computed by vectorially subtracting the position of the limb from the position of the goal location in this reference frame (**Figure 2**). Evidence for such a scheme has been observed in area 5. Here the responses of many neurons are most consistent when goal locations are identical in both eye and hand coordinates. In other words, these neurons encode reach goals not with respect to the eyes or limbs alone but with respect to both effectors. This supports the idea that an eye-centered representation of the reach vector is generated within the PPC, with PRR and area 5 both playing a role in this computation. A critical component of this scheme is the gain modulation of PRR activity by the position of the limb in eye coordinates. This gain modulation is a distributed effect, that is, the precise position of the hand in eye coordinates in PRR cannot be determined from the activity of a single cell but must instead be read out from a population of

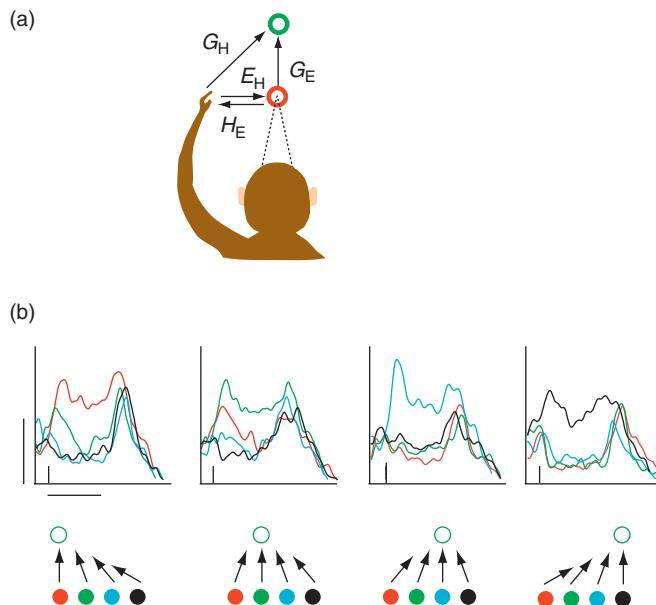

Figure 2 (a) The location of the goal in hand-centered coordinates (G_H) can be computed by vectorially subtracting the hand location in eye coordinates (H_E) from goal location in eye coordinates (G_E). (b) Example of a parietal neuron that encodes the vector G_H during the memory period of an instructed delay task. Each panel represents a different horizontal target (goal) location. The histograms in each panel show neural activity associated with movements from different starting positions (located just below the targets) and are aligned on target onset (small vertical tick mark). For this neuron, planning activity was greatest for purely vertical movements. Vertical scale bar: 40 spikes/s. Horizontal scale bar: 1 s.

gain-modulated neurons. A representation of the position of the limb in eye coordinates is also observed in PMd, with one very important difference: here rather than a distributed representation of this vector, the hand-in-eye effect is observable at the single cell level. This representation appears to be ideally suited for coordinating movements of the eyes and hand.

Parieto-Frontal Intention Networks

It is now well established that the reach areas of the PPC are richly interconnected with those of the frontal lobe. The pattern of connections has been termed a ‘neuroanatomical gradient,’ as areas located more medially or posteriorly in the PPC are connected more strongly to rostral parts of PMd, while more anteriorly located parietal areas are more strongly connected to more caudal areas of the frontal lobe, that is, caudal PMd and M1. It is also clear that many of the areas in this parieto-frontal network are not involved in specifying the forces and muscle activations necessary to move the arm but in monitoring the state of the body in relation to high-level movement goals. Other aspects of intention may also be encoded in this network. For example, it has recently been shown that correlations in spiking and local field potential activity between PMd and PRR are greater when monkeys freely choose a sequence of targets to which they are reaching than when

the sequence is instructed, suggesting that this intention network is also involved in decision making.

The pattern of connections described above coexists with another network connecting areas of the IPL with the ventral premotor cortex (PMv). As stated above, neurons in 7a and 7b of the IPL are active during limb movements. Neurons in these areas have also been shown to signal the positions of the eyes and limbs and, at least in 7a, the position of the body in space. Although these areas project to PMd and other areas of the dorsal frontal lobe, they appear to be more strongly connected with PMv. PMv neurons encode goal-related information. They are also active during ongoing reaching movements but appear to be more involved in signaling visual feedback of these movements rather than somatomotor feedback. In addition, PMv neurons do not appear to encode effector-related information (i.e., left or right arm) as strongly as neurons in PMd. This suggests that PMv, and the parietal areas to which it connects, may play a different role in intention than PMd, PRR, and area 5. In humans, the specific role of this ventral intention network is only beginning to be unraveled. However, a recent imaging study has demonstrated that recovery from neglect is associated with a rebalancing of activity in the ventral frontal and lateral parietal lobes, highlighting the importance of cooperation among the various nodes of this network for high-level cortical functions such as spatial attention and orienting behavior.

Interaction of State- and Intention-Related Activity in PMd

As indicated earlier, certain forms of neglect and apraxia are associated with damage to frontal lobe areas such as PMd, further evidence from humans for a role for this area in the formation of intentions. In humans damage to PMd can also result in asomatoagnosia, a condition where subjects describe parts of their body as missing or disappeared. This suggests that human PMd integrates visual and somatosensory information to construct the body image. A recent transcranial magnetic stimulation (TMS) study indicates that this integration may serve another purpose as well. Application of TMS over PMd impairs the ability to update movements online, a phenomenon previously described for the SPL. Thus, PMd may also integrate visual and somatic information in order to estimate the state of the limb during movement.

Intention-Related Activity

Like the areas of the parietal lobe to which it is connected, the PMd of nonhuman primates has been shown to reflect information about intended actions. For example, PMd neurons are active during the planning of arm movements and appear to specify information about both the direction and amplitude of these movements. Neurons in PMd have also been shown to encode reach goals as well as aspects of the limb trajectory and this goal-related information is combined with information about the effector that will be used to attain that goal.

State-Related Activity

PMd neurons encode not only intention-related activity but also information about the state of the body. For example, several studies have reported sensitivity to eye position in PMd though the magnitude of these effects appears to vary under different behavioral conditions. PMd neurons also encode information about both the static position and configuration of the limb as well as limb position and velocity during movement, strongly suggestive of a role for this area in state estimation. However, as in the PPC, the relative roles of motor and sensory signals in constructing an estimate of arm state are unclear in PMd. The existence of strong projections from M1 suggests that efference copy information should be readily available to PMd. PMd is also known to receive visual and somatosensory information via the parietal lobe. Thus, similar to the SPL, PMd appears to have access to all signals relevant for estimating limb state.

Coordinate Transformations Underlying Eye-Hand Coordination

In what manner are movement goals and state information integrated in PMd? Like neurons in PRR and area 5, neurons in more rostral parts of PMd appear to encode goal- or target-related information in eye-centered coordinates. Many of the same cells also encode goal-related information in limb-centered coordinates, similar to what has been observed in area 5. More recently, it has been shown that PMd neurons also encode the position of the limb in eye coordinates. As stated previously, the nature of this effect can be observed at the single cell level, that is, cells have response fields which explicitly encode the difference between current hand and fixation positions. This can be interpreted as encoding the relative location of the hand and eye, that is, hand-in-eye or eye-in-hand coordinates, an efficient and flexible representation whose benefits are described below. In more caudal parts of PMd, the representation of movement goals and state information is not as clear. Though some neurons encode reach goals in eye coordinates, hand/limb coordinates, or both, a substantial number of neurons do not appear to encode goal locations or limb position in any clear reference frame. The fact that more caudal parts of PMd do not use relative position codes makes sense in that such codes must eventually be broken down before individual commands to move the eyes and limbs can be specified and delivered to these effectors. Since caudal PMd lies immediately adjacent to M1 this area could already be specifying information solely about limb movements and in coordinates that are more intrinsic to the arm, that is, joint angles or muscle activity.

Conclusions

Information about the locations of potential goals and the positions and configurations of the various parts of the body are initially encoded in the brain in the natural coordinates of the sensors. However, orienting behavior depends critically on deriving the relative positions of goals and effectors; it is not useful to know only where an object is with respect to your eyes if what you also desire is to reach out and pick that object up. Such relative codes in the arm movement system have been known at least since the work of Georgopoulos and colleagues in the 1980s, who demonstrated that arm movement-related activity in M1 reflects the movement vector, rather than the position of the desired endpoint in space or with respect to the body. The more recent findings discussed here describe how such relative codes may be derived by nodes of the parieto-frontal intention network.

A critical component of the described scheme is the encoding of the relative position of body parts, particularly the relative coding of eye and hand position. These relative codes provide a flexible and efficient mechanism for performing sensorimotor transformations. First, a code for the relative position of the eyes and hand can be interpreted or read out by other brain areas as specifying the position of the hand in eye coordinates and thus can be used to derive a representation of the desired movement vector in this reference frame. However, relative codes allow this process to be inverted as well, for example, the position of a goal location in eye coordinates can be recovered if only the eye-in-hand and reach movement vectors are known. Such computations would be particularly useful during tasks requiring coordinated movements of the eyes and hands and could reduce errors in estimating eye and limb position that normally accumulate over time. The manner of relative coding described in PMd, where an explicit code for the eye–hand vector coexists with codes for the reach goal in both eye and limb coordinates, provides a compact estimation of the entire system state that would allow coordinated hand and eye movements to occur even while the entire body is translating through space.

Glossary

Anxiety – An anticipation of a future threat, which is a normal and adaptive response that ensures dangers are either avoided or reduced through preparation and vigilance. When a threat is poorly defined or temporally remote, the behavioral state it elicits is typically referred to as anxiety. Anxiety is a cognitively mediated anticipatory state activated to potential threats.

Auditory fear conditioning – A form of associative learning in which an initially neutral conditioned stimulus (CS; e.g., a tone) acquires aversive properties following its pairing to an unconditioned stimulus (e.g., a footshock).

Conditioned stimulus – An initially neutral stimulus (e.g., tone) that acquires aversive properties after being paired to an aversive unconditioned stimulus (e.g., a footshock).

Fear – An adaptive response to an immediate threat. It is a normal and adaptive response that ensures dangers are either avoided or reduced through preparation and vigilance. Well-defined threatening stimuli that are immediately present or imminent in the environment elicit a fear response. Fear is thus a sensory-driven and time-limited response to actual adversity.

Long-term potentiation (LTP) – A persistent strengthening of synapses that is generally induced by applying high-frequency stimulation to an afferent pathway. It is thought to be the mechanism underlying memory formation. There is some evidence that LTP-like changes are induced during learning.

Plasticity – The potential for a system or network to be modified. Modifications in synaptic efficacy (e.g., LTP induction) are taken as evidence that a network was plastic.

Unconditioned stimulus – In the context of auditory fear conditioning, the unconditioned stimulus is an aversive stimulus (generally a footshock) that yields fear responses when presented alone. After pairing it to an initially neutral, CS (e.g., a tone), the CS also generates fear responses on its own.

Introduction: From Behavior to Synaptic Plasticity

The acquisition of fear engages a complex neural network that involves a number of structures. However, when both behavior and underlying circuitry are reduced to a more basic form, a powerful framework from which to study fear emerges. This framework can be used to study the neural changes associated with normal fear learning, as well as the mechanisms that underlie many psychiatric disorders that arise from fear dysregulation. Here, we review the basic anatomical circuitry and neurophysiological plasticity associated with auditory fear conditioning, and then conclude by emphasizing the relevance of these models to fear- and anxiety-related plasticity.

Fear Conditioning and Anxiety

Fear is a response to an immediate threat, while anxiety is an anticipation of a future threat. Fear and anxiety are normal and adaptive responses that ensure dangers are either avoided or reduced through preparation and vigilance. Well-defined threatening stimuli that are immediately present or imminent in the environment elicit a fear response. When a threat is poorly defined or temporally remote, the behavioral state it elicits is typically referred to as anxiety. Fear is thus a sensory-driven and time-limited response to actual adversity, whereas anxiety is a cognitively mediated anticipatory state activated to potential threats. When a fear or anxiety response is out of proportion to that warranted by the situation, or surfaces in the absence of threat, a fear or anxiety disorder exists.

Animal models are essential for understanding the neural basis of behavior, and a number of experimental paradigms are used to study fear and anxiety. Fear, which is easier to define and measure, has been most extensively studied using Pavlovian fear conditioning – an experimental procedure in which an initially neutral stimulus (conditioned stimulus, CS; e.g., a tone) acquires the ability to elicit fear responses after being paired with an

unconditioned stimulus (US; e.g., a shock). Much evidence indicates that this type of association requires circuits that transmit information into and out of the amygdala. Although animal models of anxiety have been developed to test for anxiolytic drug efficacy, the neural circuitry that underlies these anxiety-like behaviors is not well understood. Thus, in describing the neural mechanisms that mediate fear and anxiety, we mostly rely on and draw inferences from pathways known to be implicated in fear processing through studies of fear conditioning.

Anatomy of the Fear Circuit: Pathways to, within, and Out of the Amygdala

Most work on fear conditioning has utilized an auditory fear-conditioning paradigm in which an auditory stimulus serves as the CS. The neural network underlying auditory

fear conditioning is very well characterized and involves pathways into, through, and out of the amygdala. In brief, evidence from a variety of different approaches indicates that the physiological basis of fear learning starts with the relay of sensory information to the lateral nucleus of the amygdala (LA), where the CS and US converge and initiate synaptic changes. When the CS is later encountered, it is transmitted via intra-amygdalar pathways to the central nucleus of the amygdala (CE), which controls the expression of behavioral and physiological fear responses by way of projections to brainstem and hypothalamic targets (see **Figure 1**).

Transmission of CS and US Information to the Amygdala

Information about the auditory CS is processed in thalamic areas that transmit the signals to the auditory cortex

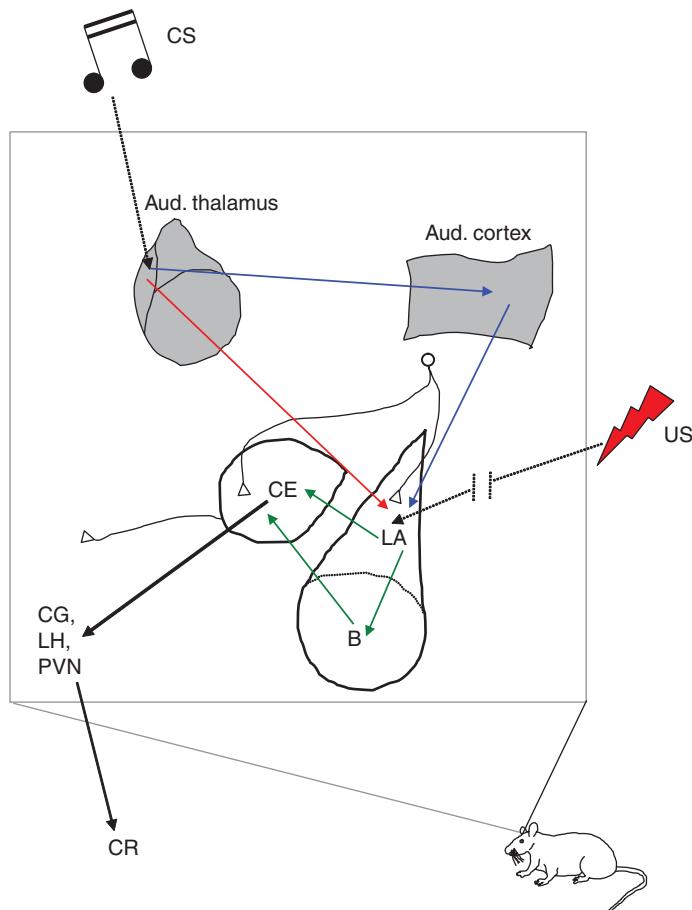

Figure 1 Anatomical circuits of auditory fear conditioning. Auditory fear conditioning is a form of associative learning in which an initially neutral conditioned stimulus (CS; e.g., a tone) acquires aversive properties after its pairing to an unconditioned stimulus (e.g., a footshock). Information about the CS travels through direct (thalamus, shown in red) and indirect (thalamus + cortex, shown in blue) pathways, and inputs from CS and US converge on single neurons in the lateral nucleus of the amygdala (LA). Following intra-amygdalar transfer of information to the central nucleus (CE; shown in green), outputs to the brainstem (central gray (CG)) and hypothalamus (lateral hypothalamus (LH)), paraventricular hypothalamus (PVN) initiate fear expression (conditioned response (CR), shown in black). This is a simplified version of the anatomical circuitry that underlies fear conditioning.

as well as directly to the amygdala. In the thalamus, the medial division of the medial geniculate nucleus and the posterior intralaminar nucleus (MGm/PIN) project directly to the LA, the sensory gateway into the amygdala. All areas of the medial geniculate nucleus also project to the auditory cortex, which, in turn, connects with LA. The US is also transmitted to the amygdala via thalamic and cortical pathways.

Both the thalamic and cortical auditory inputs to the amygdala involve excitatory glutamatergic projections. Both the direct and indirect pathways can support fear learning, but the pathways transmit different kinds of information. The thalamic route carries rapid but crude aspects of the CS; the cortical route reaches the LA more slowly, but transmits more detailed information. The direct, but not the indirect, route is thought to be necessary for auditory fear conditioning – pretraining lesions of the MGm/PIN impair the acquisition of cued fear memories, while those of the auditory cortex do not. The auditory cortex, nevertheless, plays a key role in stimuli discriminations. Effectively, the cortex is necessary for conditioning to a complex stimulus (such as frequency-modulated tones of ultrasonic vocalizations). Furthermore, cell firing is modified in the auditory cortex during conditioning. To date, however, the precise conditions that necessitate the involvement of the cortex in the acquisition of fear are not well understood.

Intra-Amygdalar Circuits and Outputs

The amygdala is composed of many different subnuclei, and these different areas are thought to play different roles in the acquisition of fear. The LA receives the initial inputs from the CS and US and is widely believed to be the key site of plastic events leading to and supporting fear conditioning. The basal (B) and CE nuclei also clearly play a role in fear expression and, possibly, acquisition. Both of these receive connections from the LA. In addition, LA connects with CE via B and the intercalated cells (ICs).

The CE projects to the various brainstem areas that have been shown to mediate the specific behaviors and physiological responses elicited by the CS. In particular, the CE projects to the hypothalamus, brainstem, and the forebrain – regions that control endocrine, autonomic, as well as behavioral responses elicited during fear conditioning. Projections from the CE to the periaqueductal gray are important for behavioral responses; CS-triggered endocrine responses are thought to involve projections to the paraventricular nucleus (PVN) of the hypothalamus; and the connections to the lateral hypothalamus mediate cardiovascular responses. Output cells from the LA are excitatory, whereas the ICs and many CE cells are inhibitory. Thus, increased input from the auditory thalamus leads to an increased glutamatergic projection from the

LA which potentiates CE output. The net result is an enhancement of behavioral and physiological responses to the threat.

The role of the B in fear conditioning is not yet fully elucidated. Pretraining B lesions do not prevent fear conditioning; however, selective lesions of its anterior, but not posterior, region are associated with deficits in both auditory and contextual fear conditioning. The B was also found to be involved in the performance of fear-motivated instrumental responses. Furthermore, post-training lesions of the B impair fear-memory expression, suggesting that though it is not required for the acquisition of fear, if it is intact during acquisition, it becomes a necessary part of the circuit, and is required for retrieval.

In sum, fear conditioning initially involves the relay of sensory information from the auditory thalamus to the LA, either directly or via auditory cortex, and then the transfer of signals over intra-amygdalar pathways to the CE. Fear responses are initiated by way of projections from the CE to various brainstem targets. The manner in which these various circuits to, within, and from the amygdala can be modified by fear conditioning is crucial to our understanding of the acquisition of fear memory.

Neurophysiology of the Fear Circuit: Synaptic Plasticity and Memory in the LA

Activity-dependent modifications in synaptic plasticity occur during learning, and these changes in the circuitry are thought to persist and make memory possible. As the site of CS-US input convergence, the LA is ideally suited as the area of plasticity underlying Pavlovian auditory fear conditioning. Here we review evidence that LA cells are plastic – have the potential to be modified – in response to input from areas implicated in the fear circuit. Converging evidence in this regard comes from a number of analytical levels – from single-cell changes, to broader network connections. Studies in this area are conducted using a variety of preparations – *in vitro* and *in vivo* (acute and freely behaving) – and plasticity is induced via both artificial means (stimulation) and more realistic paradigms (behavioral conditioning). The tremendous impact of fear in an animal's life, coupled with the relatively simple nature of its most basic underlying circuits, boosts our ability to detect changes induced by its acquisition and storage.

Single-Cell and Multiunit Firing

Pairing the CS with the US induces changes to firing properties of LA neurons – stimulus-evoked firing increases after conditioning. Single-unit studies suggest that there are two populations of LA cells in the dorsal half of the LA that undergo plasticity following

conditioning. One group, in the superior portion of the dorsal LA, shows a transient increase in firing in response to the CS. The other group, found in the inferior portion of the dorsal LA, exhibits a persistent increase in firing throughout training and testing. The superior 'transiently plastic cells' exhibit shorter firing latencies (10–15 ms) and are susceptible to extinction, whereas the inferior 'long-term plastic cells' have firing latencies that are likely indicative of a polysynaptic response (30–40 ms after the onset of the tone), and are resistant to extinction. Importantly, electrophysiological studies have shown that the same cells that receive CS inputs from the auditory thalamus and cortex also fire in response to the footshock US. This is reminiscent of the plasticity model proposed by McCullough and Pitts in 1943 and by Hebb in 1949. Hebb's model, for example, states, "when an axon of cell A repeatedly and persistently takes part in firing onto B, some growth or metabolic process takes place such that the efficiency of cell A, as one of the cells firing onto B, is increased."

Integrated networks: Artificially and behaviorally induced potentiation

Arguably the most widely studied physical instantiation of Hebbian plasticity, long-term potentiation (LTP) – an artificial means of inducing synaptic modification – has provided an experimental model that has often substituted for directly assessing the effects of learning on synaptic modification. Generally induced by applying high-frequency stimulation to afferent inputs, LTP leads to an increase in the synaptic population response of a group of cells. If the synaptic efficacy and memory hypothesis accurately reflect the mechanisms initiated in the amygdala during fear conditioning, we should expect: (1) for LTP to be inducible in the amygdala, and be bound by similar rules as fear conditioning; (2) that amygdala-dependent learning should increase synaptic strength in that structure (behaviorally induced potentiation); and (3) that preventing the induction of LTP in the LA should prevent the acquisition of fear conditioning and associated plasticity. Past studies support all of these predictions.

- (1) LTP is inducible in the LA by stimulating thalamo-amygdala and cortico-amygdala projections *in vitro* and *in vivo*. LTP in the LA has been induced both by using high-frequency stimulation (tetanus) to afferent pathways as well as a form of associative LTP, induced by pairing subthreshold presynaptic auditory inputs with postsynaptic depolarization of cells in the LA. The two forms differ mechanistically – tetanus-induced potentiation is *N*-methyl-D-aspartate (NMDA) dependent, whereas associative LTP relies on L-type voltage-dependent calcium channels (L-VDCC). Furthermore, associative LTP in the LA is sensitive to the same stimulus contingencies as fear conditioning. Bauer and colleagues have shown that

potentiation is strong when presynaptic trains precede postsynaptic depolarization 100% of the time; however, when noncontingent depolarizations are interleaved with the same number of contiguous pairings (thus decreasing the percentage of contiguous pairing over the course of an entire session) the resultant potentiation is significantly weaker. This suggests that the strength of association, and related change in synaptic efficacy, depends on the contingency between pre- and postsynaptic activity, rather than simply temporal contiguity. The same principles, described by Rescorla, apply behaviorally – contingency, rather than mere temporal overlap, is critical for fear conditioning.

- (2) Auditory stimuli elicit field potentials in the LA of awake, freely behaving rats, and the coincident induction of LTP from stimulation of the thalamic input to LA leads to an enhancement of these auditory responses (see Figure 2). Importantly, associative fear conditioning itself leads to an increase in synaptic efficacy similar to that seen following LTP induction *in vivo* and *in vitro*. Reactivation of a consolidated fear memory was also recently found to induce potentiation in the LA.
- (3) Genetically modified mice that show specific deficits in amygdala-dependent learning also show deficits in LTP induction in that structure. In addition, drugs that block LTP in the LA also interfere with fear conditioning and associated plasticity. For example, both LTP and fear conditioning are impaired by pharmacological blockade of NMDA receptors or L-type VDCCs. Pharmacologically interfering with mitogen-activated protein kinase (MAPK) signaling in the LA has also been found to interfere with LTP, as well as inhibit long-term memory storage and associated plasticity after conditioning.

Cellular and Molecular Mechanisms of LA Plasticity and Fear Learning

Modifications in synaptic strength occur in the LA during the acquisition of fear, and together, the results from previous studies provide strong support for the notion that synaptic strengthening in the LA is required for the acquisition of emotional memories. For that reason, much work reported in previous studies has focused on the mechanisms underlying LTP induction in that region. Two predominant forms of LTP have been found to occur in the LA – early (E-) and late LTP (L-LTP). The former is dependent on sufficient depolarization through calcium entry via NMDA receptors, and the latter occurs via further depolarization mediated by VDCCs. Intra-amygdalar treatments that impair E- and L-LTP, namely NMDA or VDCC blockade, also impair short- and long-term memory,

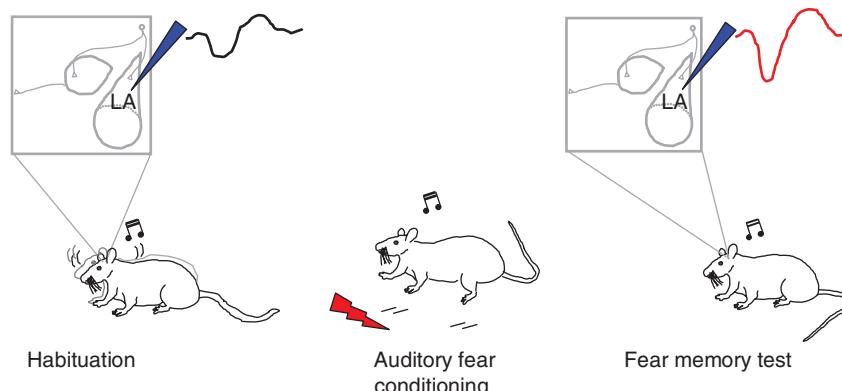

Figure 2 Fear conditioning induces synaptic potentiation at lateral amygdalar synapses. In a chronic recording preparation, the response evoked by the conditioned stimulus (CS; a tone) can be measured before (habituation, CS-evoked field potential shown in black) and after (fear-memory test, CS-evoked field potential shown in red) auditory fear conditioning. When a neutral auditory stimulus is first presented, rats will first show an orienting response, and then ignore it. After its pairing to the unconditioned stimulus (US; a footshock), the CS elicits conditioned responses (e.g., freezing), and a stronger (potentiated) response at lateral amygdalar (LA) synapses. Fear-conditioning-induced potentiation has also been demonstrated *in vitro*.

respectively. Recent studies have shown a role for calcium-regulated intracellular signaling cascades in fear acquisition. For example, both protein kinase A (PKA) and MAPK have been implicated in fear-memory consolidation and associated plasticity. These signaling cascades contribute to long-term memory formation by inducing activation of transcription factors in the nucleus (e.g., cyclic adenosine monophosphate (cAMP)-response-element-binding protein (CREB)). Ou and Gean have also recently shown that calcium influx through NMDA receptors and L-VGCC channels activates PKA and calcium calmodulin-dependent protein kinase IV (CaMKIV), each inducing CREB phosphorylation. In turn, phosphorylated CREB binds to the brain-derived neurotrophic factor (BDNF) promoter, leading to an increase in BDNF expression in the amygdala, and likely contributes to fear-memory consolidation. MAPK signaling in the LA is also necessary for the extinction of fear memories.

Rumpel and colleagues have also shown that fear conditioning drives incorporation of alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors in LA neurons in a synapse-specific manner. Interfering with AMPA receptor trafficking impairs fear conditioning as well as amygdalar LTP, suggesting that it is necessary for the acquisition of fear and associated plasticity. Plasticity at LA synapses is necessary for fear conditioning; yet, approximately only 20% of these cells show conditioning-induced plasticity. Using a transgenic mouse (TetTag) that allows persistent tagging of neurons that are *c-fos* active during a certain time window, Reijmers and colleagues showed that a portion of basolateral neurons that are active during fear conditioning are also active during memory retrieval. Han, Kushner, and colleagues have shown that approximately 20% of cells showed CREB phosphorylation (at the ser831 site) following fear conditioning, suggesting that

CREB potentially plays a role in dictating which cells are to be recruited into a fear-memory engram. These researchers then examined this idea by conducting a series of experiments in which they manipulated CREB function in a subset of LA neurons. They showed that manipulating CREB function influences the probability that individual neurons from the LA will be recruited into a memory trace. Specifically, increasing CREB function renders the neurons more likely to be recruited into the fear-memory network. The precise mechanism underlying this effect is not yet fully understood.

We should also point out that in a typical auditory fear-conditioning experiment, an animal acquires information not only about the tone and the shock, but also to the context in which this pairing occurs. Learning information about the context can also occur in the absence of the tone, using an experimental paradigm in which a shock is repeatedly presented in the context, and leads to contextual fear conditioning. We chose to focus this review on amygdalar plasticity; yet, it is clear that other structures are involved in the fear circuit. One area in particular – the hippocampus – likely plays a role in contextual fear, although its specific role needs to be studied in further detail. The neurophysiological changes that take place during contextual fear learning are also thought to involve the B and LA, as lesions to those regions generally prevent conditioning to context.

Neural Basis of Anxiety

Less is known about the neural mechanisms of anxiety than fear, largely because most of the current tasks designed to test it are not readily conducive to studying circuitry. However, two approaches are discussed below.

One theory, originally proposed by Jeffrey Gray in 1982 and expanded by Gray and McNaughton in 2000, suggested that the key to understanding anxiety and its underlying circuitry was to study the effects of antianxiety drugs. Gray worked based on the premise that a number of drugs – including alcohol, barbiturates, and benzodiazepines – decreased anxiety, despite the fact that they had different biochemical mechanisms of action. These anxiolytics have a similar effect on behavior in animal models of anxiety, and despite acting through different mechanisms, all of these drugs were found to affect septo-hippocampal theta rhythms. In addition, lesions of the septo-hippocampal circuit had a similar effect on behavior as the anxiolytics. In his initial theory, Gray proposed that septo-hippocampal circuits were at the core of anxiety. In a more recent revision of this theory, Gray and McNaughton have expanded the circuitry to also involve the amygdala and the prefrontal cortex. There is some evidence that the amygdala plays a crucial role in anxiety-related behaviors, since injections of benzodiazepines directly into that structure reduce anxiety phenotypes in animal models.

Another theory about anxiety, put forth by Michael Davis, suggests that anxiety might be a function of the bed nucleus of the stria terminalis (BNST). This brain region is an extension of the amygdala, shares similar outputs, and is involved in contextual fear conditioning. The role of the BNST in some animal models of anxiety (e.g., the elevated plus maze and open-field tests), however, has met with mixed results.

One thread that links both theories is the fact that much of the evidence is based on tasks that crucially involve contextual fear learning (i.e., passive avoidance and light-dark test). Since contextual fear conditioning depends on the hippocampus, one interpretation is that the hippocampus is involved in these tasks because they involve context processing rather than because they involve anxiety itself. On the other hand, the hippocampus may be involved in anxiety because of its role in explicit memory. That is, a large part of anxiety about future threats is based on explicit memory of past experiences with threats or with facts we have learned about threats.

Clearly, more work remains to be done in order to better understand the neural basis of anxiety. Isolating the precise neural mechanisms engaged during anxiety is challenging, yet, similar effects of neuromodulators on fear and anxiety, as discussed next, suggests that they likely engage overlapping systems.

Neuromodulation of Fear and Anxiety

The information acquired during learning is strongly altered by neuromodulatory inputs engaged either around the time of encoding, or during retrieval. We

illustrate this here with examples from the serotonergic and noradrenergic systems. Serotonin receptors are present in the amygdala, and serotonin release is known to modulate neural transmission in that region. Selective serotonin reuptake inhibitors (SSRIs) are routinely prescribed for, and have shown efficacy in, treating a number of fear and anxiety-related disorders. Burghardt and colleagues have recently shown, using fear conditioning in rats, that acute and chronic administration of SSRIs have a differential effect on fear learning. Specifically, acute administration of SSRIs enhances, and chronic treatment reduces, the acquisition of fear memories. These effects are in agreement with evidence from clinical populations that suggests that in the initial weeks of SSRI treatment, anxious patients show increased anxiety, but after several weeks, it significantly decreases.

Norepinephrine (NE) has long been thought to serve as a signal that facilitates synaptic transmission in response to biologically significant events, and thus contribute to learning and memory. Consistent with this view, locus ceruleus (LC) neurons are activated by novel, arousing, and rewarding stimuli. The specific contribution of NE to learning and memory has been studied extensively by manipulation of NE receptor subtypes systemically or within specific brain structures using a variety of different learning tasks. NE has long been implicated as playing a role in fear and anxiety. Increases in NE's metabolite, 3-methoxy-4-hydroxyphenylglycol (MHPG), are generally found in anxious individuals. In addition, increased plasma levels of NE are also associated with anxiety states.

Debiec and LeDoux have shown that intra-amygdalar or systemic administration of the nonspecific β -adrenergic receptor blocker propranolol at the time of retrieval prevents the reconsolidation of fear memories. This suggests a potential role of the noradrenergic system in modulating the intensity of a previously established memory. In a recent contextual fear-conditioning experiment, in 2007, Hu and colleagues demonstrated that NE enhances memory via phosphorylation of the GluR1 subunit of AMPA receptors (at ser845, and ser831 sites) in the hippocampus, specifically at sites that are critical for synaptic delivery. Phosphorylation of ser845 (PKA site) and ser831 (PKC/CaMKII) is known to regulate glutamate receptor 1 (GluR1) trafficking and function, and may thus be important for structural modification of synapses. Manipulations that persistently alter GluR1 trafficking show promise in attenuating fear memories, and preventing relapse.

Conclusions

Exaggerated or persistent fear is common in psychiatric disorders. The neurophysiological basis of anxiety is not very well defined; however, because anxiety and fear

engage overlapping circuitry, studying the latter provides a useful framework to understand the neural mechanisms that underlie other emotions. This is important, because deliberate actions and thoughts in threatening situations are preceded by automatic adaptive responses, and by understanding these adaptive, phylogenetically conserved reactions, we can be better equipped to keep them in check when they spin out of control. The reductionistic approach of studying a simple behavior in a simple pathway offers many advantages; however, there remains clearly more to uncover. Little is currently known about how emotional reactions transition into actions, but with the study of increasingly complex behavioral tasks and their circuitry, we hope to further our knowledge in that realm. At a minimum, auditory fear conditioning provides a good foundation to work from.

Glossary

Conditioned behaviors – Behaviors that occur to previously neutral stimuli that have been associated with unconditioned stimuli.

Cytotoxic lesions – Lesions affecting the neuronal cell bodies sparing fibers-of-passage.

Fos protein – The product of the *c-fos* immediate early gene commonly used as a marker of neuronal activity.

Unconditioned behaviors – Innate behavioral responses that do not require previous learning.

defensive behaviors (such as freezing and flight) should occur during the response to either a natural predator or an artificial harmful stimulus. This seemingly limited response repertoire suggested the plausible hypothesis that an animal's defensive behavior system processes cues about predators and an artificial threat in the same way, and this has led to a unitary view of the neural network mediating fear responses, with the central amygdalar nucleus playing a critical role in linking fear processing and defensive responses. However, it is also possible that differentiable mechanisms are engaged. Animals are naturally selected to protect themselves from dangers associated with the presence of a predator or a dominant conspecific, which evoke the sensation of fear and associated behavioral responses.

In this article, we examine the neural system analysis from studies using the unconditioned and conditioned defensive behaviors in response to a natural predator or its odor, and the defensive behaviors in subordinate rats in response to conspecific attack. Next, we provide a brief description on the neural systems related to shock-based fear conditioning, and comment on the validity of this model to predict the neural circuitry underlying defensive behaviors triggered by natural threats (i.e., a predator or a dominant conspecific).

Introduction

Fear is the response to a realistic, often imminent threat, while the term 'anxiety' tends to be applied when the source of threat is uncertain, ambiguous, or unrealistic. In his seminal work, *The Expression of the Emotions in Man and Animals*, Charles Darwin considered that the biological origin of human anxiety is based on the defensive responses that nonhumans show to threatening stimuli. These responses, therefore, can be seen as normal emotional states with an adaptive function aimed at promoting survival across species. Anxiety disorders, on the other hand, can be characterized as extreme manifestations of aspects of normal anxiety. The neural basis of anxiety has been established to a great extent in nonhumans, and recent neuroimaging studies have confirmed that human anxiety is accompanied by changes in neural systems involved in coordinating defensive responses to threats in experimental animals.

Animals exhibit defensive behaviors when they are confronted by any type of threatening stimulus. Predators, attack by conspecifics, and dangerous features of the environment represent three classes of threat stimuli that are found in almost any natural environment. The range and complexity of these stimuli may vary for different species and in different locales, but it is probably safe to say that all these classes of threats are relevant to the overwhelming majority of animal species living now or in the past.

It is generally accepted that animals have a set of several, genetically determined, prepackaged behaviors to solve certain functional problems. This idea has been used in the species-specific defensive reaction (SSDR) theory, suggesting that the same innately determined

Antipredatory Defensive Systems

Studies from the Blanchard laboratory have provided much of the background on defensive responses in rodents to cats and other predators, and to cat fur/skin odor. These studies suggest a much wider array of unconditioned defensive behaviors than measured in aversive learning procedures, and this view is strongly supported by field studies of antipredator defense. Of particular relevance, the study of defense and defensive conditioning mechanisms to nonpainful threat has proved particularly helpful in understanding the neural basis of fear and anxiety. Rodent unconditioned defensive behaviors appear to consist of at least the following: flight, hiding, freezing, defensive threat, defensive attack, and risk assessment. These are species typical (i.e., typically expressed by individuals of a given species under appropriate circumstances), but not species specific, in the sense that they occur in the same form across a variety of mammalian species. The unconditioned defensive behaviors are elicited in wild or laboratory strains without

prior relevant experience. In particular, cat exposure to rats produces in the latter intense freezing, avoidance (and hiding, if a place of concealment is available), and elements of risk assessment, such as orientation to the predator. Responses to cat exposure are very resistant to habituation, and conditioning occurs to the context in which the cat had been encountered.

As an experimental technique, the use of predator odor has recently become more common than direct exposure to a cat because of the difficulties in maintaining cats or other predators in laboratory settings. Cat fur/skin odor elicits some freezing and avoidance, typically less intensely than when a live cat is present, combined with higher levels of risk assessment than are seen when exposed to a live cat. These behaviors show rapid conditioning to the context in which the cat fur/skin odor had been present.

Next, we provide an overview of the neural systems underlying unconditioned and conditioned defensive responses to a cat, as well as cat fur/skin odor exposure.

Neural Systems Underlying Unconditioned Responses to a Predator or Its Odor

Amygdalar systems involved in predator detection

Over the last years, a great deal has been learned about the neural system involved in processing innate defensive behaviors to a predator or its odor. The amygdala occupies a central role in integrating the sensory clues related to the predator. Predator odors may in fact be processed by prey species in the accessory olfactory bulb, rather than in the main olfactory bulb. This suggests that cat odor is processed by rats more as a pheromone than as a conventional odor, and the authors suggested that cat odor may be an example of a 'kairomone' – a semiochemical released by one species that has a favorable adaptive effect on a different 'receiving' species. The accessory olfactory bulb projects principally to the medial amygdala,

and rats exposed to cat odor also show substantial activation in this nucleus, particularly in its posterodorsal part. In line with this view, rats with cytotoxic lesions in the medial nucleus, but not in the central nucleus, exhibited a significant reduction in unconditioned fear responses to cat odor. During exposure to a live predator, in addition to activation of the posterodorsal part of the medial amygdalar nucleus, a distinct activation in two other amygdalar sites, namely, the posterior basomedial amygdalar nucleus and caudal levels of the lateral amygdalar nucleus, has also been observed. Importantly, these amygdalar nuclei receive inputs from visual and auditory association areas, and are likely to integrate predator-derived sensory clues, other than olfactory ones. As shown in **Figure 1**, the amygdalar sites related to predator detection project to the dorsomedial part of the ventromedial nucleus of the hypothalamus, which is also particularly mobilized during exposure to a live predator or its odor, and part of the medial hypothalamic defensive system. Therefore, studies using rats exposed to a live cat or its fur odor suggest an amygdalar–hypothalamic path to detect a live predator or its cues. Recent work testing mice exposed to rats validates the idea of this particular amygdalar–hypothalamic path for predator detection in other prey species.

The hippocampal formation and the contextual analysis for predatory environment

Apart from the well-known hippocampal functions related to mnemonic processing, spatial learning, and navigation, the hippocampus also works as a context analyzer. In this regard, it is relevant to point out that the hippocampal formation receives inputs from the amygdalar sites involved in detecting predator-related cues (**Figure 1**) and, therefore, is likely to be involved in associating predator threats to a given environment.

The septohippocampal system is directly related to the medial hypothalamic defensive system, and, therefore, is

in a position to control antipredatory defensive responses. In line with this view, the intermediate regions of field CA1 and subiculum target distinct septal regions projecting to the anterior hypothalamic nucleus, which is part of the medial hypothalamic defensive system.

The medial hypothalamic defensive system

As shown in **Figure 2**, exposure to a cat or its odor induces in the medial hypothalamic zone a distinct Fos up-regulation in the anterior hypothalamic nucleus, the dorsomedial part of the ventromedial hypothalamic nucleus, and the dorsal premammillary nucleus.

Both the anterior hypothalamic nucleus and the dorsomedial part of the ventromedial nucleus project to the

dorsal premammillary nucleus, which, by far, represents the most sensitive brain region responding to a predator or its clues, and where lesions have been most effective in reducing antipredator defensive responses. In fact, the anterior hypothalamic nucleus, the dorsomedial part of the ventromedial hypothalamic nucleus, and the dorsal premammillary nucleus (PMd) are particularly interconnected, forming a partially segregated circuit in the medial zone of the hypothalamus, the so-called medial hypothalamic defensive circuit. Notably, the dorsal premammillary nucleus appears to work as an amplifier for the neural processing in the medial hypothalamic defensive circuit. This would explain why this region is so responsive to predator threats, and why lesions therein are able to reduce defensive responses so

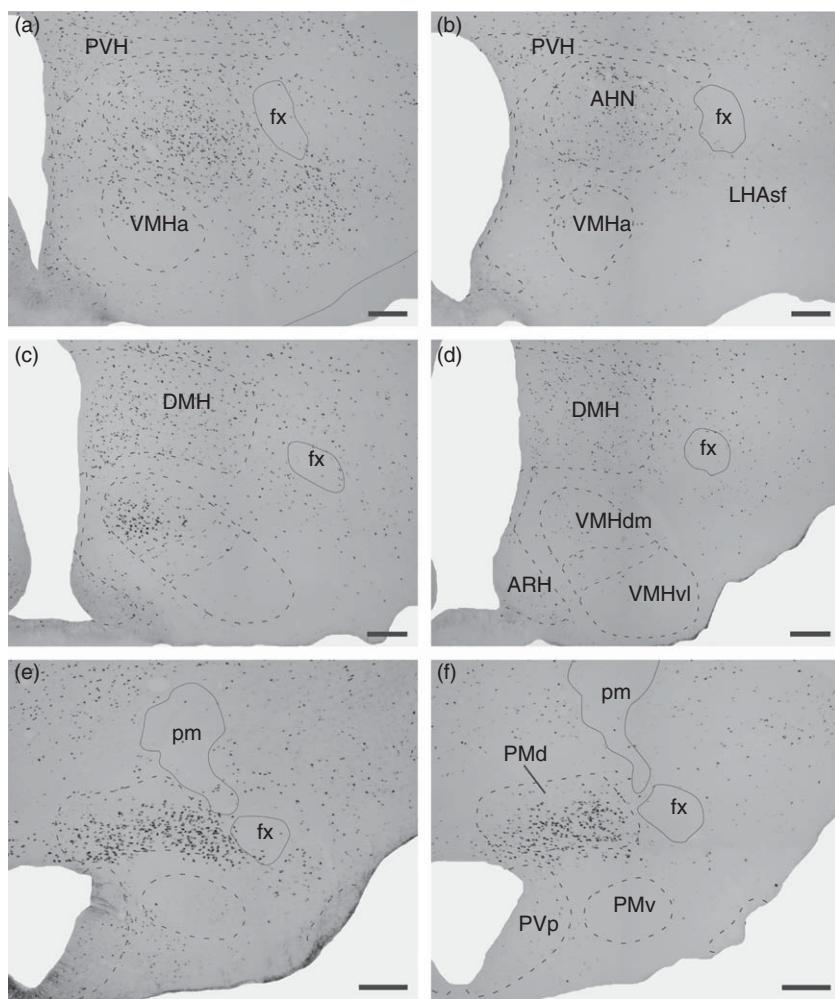

Figure 2 Photomicrographs of transverse Fos-stained sections of the anterior hypothalamic nucleus and subfornical region of the lateral hypothalamic area (a, b), ventromedial hypothalamic nucleus (c, d), and dorsal premammillary nucleus (e, f) from a rat exposed to a cat (left-hand column, a, c, and e) and from an animal exposed to the predatory context (right-hand column, b, d, and f). drastically. However, it is noteworthy that lesions in the PMd have a minimal effect on nonpredator threat stimuli, such as elevated plus maze and postshock contextual cues.

In the lateral hypothalamic zone, the lateral preoptic area and the subfornical region also present a significant Fos increase in response to cat exposure. The lateral preoptic area has been implicated in the modulation of somatomotor responses and general arousal associated with motivated behaviors. Conversely, the subfornical region, similar to the anterior hypothalamic nucleus, also integrates information from the septohippocampal system, and projects to all three medial hypothalamic sites largely activated during cat exposure (see **Figure 1**).

The medial hypothalamic defensive system, in particular the dorsal premammillary nucleus, also receives inputs from another lateral hypothalamic region located immediately dorsal to the supraoptic nucleus, heavily targeted by the lateral component of the retinohypothalamic tract. Retinal ganglion cells projecting to this lateral hypothalamic region are likely to convey information about environmental light intensity. In the context of antipredator defensive responses, it seems plausible to suggest that different behavioral strategies might be expressed depending on environmental luminescence. For example, instead of flight behaviors, freezing immobility seems to be particularly effective as a camouflage in darkness, where freezing greatly reduces prey visibility and noise generation. Moreover, it seems reasonable to believe that this path may, at least in part, mediate the well-documented anxiogenic profile induced by high levels of environmental luminescence.

More recently, an additional prey–predator dyad, mice and rats, respectively, has been used to investigate the hypothalamic systems underlying defensive responses. In the mouse, predator exposure also induces a striking activation of the medial hypothalamic defensive system, giving support to the concept that hypothalamic processing in response to a predator should be preserved across different prey species.

The periaqueductal gray and the integration of antipredatory responses

The periaqueductal gray (PAG) represents the main brainstem target of the medial hypothalamic defensive system, and is critical for the expression of defensive responses. Of special relevance, the pattern of projection from the medial hypothalamic defensive system to the PAG largely overlaps the pattern of PAG activation in animals exposed to a predator or its odor, where Fos expression was mostly seen in the rostral two-thirds of the PAG in the dorsomedial and dorsolateral regions, whereas in the caudal PAG, a less intense, but more widespread activation, was observed. A similar pattern of PAG activation was also described after administration of drugs known to induce panic in humans. In fact,

particularly the dorsolateral PAG appears to play a critical role for integrating forebrain limbic information related to the presence of a natural predator or its odor.

Neural Systems Underlying Conditioned Responses to a Predator or Its Odor

Rats rapidly acquire contextual conditioned defensive responses to the environment where they had previously encountered a predator, or its odor. Thus, long-term risk assessment, as well as freezing and avoidance, are seen in the area where a live cat or its skin/fur odor had been encountered.

The dorsal PMd also seems to be a critical site to influence mnemonic mechanisms linking predatory threats to the associated context. Blocking the N-methyl-D-aspartic acid (NMDA)-mediated neurotransmission of the PMd during cat-odor exposure drastically reduces conditioned defensive responses to the associated environment. This effect in contextual learning may be viewed either as an impairment in the memory consolidation process, or, alternatively, as the result of the decreased emotional component of the aversive event during the learning stage. However, PMd lesions do not seem to affect predator detection, and therefore, PMd-lesioned animals certainly have the aversive experience to the predator presence. The most likely pathway influencing mnemonic mechanisms linking predatory threats to the associated context is the PMd-projecting branch to the ventral anteromedial thalamic nucleus. The anterior thalamic nucleus has been shown to be involved in contextual memory mechanisms. Notably, β -adrenergic blockade of the PMd also produces a deficit in the contextual fear conditioning to cat odor. The effects of β -adrenoceptors on the consolidation processes of aversive memories have been consistently demonstrated in studies using shock-based inhibitory avoidance, as well as shock-based contextual and cued fear conditioning, and have stressed the role of the basolateral amygdala in mediating the effects of β -adrenoceptors on the consolidation processes of aversive memories. Accordingly, an alternative view seems to emerge suggesting a path comprising the PMd and the ventral anteromedial thalamic nucleus as mediating the effects of β -adrenoceptors on the emotional memory processing to predator threats (see **Figure 1**). Notably, in contrast to what has been found using shock-based inhibitory avoidance and fear conditioning, basolateral amygdalar lesion or pharmacological inactivation, appear to produce only a relatively small reduction in cat-odor contextual conditioned responses. This relationship between the PMd and memory processing perhaps helps to explain why exposure to a cat or its odor, which induces a striking PMd activation, produces such a rapid and robust conditioned defensive behavior, while the

trimethylthiazoline (a synthetic compound isolated from fox feces) which does not activate the PMd, fails to support rapid and robust conditioned responses.

Studies examining the neural system responsible for contextual conditioned responses to cat odor observed a robust activation of the PMd in response to cat-odor-associated context, and suggested that there is an overlap between the neural systems associated with the expression of unconditioned and contextual conditioned antipredator defensive responses. In line with this view, rats exposed to a hostile environment, where a live cat had been previously encountered, present a partial activation of the medial hypothalamic defensive system, where increased Fos expression was found in the anterior hypothalamic nucleus and the PMd. As previously noted, the anterior hypothalamic nucleus integrates most of the septohippocampal inputs to the medial hypothalamic defensive system, and lesion studies have shown that damage to the ventral hippocampus significantly attenuated conditioned defensive behaviors following re-exposure to contexts associated with either a live cat or its odor. Moreover, pharmacological PMd inactivation with muscimol drastically reduced conditioned defensive behaviors during exposure to the hostile environment, where a live cat had been previously encountered.

In contrast to the anterior hypothalamic nucleus and the PMd, the dorsomedial part of the ventromedial hypothalamic nucleus and its allied amygdalar paths, which seem particularly involved in detecting the actual predator-related stimuli, either a live cat or its odor, do not respond to predator-related contextual cues. Taken as a whole, the evidence suggests that the medial hypothalamic defensive system, in particular the anterior hypothalamic nucleus and the PMd, should be involved in integrating antipredator contextual conditioning responses as well (Figure 3). Curiously, previous fear-conditioning studies using foot-shock do not identify the involvement of any element of the medial hypothalamic defensive system.

As with unconditioned antipredator defensive responses, the PAG seems to be a critical site for organizing the expression of contextual conditioned antipredator responses. Animals exposed to the environment where a live cat had been previously encountered present a pattern of PAG activation similar to the one seen in response to the actual predator, but considerably less intense.

Neural Systems Underlying Defensive Responses to a Dominant Conspecific

Instinctive responses accompanied by fear have also evolved to protect individuals from opponents of the same species (dominant conspecifics). The neural basis of defensive behavior seen in subordinate rats exposed to dominant males has just begun to be unraveled in studies using the resident-intruder test. For the resident-intruder test, residents are first housed individually with a female rat for several weeks. On the test day, the female is removed and an unfamiliar male intruder is placed in the home chamber. After the first resident attack with a painful experience (i.e., a bite), intruders remain passively frozen in the position they were left by the resident (passive defense) for a long period. However, during the attack, intruders also present an active form of defense by trying to push the resident away, assuming an upright position with sparse boxing, and occasionally dashing away from the resident (active defense). The investigation on Fos-activation pattern in intruder conspecific animals revealed quite a different pattern from that found in rats exposed to a natural predator. Intruder rats exposed to resident males upregulate Fos expression in the medial preoptic area, ventrolateral part of the ventromedial nucleus, ventral premammillary nucleus, and PMd. Careful anatomical inspection indicates, however, that PMd-activation patterns are not identical between intruders and rats exposed to a predator or predatory context. While, in rats exposed to a predator or predatory context, Fos up-regulation is centered in ventrolateral regions of the PMd (Figure 2), up-regulation following exposure to a conspecific resident is centered in dorsomedial regions of the nucleus. However, exactly how information related to cues involving the social recognition of dominant conspecifics reaches the dorsomedial region of the PMd remains to be established neuroanatomically.

Similarly to what was described for predatory threats, PMd lesions also disrupt fear responses during social agonistic encounters. In fact, PMd-lesioned intruders lose passive defensive postures such as freezing and the stereotyped, sustained on-the-back position after resident departure, and do not try to escape from the resident. The

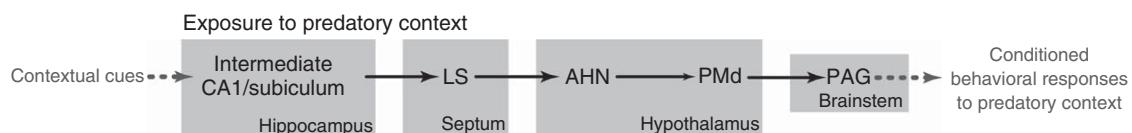

Figure 3 Schematic diagram showing the brain systems involved in processing contextual conditioned predatory threats, as well as in organizing conditioned fear responses to predatory threats. AHN, anterior hypothalamic nucleus; CA1, field CA1; LS, lateral septal nucleus; PAG, periaqueductal gray; and PMd, dorsal premammillary nucleus. With permission from Cezario AF, Ribeiro-Barbosa ER, Baldo MVC, and Canteras NS (2008) Hypothalamic sites responding to predator threats: The role of the dorsal premammillary nucleus in unconditioned and conditioned anti-predatory defensive behavior. *European Journal of Neuroscience* 28: 1003–1015.

behavior of the animals suggests that their fear of the dominant conspecific is drastically reduced while active defense responses are maintained, and they can keep the resident at bay during the attack by standing upright and boxing.

The evidence thus far indicates that PMd lesions profoundly and selectively impair defensive behavioral responses to a predator and a dominant conspecific, and that ventrolateral regions are preferentially activated in the former, whereas dorsomedial regions are preferentially activated in the latter. As noted above, the PMd is a major source of axonal inputs to the PAG, which apparently acts as a downstream mediator of PMd influences on defensive behavioral responses. Complementary to what was observed for predatory threat, the behavioral response to a dominant conspecific is associated with a pattern of Fos up-regulation in the PAG that matches closely the axonal projection pattern from the dorsomedial part of the PMd to PAG, which during conspecific threats, upregulates Fos expression in its lateral and dorsomedial divisions.

The current evidence indicates that the hypothalamus plays a critical role in responses to both predatory and conspecific threats, and that fear reactions evoked by these different natural-threat categories are processed by distinct neural pathways.

in the lateral nucleus. In fact, both acquisition and retention of fear conditioning occur in the lateral nucleus, where electrolytic and excitotoxic lesions, as well as pharmacological blockade, prevent acquisition and expression of fear conditioning. The lateral nucleus presents clear synapse plasticity during fear conditioning, and changes the way a conditioned stimulus is processed after the shock pairing. The lateral nucleus, in turn, projects to the central nucleus. The central nucleus, via projections to the hypothalamus and brainstem, is critical for the expression of fear conditioning. In fact, lesions of the central nucleus disrupt freezing, along with the autonomic reactions observed during fear conditioning. More recent studies, however, have also suggested a role for the central nucleus in learning and storage of fear conditioning.

However, this relatively well-developed neural system model for general fear responses does not apply to innate fear responses elicited by ethologically relevant threats. Thus, lesions of the central nucleus have at best marginal effects on defensive responses to a predator or predator odor, and latent Toxoplasma infection with parasite entry into the rodent brain, and a subsequent loss of innate defensive responses to cat odor has no effect on fear responses to a conditioned stimulus previously paired with a shock.

Pavlovian Fear-Conditioning Studies

The prevailing view of central fear system organization emerged from paradigms using electric shock as a conditioning stimulus. Based on the assumption that animals display an essentially unitary defensive response to any and all types of threats, it has been suggested that a general core circuit or neural system underlies all types of fear.

Studies on the neural basis of Pavlovian conditioned fear indicate the amygdala as a major player in learning, storage, and expression of fear conditioning. Among the amygdalar regions, two nuclei have been particularly focused on the fear-conditioning research, namely, the lateral and central nuclei. As shown in **Figure 4**, associative learning between the conditioned and unconditioned stimuli is likely to occur

Concluding Remarks

Different animal-model approaches have distinct backgrounds, and therefore, they tell us different things. Fear responses to ethologically relevant threats, such as a predator or dominant conspecific, should be comparable to other types of goal-oriented behaviors inasmuch as they are accompanied by powerful motivational components. As is the case for other classes of goal-oriented behaviors like ingestion and reproduction, evidence suggests that the hypothalamus plays an essential role in integrating defensive responses to life-endangering natural threats, and further indicates that different neural circuits mediate hypothalamic processing and behavioral responses to different classes of natural threats.

Glossary

- Conditioned reinforcement** – The process by which a Pavlovian conditioned stimulus can act as a reinforcer.
- Discounting** – The reduction in economic utility of a goal as a function of some parameter of that goal (such as the delay to obtaining it, the probability of obtaining it, or its magnitude).
- Goal-directed action** – Behavior that depends upon a joint representation of (1) the instrumental contingency between a subject's actions and the consequences or outcomes of those actions, and (2) the value (instrumental incentive value) of those outcomes.
- Habit (stimulus–response habit)** – Behavior that depends on a direct association between environmental stimuli and behavioral responses.
- Incentive learning** – The process by which actual experience of a reinforcer, in a particular motivational state, leads to learning or modification of the incentive value governing goal-directed action.
- Instrumental (operant) conditioning** – The modification of behavior in response to a causal contingency between a subject's behavior and significant environmental consequences.
- P(A|B)** – Probability of A occurring, given that B has occurred.
- Pavlovian (classical) conditioning** – The association of neutral stimuli with biologically significant events (unconditioned stimuli); as a result of the association, the neutral stimuli become conditioned stimuli.
- Pavlovian-instrumental transfer** – The influence of Pavlovian conditioned stimuli upon the rate of ongoing instrumental responding.
- Reinforcer** – Events whose occurrence or removal strengthens preceding behavioral responses. Those that strengthen preceding responses are positive reinforcers; events whose removal strengthens preceding responses are negative reinforcers.
- Reward** – a term with variable uses, but typically (as here) used to mean an appetitive stimulus and positive reinforcer.

mechanisms for action. Ongoing experimental developments in the field of animal learning theory have elucidated multiple psychological processes contributing to action, and significant progress has been made recently in determining the neural substrates of these processes. Behavior has also been studied in terms of economic decision making, yielding further information about brain function. Contemporary views of motivated action will first be presented briefly, to allow discussion of its neural basis.

Basic Motivational States

Motivational states such as hunger and thirst are intuitively obvious through personal experience, but defining motivational states is instructive. Motivational states are inferred in other animals by observing their behavior, and a circular argument must be avoided. Suppose an experimenter arranges matters so response R produces outcome O, and the subject performs R frequently. It contributes nothing to suggest that the subject lacks O and has an O-seeking drive, which motivates its behavior, as this is circular (R is motivated by O-drive; O-drive is inferred from the performance of R). Likewise, it contributes nothing to suggest that the subject likes performing R: any behavior can be explained by postulating that the behavior itself is the subject's objective. Skinner defined reinforcers by their effect on behavior (events that strengthen preceding responses are positive reinforcers; events whose removal strengthens preceding responses are negative reinforcers) and, to avoid circularity, held that behavior cannot be said to have altered as a consequence of reinforcement.

Nonetheless, it need not be circular to suggest motivational states as 'hidden' explanatory variables. Concepts such as thirst are useful because they are excellent and parsimonious predictors of behavior and are themselves easily predicted. For example, thirst may be elicited by many well-known stimuli (water deprivation, eating dry food, hypertonic saline injection, angiotensin II) and predicts many behaviors (volume of water drunk, speed of drinking, the amount of aversive adulterant required to stop the drinking, and the amount of work the subject will perform to obtain water).

Such ideas lead naturally to concepts of motivation in terms of 'drive reduction' and homeostasis. These concepts provide clear descriptions of many simple consumptive behaviors and remain of interest, for

Psychology of Motivated Action

The study of motivation is the study of the reasons why animals act. Neuroscientific approaches to this question depend on a sound understanding of the psychological

example, in the study of food intake and long-term body weight regulation. Equally, animals' actions are not always directed to a clear physiological need: obvious examples are sexual behavior, the consumption of addictive plant products, and electrical brain self-stimulation, although homeostatic concepts and related ideas such as allostasis (where a homeostatic set point is chronically changed at physiological cost to the organism) have been applied to the regulation of 'reward' intake more generally, including in the context of addiction. However, not all motivated behavior yields to a simple homeostatic analysis. It is useful, therefore, to consider routes to action and economic perspectives on behavior more generally.

Unlearned Responses

Some actions are not motivated in the intuitive sense at all: complex behavioral responses may be innately specified, with specific triggering stimuli (such as swallowing, or the manner in which some geese roll eggs or egg-like objects into their nests, continuing the movement even if the egg is lost or removed by an experimenter).

Pavlovian Conditioning

In a Pavlovian conditioning procedure, an initially neutral stimulus (the (to-be-)conditioned stimulus, or CS) is presented to the subject paired with a motivationally significant unconditioned stimulus (US) that, on its own, elicits an unconditioned behavioral response (UR). This CS-US pairing can create associations between internal representations of the CS and the US (stimulus-stimulus associations); it can also create associations between the CS and the UR (stimulus-response associations), and it can create associations between the CS and a representation of value or affect ('good' or 'bad' emotional states). Pavlovian conditioning therefore creates several psychological routes to action.

Of note, while some conditioned responses are concerned with direct physical responses to a predicted stimulus (e.g. blinking, salivation), other so-called 'preparatory' conditioned responses are directly concerned with motivated action. For example, subjects may approach appetitive CSs; this Pavlovian conditioned approach response brings the subject directly towards stimuli that are likely to be behavioral goals.

Goal-Directed Action

In instrumental conditioning studies, the subject's own behavior influences the environment. For example, an experimenter might arrange a contingency between a laboratory rat pressing a lever (action) and receiving food (outcome). An intuitive view might be that the rat comes to press the lever because it learns that the action

causes the outcome, and because it wants the outcome – that is, its actions are goal-directed. Dickinson, Balleine, and colleagues have shown that rats can indeed represent the *action-outcome contingency* and the *instrumental incentive value* of the food, and put these two psychological representations (which are explicit or declarative) together dynamically to act. Changes to either the contingency (e.g., by reducing $P[\text{outcome} | \text{action}] - P[\text{outcome} | \text{no action}]$) or the value of the food affect responding. Environmental cues can act as *discriminative stimuli* telling the subject which instrumental contingencies are in force.

Some caveats apply. Not all actions can be goal directed in a given species; for example, while rats can represent action-outcome contingencies involving lever pressing with ease, not all actions are represented so readily: it is very hard to train rodents to scratch themselves for reward. More significantly, some actions may be trained easily yet not be under the control of the action-outcome contingency: for example, locomotor behavior can be controlled by Pavlovian contingencies (e.g., when an approach response is elicited directly as a Pavlovian conditioned response, described above), and so the goal-directed nature of a given action cannot be taken for granted in neuroscientific experiments.

Incentive Value, Incentive Learning, and Hedonic Assessment

The instrumental incentive value that governs goal-directed action is responsive to primary motivational state: for example, hungry rats will work more for food than sated rats. Counterintuitively, the representation that relates outcome value to motivational state must be learned. Thus, rats do not know, until they have learned, that food is worth more when they are hungry than when they are sated, or that heroin is worth more when they are in the somewhat artificial motivational state of heroin withdrawal. They learn these relationships through a process termed *incentive learning*. Motivational states (hunger, heroin withdrawal, etc.) directly but covertly 'prime' the brain to deliver a *hedonic experience* of outcomes (food, heroin, etc.) that depends directly and unconditionally upon the motivational state. However, actual experience of this hedonic reaction is necessary to 'teach' the value systems that govern action, so that goal-directed behavior can in the future take appropriate account of the motivational state.

Stimulus-Response Habits

A further mechanism of responding is one envisaged from the earliest days of animal learning theory: that the delivery of reward strengthens a direct association between environmental stimuli and the response that preceded the

reward. These stimulus–response associations are referred to as ‘habits’ because, once learned, the occurrence of the response is triggered by the environmental stimuli without depending on the current value of the outcome to the subject. For example, if a rat has developed a habitual lever-press response that gains it food, then devaluation of the food (by satiating the rat, or pairing the food with nausea) does not prevent performance of the habit. Habits represent ‘procedural’ learning in which the outcome itself is not encoded in the association. The degree to which habits come to control behavior depends upon the schedule of reinforcement on which subjects are trained.

Conditioned Motivation: Pavlovian–Instrumental Transfer

A final well-established psychological phenomenon affecting motivated responding is that stimuli with emotional significance acquired through Pavlovian conditioning can affect the rate of instrumental responding. This is termed Pavlovian–instrumental transfer (PIT). In the simplest form (‘simple PIT’), performance of a lever-press response for food can be elevated by presenting, independently of the subject’s behavior, a CS previously paired with food. The strength of the effect depends on the subject’s current motivational state. The effect of such Pavlovian stimuli may be divided into two. There is a general motivating effect (‘general PIT’), so that a CS for a sucrose solution will enhance lever-pressing for sucrose solution, but also for dry food pellets, when the subject is thirsty. This phenomenon is often described as *conditioned motivation*. In addition, CSs may act selectively to potentiate actions with which they share an outcome (‘outcome-specific PIT’; in this example, potentiating lever-pressing for sucrose more than for food), but this does not depend on current motivational state.

Caveats in the Interpretation of Neuroscientific Studies of Motivated Responding

It will immediately be obvious from the discussion above is that it is not possible to characterize an action as, for example, goal-directed, habitual, or Pavlovian without experimentally testing it. The same actions can be generated by different psychological processes and neural systems (**Figure 1**). Thus, simple studies of lever-pressing, approach behavior, or other tasks in laboratory subjects may in fact contain a mixture of types of action, and this is relevant when brain activity is measured or manipulated.

Economic Approaches to Motivation

Traditional economic analyses of behavior begin by assuming that agents are rational (for example, not possessing intransitive preferences) and somehow implement a ‘utility function’ that quantifies preferences. If these agents then learn action–outcome relationships, they can choose actions to maximize their expected utility. These assumptions may be used to calculate subjects’ preferences and utility functions based on their actions, allowing prediction of future behavior.

Behavioral economics extends this approach by noting nonrational phenomena and utility functions that lead to temporally inconsistent choices. For example, Kahneman and Tversky showed that decisions are affected by the context in which they are presented (framing). Ainslie and others have emphasized that the way in which subjects make decisions about delayed rewards is based on a so-called hyperbolic temporal discounting function, in which value is proportional to $1/(1 + K \times \text{delay})$, where K is the individual’s discounting parameter. This leads to time-inconsistent choices such as preference reversal, in which A (e.g., dieting, drug abstinence) may be preferred to B (e.g., dessert, drug) if the decision is made a long time in advance, but B may be preferred to A when the subject is temporally closer to the outcomes. Exaggerated temporal myopia is associated with drug addiction.

Neuroscientific applications to date have included examining the effects of pharmacological and/or anatomical manipulations on the utility function, along with functional imaging correlates of parameters influencing decisions, discussed below.

It must be acknowledged that although the ‘psychological process’ and ‘behavioral economic’ approaches both analyse the same behavior, they have not been fully unified. For example, although it is often tacitly assumed (particularly in human experiments) that economic utility corresponds to instrumental incentive value, this need not always be the case; it is not known exactly in what way goal-directed action, PIT, and habits are influenced by factors such as delays to reward or probabilities of reward arrival, and how their differential contribution to behavior varies with these parameters.

Neuroscience of Basic Motivational States and Hedonic Reactions

Incentive learning depends upon information about basic motivational states. The hypothalamus serves as the final controller of many bodily homeostatic systems, including endocrine function, thermoregulation, autonomic control, and circadian rhythmicity. It plays a key role in initiating ‘consummatory’ behaviors, such as eating, copulation, and

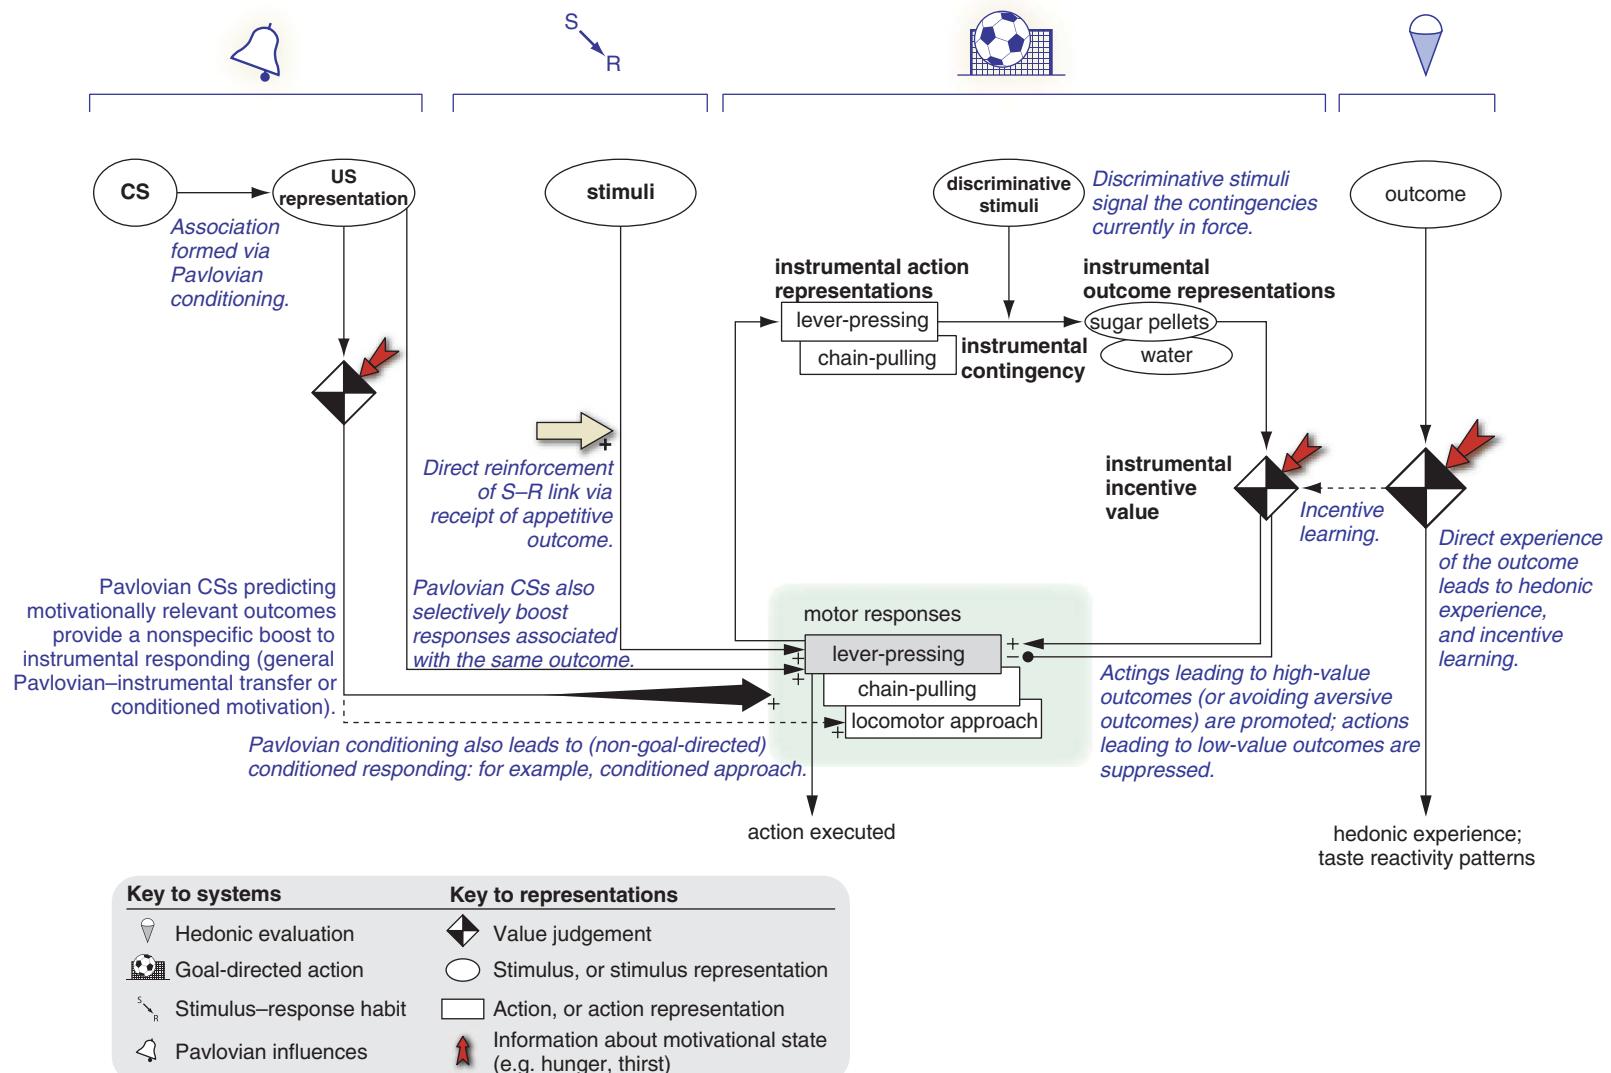

Figure 1 Selected psychological routes to action, including goal-directed action (with examples of actions and goals shown), the learning via hedonic experience of the incentive values governing goal-directed action, stimulus–response habits, Pavlovian influences on instrumental responding (general Pavlovian–instrumental transfer, or conditioned motivation, and outcome-specific Pavlovian–instrumental transfer), and Pavlovian conditioned locomotor approach. See the main text for further explanation. Other aspects of Pavlovian conditioning, and unlearned behaviors, are not shown. (S, stimulus; R, response; CS, conditioned stimulus; US, unconditioned stimulus.)

acts of aggression. It is also responsible for detecting many of the physiological variables relevant to motivational states such as hunger and thirst (such as blood glucose, gut hormones released in response to feeding, tissue osmolality, and hormones released in response to fluid depletion). It is involved in food intake regulation and in the expression of food preferences. The neuroscience of these and related systems is discussed elsewhere in this encyclopedia. A classic example of the distinction between hypothalamic ‘consummatory’ and telencephalic ‘appetitive’ motivation (and hormonal influences thereon) is that lesions of the medial preoptic area of the hypothalamus impair male rats’ ability to copulate with females, but leave their motivation to lever-press for females intact; in contrast, lesions of the basolateral amygdala impair lever-pressing but not copulation, while loss of testosterone impairs both.

As discussed above, hedonic experience triggers incentive learning and is thus required to link basic motivational state information to systems for goal-directed action. Berridge and colleagues have argued that orofacial reactions of several species to food stimuli (taste reactivity patterns) measure hedonic experience; these reactions behave in a manner consistent with the ‘hedonic evaluation’ system, such as tracking motivational state directly. Several neural systems contribute to hedonic experience by this measure, including opioid systems in the nucleus accumbens shell (also shown by Kelley and colleagues to be involved in food preference determination) and in the ventral pallidum, in addition to benzodiazepine- or gamma-aminobutyric acid (GABA)-sensitive systems in the pontine parabrachial nucleus. In keeping with this, incentive learning is affected by benzodiazepines, and by the ‘satiety hormone’ cholecystokinin in interaction with serotonin systems.

Structures and Neuromodulators Supporting Motivated Action

Many neural structures contribute to Pavlovian conditioned responding, and valuation in Pavlovian contexts (such as responding to the value of passively presented stimuli), but not all these routes to action will be discussed. Instead, goal-directed action, habits, and Pavlovian conditioned motivation will be emphasized, and causal (interventional, e.g., lesion) studies of them in particular. These processes rely on a number of valuation systems (discussed above and with neuroeconomics, below). Likewise, appetitive motivation will be emphasized over aversively motivated behavior.

Action–Outcome Contingency and Incentive Learning

Work led by Balleine and others has examined the role of neural structures in goal-directed action. As discussed above, such action depends on the twin representations of the action–outcome (instrumental) contingency and the instrumental incentive value of the outcome. Goal-directed action may be tested for by contingency degradation (typically, two responses that deliver two outcomes are used; one of the outcomes is then also given noncontingently, reducing the contingency for that outcome) and outcome revaluation (in which the value of the outcome, usually a food, is typically reduced by feeding to satiation or associating it with nausea, before responding is retested). These tests of responding are carried out in extinction (without food being delivered) to prevent new learning at the time of testing.

Lesions of the rat medial prefrontal or prelimbic cortex impair the acquisition of goal-directed behavior, as assessed by contingency degradation or outcome devaluation, without preventing subjects from discriminating the actions or the outcomes themselves, or preventing them from acquiring instrumental responding *per se* (the responding such animals do acquire presumably reflecting habitual responding at least in part). However, following training, medial prefrontal cortex lesions do not disrupt sensitivity to outcome devaluation, suggesting that action–outcome associations and incentive values are not permanently stored in this structure. Similar results are seen with lesions of the mediodorsal nucleus of the thalamus.

In contrast, insensitivity to contingency degradation is induced by lesions of the dorsomedial striatum whether those lesions are made before or after training, indicating that this striatal region is involved in action–outcome encoding, and similar effects are seen with temporary N-methyl-D-aspartate glutamate receptor blockade in the dorsomedial striatum at the time of instrumental learning.

Lesions of the basolateral amygdala attenuate the effects of contingency degradation and outcome devaluation in rats, likely by disrupting aspects of the discrimination or encoding of the instrumental outcomes. Lesions of the basolateral amygdala also disrupt Pavlovian motivational processes (discussed below).

The nucleus accumbens makes a complex contribution to motivated action, and is discussed further below. Kelley and colleagues have shown that protein synthesis inhibition within the nucleus accumbens after instrumental training sessions impairs subsequent performance, implying that it contributes to the consolidation of instrumental behavior. However, lesions of the nucleus accumbens do not in general prevent rats from passing the core tests of goal-directed action.

Excitotoxic lesions of the dorsal hippocampus do not affect goal-directed action, but lesions that disrupt the entorhinal cortex and subiculum, or their efferents traversing the hippocampus, impair sensitivity to contingency degradation. This may be due to the involvement of this region in contextual conditioning, since the detection of instrumental contingency requires the comparison of action–outcome relationships, $P(\text{outcome}|\text{action})$, to no-action–outcome or context–outcome relationships, $P(\text{outcome}|\text{no action})$.

Rats with lesions of the insular cortex (insula), the primary gustatory cortex, perform normally on contingency tests, but fail the test of outcome devaluation until the food rewards are actually delivered. This suggests that the insula is involved in storing memories of the incentive value of foods, for use when the foods are not present.

Stimulus–Response Habits

A role for the dorsal striatum in habit learning had been suggested for many years before modern behavioral techniques confirmed this view. Lesions of the dorsolateral striatum abolish habitual responding, leaving actions under the control of the goal-directed system. Killcross and colleagues have demonstrated the same effect after lesions of the rat infralimbic cortex. The role of striatal dopamine in habit learning is discussed below. However, the involvement of other regions of the striatum in goal-directed action (see above) should also be noted.

Conditioned Motivation: Pavlovian–Instrumental Transfer and Related Phenomena

General PIT (conditioned motivation, through which a CS simply energizes behavior) is abolished by lesions of the central nucleus of the amygdala. Such lesions also abolish the acquisition of appetitive Pavlovian conditioned approach, though its role here is confined to learning or teaching this response, since lesions made after training do not affect conditioned approach. The central nucleus of the amygdala may be one controller of the mesolimbic dopamine system, discussed further below, and inactivation of the ventral tegmental area attenuates PIT, as do lesions of the nucleus accumbens shell, one of its targets.

The nucleus accumbens core, which is not required for goal-directed learning, nevertheless strongly influences instrumental responding, including via Pavlovian mechanisms. For example, nucleus accumbens core lesions impair Pavlovian conditioned approach, Pavlovian conditioned place preference, and Pavlovian–instrumental transfer. Conditioned reinforcement is a phenomenon where subjects work for previously learned appetitive Pavlovian CSs. Infusion of amphetamine into the nucleus accumbens enhances the power of

conditioned reinforcement to motivate behavior; the vigor of this effect depends on the nucleus accumbens shell, whilst its direction depends on the nucleus accumbens core.

Lesions of the orbitofrontal cortex, whilst not affecting the outcome devaluation test of goal-directed action described above, disrupt outcome-specific PIT, suggesting that the orbitofrontal cortex is involved in encoding the outcome in Pavlovian but not instrumental conditioning (see also the discussion below). The mediodorsal thalamus is also required for this task.

Similarly, lesions of the basolateral amygdala abolish outcome-specific PIT. Holland, Gallagher, and colleagues have also shown that they abolish the ability of conditioned stimuli to potentiate feeding behavior, an effect that depends upon projections to the lateral hypothalamus. Disconnection (by crossed unilateral lesions) of the basolateral amygdala from the orbitofrontal cortex in macaques impairs choice based upon stimulus–outcome associations when that outcome changes in value. The basolateral amygdala is involved in a host of tasks involving the direction of instrumental (and other) behavior by CS-activated representations of specific and motivationally significant outcomes. This includes conditioned reinforcement, and more complex behavioral tasks such as second-order schedules, in which responding is motivated by an end goal and also by intermittent response-contingent Pavlovian CSs ultimately paired with the final goal. Again, information about conditioned reinforcement is processed through the nucleus accumbens, basolateral amygdala, and orbitofrontal cortex, with the orbitofrontal cortex being important for conditioned reinforcement based on the outcome-specific associations of the conditioned stimulus. In the case of cocaine seeking under second-order schedules, there is evidence that a direct functional connection between the basolateral amygdala and the nucleus accumbens core is required for normal motivated instrumental behavior.

Dopamine Systems and Their Interaction with the Striatum

The midbrain dopamine system, projecting from the substantia nigra pars compacta to the dorsal striatum (nigrostriatal dopamine) and from the ventral tegmental area to the ventral striatum (mesolimbic dopamine) and the prefrontal cortex (mesocortical dopamine), has long been implicated in motivation. The discovery by Olds and Milner that rats would electrically self-stimulate regions of their brain with extreme tenacity and persistence, even crossing electrified floors to reach the stimulating lever, was followed by the observation that many of the ‘hot spots’ for self-stimulation matched the course of axons of mesolimbic dopamine neurons. In recent years, the principle has been used to provide

radio ‘remote control’ of rats by reinforcing directional change with brain microstimulation. Dopamine-releasing drugs including amphetamine and cocaine are powerful reinforcers, and all natural appetitive reinforcers studied increase the release of mesolimbic dopamine.

Dopamine is clearly central to motivational processes. However, dopamine systems appear not to play a role in hedonic experience, instrumental incentive learning, or assessing the magnitude of food rewards. Instead, dopamine plays a major role in Pavlovian conditioned motivation. For example, the strength of PIT, a prototypical measure of conditioned motivation, depends on intact dopamine systems. Dopamine depletion of the nucleus accumbens prevents the acquisition of Pavlovian conditioned approach. As discussed above, amphetamine injection into the nucleus accumbens magnifies the effect of Pavlovian conditioned reinforcers, and this depends on accumbens dopamine. The role of dopamine in response effort is discussed below. Accumbens dopamine is also necessary for ‘preparatory’ behaviors directed at reinforcers themselves: for example, depletion of accumbens dopamine disrupts food hoarding and the locomotor activation induced by food in rats, without disrupting the ‘consummatory’ behavior, eating.

Electrophysiological studies by Schultz and others have shown that midbrain dopamine neurons signal reward prediction error, firing when unpredicted reward is delivered, but transferring this firing to reward-predictive CSs, and decreasing their firing when predicted reward is omitted. A natural idea that follows from this observation and studies of intracranial self-stimulation is that dopamine ‘stamps in’ active patterns of neural activity in its targets, for example consolidating stimulus-response associations in the striatum to become habits. There is evidence in support of this view; for example, dopamine manipulations affect learning rates in humans, amphetamine sensitization (by repeated amphetamine administration) enhances the speed of acquisition of stimulus-response habits, posttraining intra-caudate amphetamine injections enhance learning of stimulus-response tasks, and dorsolateral striatal dopamine depletion impairs habit learning. Likewise, the acquisition of Pavlovian conditioned approach is impaired much more by dopamine depletion of the nucleus accumbens than is its performance, and posttraining dopamine D1 receptor antagonist infusion into the accumbens blocks this acquisition. It is likely that the conjunction of presynaptic (cortical) activity, postsynaptic (striatal) activity, and dopamine release causes long-lasting corticostriatal synaptic strength changes, and this underlies at least part of the process of reinforcement. Dopamine and *N*-methyl-D-aspartate receptor activity in the medial prefrontal cortex is also required for normal acquisition of instrumental responding. However, the precise manner in which such behavior is reinforced, and the anatomical

sites in which habits and other relevant representations are initially formed and eventually reside remains to be determined.

As described above, dopamine is not required for all reinforcement-related learning. Moreover, its effect depends on the target region involved: for example, dopamine in parts of the dorsal striatum may help to consolidate stimulus-response habits, and triggers previously learned behavior, while dopamine in the ventral striatum may help to consolidate and to amplify the impact (and perhaps salience) of conditioned and unconditioned stimuli on instrumental behavior. Differences may exist in responding for drugs of abuse. Established cue-controlled responding for cocaine depends more on dorsal than ventral striatal dopamine; this may reflect habitual or compulsive behavior, which has been shown to dominate responding for some types of drug of abuse. However, this behavior is not free of the influence of the accumbens via other neurochemical systems, and the dorsal and ventral striatum interact (via mechanisms that are still debated) to control responding on cue-controlled schedules of cocaine reinforcement.

The role of dopamine in aversive motivation must not be neglected: for example, accumbens dopamine is elevated in response to conditioned and unconditioned aversive stimuli and is required for normal avoidance behavior; similarly, lesions of the accumbens can impair aversive conditioning tasks, including the modulation of behavioral speed by cues predictive of aversive outcomes, though this topic has not received as much attention as appetitive motivation.

Other Neurochemical Systems

Other neuromodulator systems also play a role in motivated behavior. For example, acetylcholine transmission in the nucleus accumbens is required for normal cue-triggered heroin seeking and acetylcholine influences the ventral tegmental area in simple instrumental acquisition. Serotonin systems modulate the impact of punishment on behavior and promote response inhibition. Other systems (such as hypothalamic orexin neurons) have motivational roles that have yet to be characterized fully. However, the contribution of these systems has been studied less than that of dopamine and space prohibits a full review here.

Neuroeconomic Studies of Motivation

The value of outcomes is a function of their magnitude, the delay to their arrival, and their probability of delivery. The cost of obtaining a desirable outcome, including the effort required, also plays a role in decision making. A number of studies have examined the neural substrates

of complex choice, including abnormalities in executive control and decision making seen in drug addicts, but we will not examine these here. Instead, taking subjects' choices as evidence for their valuation systems (as discussed above), we will consider a number of studies that have examined the neural systems underlying calculations of utility.

Pharmacological Studies

Low levels of serotonin metabolites in the cerebrospinal fluid are correlated with impulsivity and risk taking in several species. Forebrain serotonin depletion tends to steepen the discounting function for delayed rewards, making animals value delayed rewards less. However, the specific effects of serotonin manipulations are complex, varying with receptor subtype and with acute versus chronic manipulations. Forebrain serotonin depletion does not appear to affect the discrimination of reinforcer magnitude, or choice involving reward probability. Richards and colleagues have shown that dopamine D2 receptor activity is necessary for normal choice of delayed rewards, whereas D1 receptor antagonists do not affect such choices. While dopamine neurons may carry information about reward uncertainty in their firing patterns, little is known of the causal role of dopamine in selecting rewards based on their probability.

On the response cost side, Salamone and colleagues have shown that dopamine depletion of the nucleus accumbens substantially reduces the ability of rats to perform instrumental responses when the work requirement is high, but not when it is low, indicating that dopamine here has a significant motivational role. The ventral pallidum is an important downstream target of the nucleus accumbens, and similar 'anergia' can follow pallidal manipulations.

Lesion Studies

Rats' ability to choose large, delayed rewards over small, immediate rewards ('self-controlled' choice) is impaired by lesions of the nucleus accumbens core. Such lesions also impair rats' ability to learn instrumental conditioning tasks with action–outcome delays, and to choose uncertain large rewards over certain small rewards, but do not appear to alter the processing of reward magnitude information.

Bradshaw and colleagues have shown that the orbitofrontal cortex and its dopamine innervation are required for normal valuation of delayed rewards (with lesions inducing steeper discounting) and for the assessment of reward magnitude (with lesions increasing sensitivity to the difference between large and small rewards). The orbitofrontal cortex is also required for normal choice based on reward probability (with lesions steepening

uncertainty discounting and producing risk-averse choice).

Lesions of the basolateral amygdala also impair self-controlled choice, although the specific contribution of this structure to the processing of reward delay and magnitude information is not yet clear. An opposite effect (increased self-control) has been seen after lesions of the subthalamic nucleus, but the same caveats apply.

Excitotoxic lesions of the hippocampus likewise impair self-controlled choice, and the available evidence suggests that such lesions do not disrupt reward magnitude perception. In contrast, hippocampal lesions delay-dependently improve simple instrumental conditioning with delayed reinforcement, perhaps because in this situation the lesions hinder context–outcome associations, promoting response–outcome associations instead.

The anterior cingulate cortex, in contrast, is involved in the assessment of the effort required to obtain a reward; Rushworth and colleagues have shown that rats with lesions here become 'lazy,' or less willing to invest energy for reward. However, the dopaminergic projection to this region is not critical for this.

Correlative Studies

Human functional brain imaging and animal electrophysiology of economic decision making is an expanding field, and has demonstrated neural structures whose activity correlates with reward anticipation and parameters of reward delivery; only a few examples will be given. Many structures thus highlighted accord with the lesion studies summarized above. For example, the nucleus accumbens responds to anticipated rewards in rodents, primates, and birds, and accumbens activation precedes the selection of high-reward, high-risk choices in humans. Theoretical suggestions regarding the observed hyperbolic form of the delay-discounting utility function (whose significance is discussed above) have also been applied to such results. For example, hyperbolic temporal discounting may be due to some combination of a declarative system exhibiting minimal or a simpler form of discounting, reduced associative learning with long delays, and phenomena (perhaps including or related to PIT) that make rewards more salient and promote their choice when they are immediately available. McClure and colleagues have shown that lateral prefrontal and intraparietal cortical regions are activated in a delay-independent manner in temporal discounting tasks, while regions including the ventral striatum and orbitofrontal cortex are preferentially activated by relatively immediate rewards. These results contrast with lesion studies showing that the latter structures promote choice of delayed rewards. An example of the application of economic parameters at high temporal resolution is the demonstration that midbrain

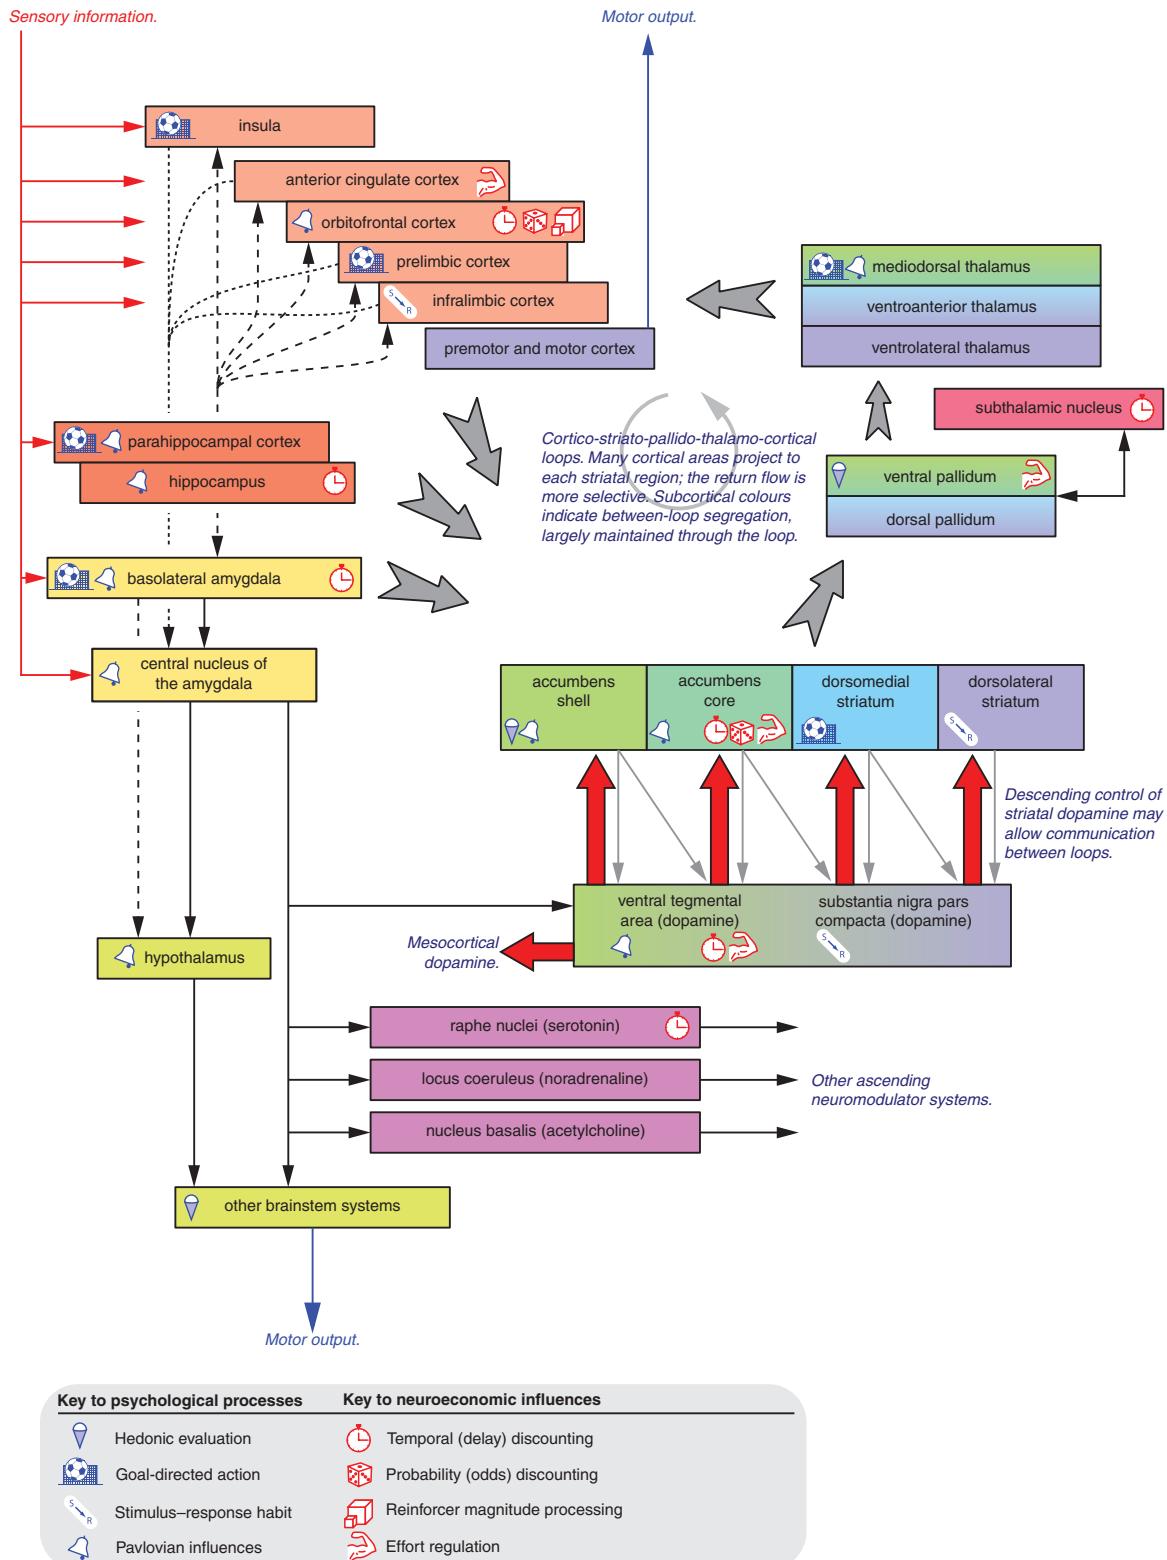

Figure 2 Selected neural structures contributing to motivated action. (The figure is based on the rat brain. The anatomical caudate–putamen distinction in the primate is not as evident in the rat dorsal striatum. The nucleus accumbens is the largest part of the ventral striatum. Prelimbic cortex and infralimbic cortex are regions of rat medial prefrontal cortex; the prelimbic cortex has some functional homology with primate dorsolateral prefrontal cortex.) Many connections are omitted in this figure, and the central corticostriatopallidothalamocortical ('corticostriatal') loops are shown only in outline. Icons on each structure show (in blue) psychological processes subserved by the structure or neuromodulator system, and (in red) neuroeconomic parameters affected by manipulations of the structure. Absence of an icon may indicate either lack of involvement or lack of evidence; space does not permit a complete characterization here. Some structures' involvement may be characterized in alternative ways; for example, one way in which the hippocampus and adjacent cortical areas probably contribute to goal-directed action, Pavlovian conditioning, and responding for delayed reward is by implementing representations of context.

dopamine neuronal responses to CSs exhibit hyperbolic discounting according to reward delay. The causal role of the responses identified by studies such as these has yet to be clarified.

Synthesis and Application to Addiction

The psychological processes outlined in **Figure 1** are implemented by a range of neural structures outlined in **Figure 2**. Systems including the hypothalamus implement basic motivational states and simple ‘consummatory’ behaviors directed at goals that have been achieved. On top of this, several highly complex systems implement behavior to obtain these goals. These include a sophisticated declarative system encoding action–outcome relationships and outcome values, requiring transient involvement of a circuit involving the rat medial prefrontal (prelimbic) cortex and mediodorsal thalamus, and longer-lasting involvement of the dorsomedial striatum; the basolateral amygdala encodes aspects of the predicted goals of behavior, and the memory of the values of foodstuffs also requires gustatory cortex. A simpler habit system depends upon the dorsolateral striatum (likely taught and triggered by dopamine systems) and the rat infralimbic cortex. The direction and invigoration of goal-seeking and preparatory behavior, including by Pavlovian conditioned stimuli, is strongly influenced by information passing through the basolateral amygdala, nucleus accumbens, and in some situations more dorsal regions of the striatum. These and a range of other neurochemical and neuroanatomical systems influence choice between outcomes differing in their probability, delay, and size. The dopamine innervation of the nucleus accumbens, and its pallidal outflow, together with the anterior cingulate cortex, contributes to response effort. In naturalistic settings, goals are frequently available only after a delay, are signaled by environmental stimuli, and require effort to achieve, and a structure such as the nucleus accumbens contributes to motivating behavior in all these situations. Taken as a whole, these systems implement the utility functions that direct behavior.

The concepts outlined here apply as readily to ‘abnormal’ motivations such as drug addiction. Drug seeking may occur for many reasons: drugs are taken for their hedonic value, or their effect on the hedonic value of other rewards, sometimes requiring escalating doses to attain the same effect; users may learn that the drug relieves aversive motivational states such as withdrawal (and the interaction between tolerance to appetitive effects and the avoidance of withdrawal is emphasized in opponent-process theories); drug-associated cues can promote and trigger drug seeking;

drugs may directly amplify the brain’s systems for providing motivation or for learning habits; drugs gain high economic utility to the user through a variety of these processes; drugs alter the normal processing of utility to produce effects such as ‘short-term thinking.’ Current research is elucidating the neural basis of these processes, just as for physiologically necessary motivations, and individual differences in vulnerability to addiction.

Glossary

Autonomic nervous system – It can be subdivided into sympathetic and parasympathetic nervous systems. These systems are involved in the rapid and autonomic control of peripheral organs, including the cardiovascular system required for rest and activity.

c-fos Expression – One of the immediate early genes that become activated after the excitation of a neuron and that remain activated during 1–2 h. The pattern of c-fos expression is used to visualize the neuronal network activated during a certain type of behavior.

Dopamine – An aminergic neurotransmitter system that can be subdivided into two major subdivisions. The nigrostriatal dopaminergic system has the main function of motor control. The mesolimbic dopamine system has its cell bodies in the ventral tegmental area and innervates all neuronal structures of the limbic system.

Gonadal steroids – Steroid hormones produced by the gonads. The male testes produce testosterone and the female ovaries produce estradiol and progesterone. In the brain, testosterone is converted to estradiol by the enzyme aromatase and to dihydrotestosterone by 5- α -reductase.

Offensive aggression – A form of social communication aimed at the active control of the social environment.

Serotonin – An indoleaminergic neurotransmitter whose cell bodies are located in the midline raphe nuclei of the brainstem. Serotonergic neurons innervate virtually every brain structure.

Vasopressin – A peptide produced by magnocellular neurons in the supraoptic and the paraventricular nuclei of the hypothalamus, whose axons project to the posterior pituitary. When released in peripheral circulation, it acts as an antidiuretic hormone, vasoconstrictor, and activator of the hypothalamic–pituitary–adrenal (HPA) axis. Vasopressin is also produced by parvocellular neurons in several distinct brain areas. Within the brain, it acts as a neuropeptide.

aggression is elicited in response to threat or attack by an offensive conspecific, offensive behavior is a form of agonistic behavior initiated by the aggressor and displayed in the context of competition for resources. For example, an offensive male may compete with other males for food, a territory, or females. From a biological point of view, offensive aggressive behavior is a highly functional form of social communication leading to active control of the social environment. It is characterized by a set of species-typical behaviors performed in close interaction with the opponent. Although offensive aggression is highly functional, it is potentially harmful. Therefore, throughout the animal kingdom, strong negative feedback mechanisms have been developed, such as taboos, ritualization, submission, reconciliation, and appeasement, to keep aggression in control and to prevent its potentially adverse consequences. Offensive aggression can thus be defined as a form of social communication aimed at the active control of the social environment. Much of the scientific and public interest in aggression is, however, motivated by the violent, hostile, and presumably less adaptive forms of aggression observed in everyday human life and, clinically, across a wide spectrum of psychiatric and neurological disorders. In this view, violence can be defined as a pathological form of aggressive behavior that is not subjected to inhibitory control mechanisms and that has lost its function in social communication. The relationship between the functional and maladaptive extremes of the offensive aggression spectrum is still far from clear and forms a major obstacle in the integration of animal research with data on human aggression. For the sake of clarity, the neurobiology of violent aggression is not discussed here.

Offensive aggression in animals relates to reactive, hostile, or impulsive aggression in humans. This form of aggression is also called affective aggression and has its strong initiative engagement and autonomic arousal in common with offensive aggression in animals. Moreover, in both animals and humans, this form of aggressive behavior is usually initiated in response to a perceived stress such as the intrusion of an unfamiliar conspecific into the territory. Although both males and females perform offensive aggression, there is a clear gender difference in the frequency and intensity of aggression. Males may perform frequent and fierce offensive aggression in a territorial and sociosexual context. Females show defensive maternal aggression mostly in a maternal context, but low-to-medium levels of offensive aggression can certainly be observed in all female groups in relation to the social hierarchy.

Offensive Aggression

The distinction between offensive and defensive aggression plays a prominent role in understanding the biology and physiology of aggression in animals. While defensive

Neuronal Network

The neuronal network of brain regions involved in offensive aggression has mainly been analyzed in experimental animals such as rats, mice, and hamsters. A network approach in animals is generally based on the pattern of activation of immediate early genes. *c-fos* is such an immediate early gene that shows a prolonged enhanced expression after the excitation of a neuron. Its expression can be visualized using immunohistochemical techniques and is used as a marker of enhanced neuronal activity. Application of this technique in offensive aggression in rats and hamsters reveals a neuronal network that includes the amygdala, the prefrontal cortex, the septal area, several hypothalamic nuclei, and the midbrain periaqueductal gray (see **Figure 1**). This general pattern of activation was confirmed more recently by modern brain imaging techniques such as functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) that allow the *in vivo* analysis of entire neuronal networks involved in certain kinds of behavior. Presumably, due to their constant high activity, brain structures involved in the direct control of motor output usually do not show up in this type of network analyses. Therefore, to make the picture more complete, the general pathway, including basal ganglia, thalamus, and motor cortex, through which emotion is translated into motion has been included in **Figure 1**. The figure also illustrates the brain structures involved in the neuroendocrine and autonomic support of behavior, including offensive aggression. Comparative research indicates that this highly interconnected network for offensive aggression is remarkably similar in many vertebrate

species, including human beings, indicating that it is evolutionarily ancient and well conserved.

Network Components

Hypothalamus

Classic studies in rats, cats, and monkeys using electrical/chemical stimulation of small populations of neurons have revealed a hypothalamic attack area in which offensive attack can be elicited. This area consists of the intermediate hypothalamic area and the ventral pole of ventromedial hypothalamic nucleus. Upon weak electrical stimulation of this area in male rats, they almost immediately start an aggressive attack that stops at the moment the current is switched off. Neuroanatomical studies showed that the hypothalamic attack area forms a crossroad between input from the medial nucleus of the amygdala and the prefrontal cortex and output to the periaqueductal gray, the mediodorsal thalamus, and the lateral septal area (**Figure 1**). Consistent with the general function of the hypothalamus in behavior, it seems likely that this brain area is involved in the neuroendocrine and autonomic support of offensive aggressive behavior.

A second important hypothalamic structure involved in offensive aggression is the medial preoptic area. This area is characterized by its high density of gonadal steroid receptors and gonadal-steroid-converting enzymes such as aromatase and 5- α -reductase. This hypothalamic structure is sexually dimorphic and its function has mainly been explored in sexual behavior and maternal aggression. A few studies show that it is also involved in offensive aggression. For example, the modulation of

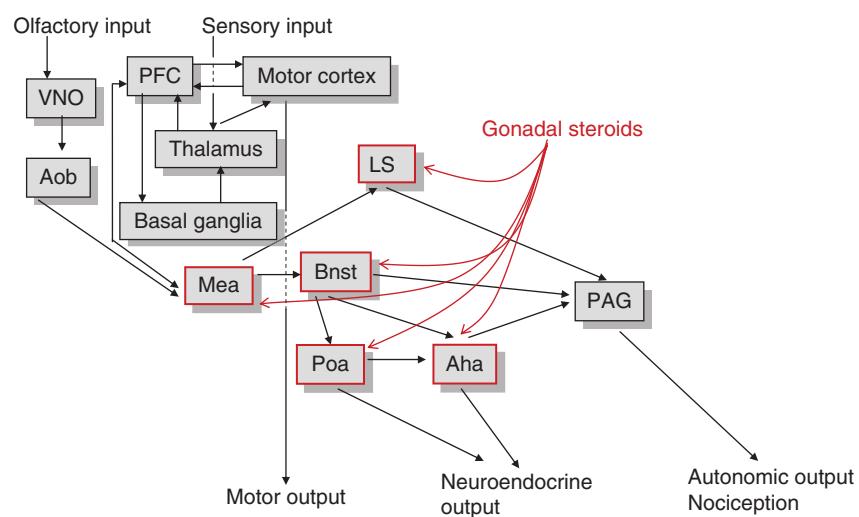

Figure 1 Neuronal network involved in offensive aggressive behavior and the organization of the accompanying neuroendocrine and autonomic activation. VNO, vomeronasal organ; Aob, accessory olfactory bulb; Mea, medial nucleus of the amygdala; PFC, prefrontal cortex; Bnst, bed nucleus of the stria terminalis; Poa, preoptic area; LS, lateral septal area; Aha, anterior hypothalamic nucleus; PAG, periaqueductal gray.

aggressive behavior by seasonal factors in seasonal breeding species is partly mediated by the sensitivity of gonadal steroid receptors in this brain area.

Amygdala

The amygdala consists of a range of interconnected nuclei having a common output through the central nucleus and the bed nucleus of the stria terminalis (Bnst). In particular, the medial amygdala (Mea) and the Bnst have been implicated in offensive aggression. The medial amygdala receives direct input from the accessory olfactory bulb, which, in turn, is the main relay station of olfactory information originating from the vomeronasal organ (**Figure 1**). This part of the olfactory system is specialized in the detecting species-specific chemosensory signals. Hence, olfactory stimuli that are relevant for social behavior in general have a dedicated entrance into the brain, reaching the medial amygdala almost directly. The medial amygdala is characterized by a high density of both estrogen and androgen receptors. These receptors are located, in particular, on neurons that produce the neuropeptide vasopressin (AVP). The synthesis of AVP in these neurons is enhanced by testosterone. This testosterone-dependent vasopressinergic system is sexually dimorphic and projects to the lateral septal area. The medial amygdala has an important function in the modulation of social behavior based on social experience.

Septum

The lateral septum is reciprocally connected to the medial amygdala. It is characterized by a sexual dimorphic density of vasopressinergic fibers originating from the medial amygdala. Males have a higher AVP fiber density than females, and, within the male gender, the density is negatively correlated with offensive aggression. Both in rats and in mice, highly aggressive males have a less dense vasopressinergic innervation of the lateral septum than less aggressive males. Early studies showed that lesions of the septal area in rats induce the septal rage syndrome, which is, in fact, an extremely defensive reaction to both conspecifics and humans. This suggests that the contribution of the septum in offensive behavior might be more anxiety related. Indeed, recent studies using microdialysis of vasopressin during offensive aggression in rats show that male rats characterized by low anxiety and high aggression reduce AVP release in the lateral septum. It seems that septal AVP is involved in the acute modulation of nonaggressive social and anxiety-related behaviors.

Prefrontal Cortex

The prefrontal cortex consists of a number of subregions defined on the basis of their connections with thalamic

nuclei and neuronal cyto-architecture. Although the degree of complexity increases in higher vertebrates, there is a clear homology of prefrontal structures across a wide variety of vertebrate species. The prefrontal cortex is closely connected to both the amygdala and the brain structures involved in motor output, such as the motor cortex and the basal ganglia (see **Figure 1**). In particular, the orbitofrontal cortex has been associated with the inhibitory control of offensive aggression in a number of species. This brain area is more generally involved in behavioral inhibition or impulsivity and the planning of motor output. Indeed, measures of impulsivity in male hamsters are positively correlated with offensive aggression and prefrontal cortex activity measured by c-fos expression. Moreover, reduced prefrontal cortex functioning has been associated with impulsive and violent forms of aggression in animals and humans.

Periaqueductal Gray

c-fos studies show that the periaqueductal gray is activated during offensive aggression. It is therefore generally considered to be part of the neuronal network of offensive aggression. However electrical and neurochemical manipulation of this brainstem structure mainly affects defensive behavior and many of the accompanying sympathetic and parasympathetic responses rather than true offense. Moreover, the structure is involved in the control of pain. Hence, it is conceivable that the periaqueductal gray has a role in the network of offensive aggression mainly by controlling autonomic arousal and antinociception that accompany offensive aggression.

Modulation of the Neuronal Network

Serotonin

All components of the neuronal network for offensive aggression are substantially innervated by serotonergic (5-HT) neurons originating in the dorsal and median raphe nuclei in the brainstem. More than any other neurochemical system, this evolutionary ancient and very well conserved neurotransmitter system is considered the primary molecular modulator of aggression in a wide variety of animal species. However, the nature of this linkage is complex, and it has proven difficult to unravel the precise role of this amine in the predisposition for and execution of offensive aggressive behavior in both its normal and pathological forms. For decades, high levels of aggressive behavior were associated with low serotonergic neurotransmission. This serotonin deficiency hypothesis seems consistent with the fact that serotonergic receptor agonists used to mimic higher serotonergic activity generally reduce aggressive behavior. However, recent studies of the functional status of the

5-HT system before, during, and after the execution of normal adaptive and abnormal pathological forms of aggression have led to a somewhat different view. Display of normal, adaptive offensive aggressive behavior aimed at territorial control and social dominance is associated with a higher 5-HT neuronal activity. A negative correlation between aggression and 5-HT as expressed in the deficiency hypothesis seems to be a trait-like characteristic of pathological forms of aggression (e.g., violence). For example, a clear positive correlation was found between the level of offensive aggression and basal CSF concentrations of 5-HT and/or its metabolite 5-HIAA. A highly significant negative correlation between aggression and 5-HT levels was found only upon inclusion of samples from abnormal and excessively aggressive trained fighter animals. A critical evaluation of the csf 5-HIAA data in aggressive humans confirms the idea that the serotonergic deficiency appears to hold, in particular, in specific groups of individuals who engage in impulsive and violent forms of aggressive behavior rather than in individuals with instrumental (functional) forms of offensive aggression.

Acute treatment with 5-HT_{1A} and 5-HT_{1B} receptor agonists is known to potently and selectively suppress aggressive behavior in a variety of species. Apart from acting on receptors at postsynaptic sites, these two receptor subtypes are the two main serotonergic autoreceptors involved in the negative feedback control of the 5-HT neuron at the level of the synapse (5-HT_{1B}) and at the level of the cell soma (5-HT_{1A}). Activation of these receptors by agonists will potently activate the negative feedback and thereby reduce 5-HT neurotransmission. It appears that the anti-aggressive effects of these compounds are largely expressed through their action on the inhibitory autoreceptors located at the cell soma and the nerve terminal, presumably attenuating intruder-activated 5-HT neurotransmission.

Dopamine

Dopamine has several important functions in the general control of behavior. The nigrostriatal dopaminergic system has a central function in the control of motor output, which is obviously important for offensive aggression as well. The involvement of the mesolimbic dopaminergic system in behavior is only partially understood. The balance between the dopaminergic and serotonergic innervation of the prefrontal cortex is an important determining factor in prefrontal cortex functioning and hence in impulsivity and control of goal-directed behavior, including offensive aggression. The dopaminergic projection from the ventral tegmental area to the nucleus accumbens is generally considered to be involved in reward and the development of addiction. Several studies show that offensive aggression can be highly rewarding, which is consistent with the release of dopamine in the

nucleus accumbens in the offensive male during an aggressive interaction. Moreover, the aggressive phenotype in rats and mice is more generally characterized by a highly sensitive dopaminergic system, which is consistent with a higher vulnerability to substance abuse, as demonstrated in animal models of cocaine self-administration.

Gonadal hormones

Testosterone is the gonadal steroid hormone that has been traditionally associated with male offensive aggression. Indeed, castration in adulthood may reduce aggression, but the correlation between levels of circulating testosterone and aggression is often low or even absent. The behavioral effects of testosterone are partly due to its action on peripheral secondary sex characteristics, changing the stimulus characteristics of the animal. Equally important, however, is its action on the brain. During development, testosterone plays an important role organizing brain and behavior into a more masculine direction. Characteristic of the neuronal network for offensive behavior is that the forebrain structures, in particular, are sensitive to gonadal steroids. The medial amygdala, the Bnst, and the preoptic area are characterized by a high density of estrogen and androgen receptors. Moreover, these structures contain high amounts of aromatase and 5- α reductase, enzymes that convert testosterone into estradiol and the androgen dihydro-testosterone, respectively. Both metabolites of testosterone play a distinct role in the modulation of offensive aggression through their respective action on estrogen and androgen receptors. In particular, the ER α receptor has been implicated in the modulation of offensive aggression. Hence, individual variation in offensive aggression may depend on the density of ER α and the amount of aromatase present in various brain areas. Indeed, aggressive males show higher numbers of ER- α -expressing cells in the lateral septal area, the Bnst, and the preoptic area, and the number of ER α receptors increase with aggression in seasonal reproducing animals. Some evidence suggests that aromatase, and hence the conversion of testosterone into estradiol, depends on experiential factors independent of the level of circulating testosterone. This might explain the absence of a clear correlation between testosterone and aggression in many species.

Vasopressin

The neuropeptide vasopressin plays an important role in the regulation of offensive aggression. Its role in aggression seems to be highly conserved throughout the animal kingdom. The cell bodies of neurons producing the neuropeptide vasopressin are present in a number of brain areas such as the medial amygdala, the Bnst, the supraoptic nucleus, and the paraventricular nucleus of the hypothalamus. These latter two structures are involved

in the release of vasopressin as a hormone in the general circulation through the portal system of the pituitary.

The AVP neurons originating from the Mea and the Bnst are sensitive to the circulating levels of testosterone through both ER α and the androgen receptor. Moreover, the density of AVP neurons in these brain areas and their projection to the lateral septal area are sexually dimorphic. Males have more AVP-producing neurons and nerve terminals than females do. AVP receptors are widely distributed in the brain, but present in higher densities in the lateral septum, anterior hypothalamus, and Bnst. When administered locally in, for example, the anterior hypothalamus, vasopressin generally facilitates offensive aggression through its action on the AVP1a receptor subtype. Studies in hamsters indicate that not only AVP synthesis is dependent on circulating gonadal steroids, but also AVP binding to its receptor in certain brain areas. This strongly suggests that this neuropeptide is involved in the orchestration of brain processes and behavior in response to fluctuations in gonadal hormones. The modulation of offensive behavior is a clear example of this. In addition to this gonadal-steroid-dependent modulation, AVP is also involved in the social-memory-dependent modulation of offensive aggression. For example, repeated winning experience and social dominance enhances AVP1a receptor binding independent of the levels of gonadal steroids.

Neurogenetics

The era of molecular genetics has generated a wealth of transgenic animals, some of which were specifically targeted at genes related to offensive aggression. Others were developed for different purposes, but appeared to differ from their controls in the level of aggressive behavior. Hence, analysis of the neurobiological systems affected in these transgenic animals may elucidate additional components of the neurobiology of offensive aggression.

Manipulation of genes involved in the molecular cascade of serotonergic, dopaminergic, and vasopressinergic neurotransmission clearly affect offensive behavior as predicted from the current knowledge of the involvement of these systems in offensive aggression. An example of this is given in **Table 1** which summarizes the effects on offensive aggression of genetic modification in various components of the serotonergic system.

Currently, there are over 70 genetically modified mouse lines known that show increased or decreased levels of offensive aggression. Several of these transgenic animals show changes in aggressive behavior that could not be predicted from the existing knowledge of the molecular neurobiology of aggression. This holds, in particular, for nitric oxide (NO), which is involved in the modulation of neuronal activity in the cortex and medulla. Mice that lack the gene nitric oxide synthase (nNOS), required for the synthesis of NO, are extremely aggressive if not violent. It is not known how NO fits into the general neurobiological network of aggression as outlined in **Figure 1**. However, changes in serotonergic neurotransmission through unknown molecular pathways seem to be a common factor in the increased level of aggression in many transgenic mouse lines.

Concluding Remarks

Several studies indicate that the neuronal network of offensive behavior as described above is not exclusively involved in this type of behavior. In particular, the medial amygdala and the caudal medial preoptic area are also involved in sexual behavior. It seems that the different forms of social behavior are only partially separated by hard-wired neural systems in the brain and share several higher-order brain areas as well. Several of these areas bind gonadal steroids, and it is suggested that the different forms of social behavior are associated with a differential activation pattern of the various components of the neuronal

Table 1 Genetic modification of serotonergic signaling and its effects on offensive aggression

network. Hence, one has to consider the possibility that a large part of the brain is not organized along the lines of behavioral systems such as offensive aggression. Indeed, a number of studies in a variety of species show the multi-dimensional nature of offensive aggression. For example, a high level of offensive aggression is correlated with high impulsivity, indicating low inhibitory control by the pre-frontal cortex. It is likely that a low prefrontal cortex function will also affect impulse control in the context of sexual behavior or food intake. Offensive aggression is also correlated with a general tendency to actively cope with different kinds of environmental challenges. It can be considered more generally as proactive coping with any kind of environmental stressor. The antipode of this proactive coping is a reactive coping style. This is expressed as the absence of self-initiated aggressive behavior in a social situation and passivity in other challenging environmental conditions. These divergent coping styles have now been observed in a wide variety of species and determine adaptive capacity and vulnerability to stress-related pathologies, including disorders characterized by outbursts of intense aggression and violence. This leads to the general view that part of the neuronal network for offensive aggression is not specifically involved in this type of behavior, but may control more generally the aspects of proactive coping and/or social behavior.

Place Cells

A K Martig and S J Y Mizumori, University of Washington, Seattle, WA, USA

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Backward expansion – The center of mass of a place field's firing rate distribution will shift in a direction opposite to the trajectory of the subject such that the field becomes skewed.

Context discrimination hypothesis (CDH) – Hippocampus contributes to complex forms of learning and memory by discriminating meaningful contexts.

Grid cell – A neuron that exhibits elevated firing in a repetitive, triangular, grid-like pattern within an environment.

Pattern completion – The ability of a network to retrieve a stored representation of information to generate a whole representation from degraded or sparse inputs.

Pattern separation – The ability of a network to disambiguate similar input patterns.

Phase precession – Place cell discharges are phase-locked to theta rhythm oscillations such that the first spike of successive spike bursts begins at progressively earlier phases of the theta cycle.

Place cell – A neuron that exhibits location specific elevations in firing rate.

Theta rhythm – 4–12 Hertz oscillations generated by the activation of excitatory and inhibitory neuronal populations.

neuron will increase its firing rate when the rat is in a particular location of the environment (Figure 1). HPC place cells have been studied at length to determine how they contribute to mnemonic processes ascribed to HPC. It is speculated that population activity from place cells provides a spatial framework within which information is encoded that can be used to guide spatial navigation and direct learning and memory processes.

Quantification of Place Field Properties

HPC place fields exhibit properties that can be used to quantify the quality of the place representation. The reliability of the field is often a measure that determines how consistently the cell fires when an animal passes through the field of the cell. The specificity of the field is a measure of the sharpness of the place field. For example, place fields in the CA1 region of HPC (Figure 2) have been found to be broader or larger than those in CA3. Thus, fields in CA1 are thought to be less spatially specific than those in CA3. Spatial correlation measures are used to quantify the degree to which the location of a field shifts or the within-field firing rate changes. In general, these properties illustrate how rate coding can represent the stability of a place field.

Place fields can also be studied in terms of the temporal properties of the firing rate, and these are reflected in phenomena called 'phase precession' and 'backward expansion.' Phase precession is related to the fact that the occurrences of place cell discharges are phase-locked to the theta rhythm (4–12-Hz network oscillations generated by activation of excitatory and inhibitory neuronal populations). That is, spike timing relative to theta is not random and tends to occur during a specific phase of the 360° theta cycle. When an animal travels through a place field, the first spike of successive spike bursts occurs at progressively earlier phases of the theta cycle, a phenomenon referred to as 'phase precession' (Figure 3). In other words, as a rat enters a place field the first spikes occur late in the theta cycle and as a rat leaves the field the last spikes occur early in the theta cycle. Furthermore, as an animal passes through a field several times within a behavioral epoch, the center of mass of the place field's firing-rate distribution will shift in a direction opposite to the trajectory of the rat such that the field becomes skewed. This phenomenon is known as 'backward expansion' (Figure 3). These basic temporal properties are

Introduction

The role of hippocampus (HPC) in learning and memory has been studied extensively since the discovery of severe memory impairments in patient HM after bilateral removal of his HPC. Over the years, HPC has been found to be involved in multiple forms of learning and memory. Lesion and pharmacological manipulations of HPC have revealed its role in spatial processing, relational learning, declarative learning, episodic memory, and context processing. Given the major role that HPC plays in spatial learning and memory, and the ease with which rats can learn and be tested on spatial tasks, electrophysiologists sought to determine HPC neural correlates of spatial processing in behaving rats (Figure 1). When rats actively move through extended environmental space, the most predominant behavioral correlate of individual HPC neurons is location-selective firing; that is, an individual

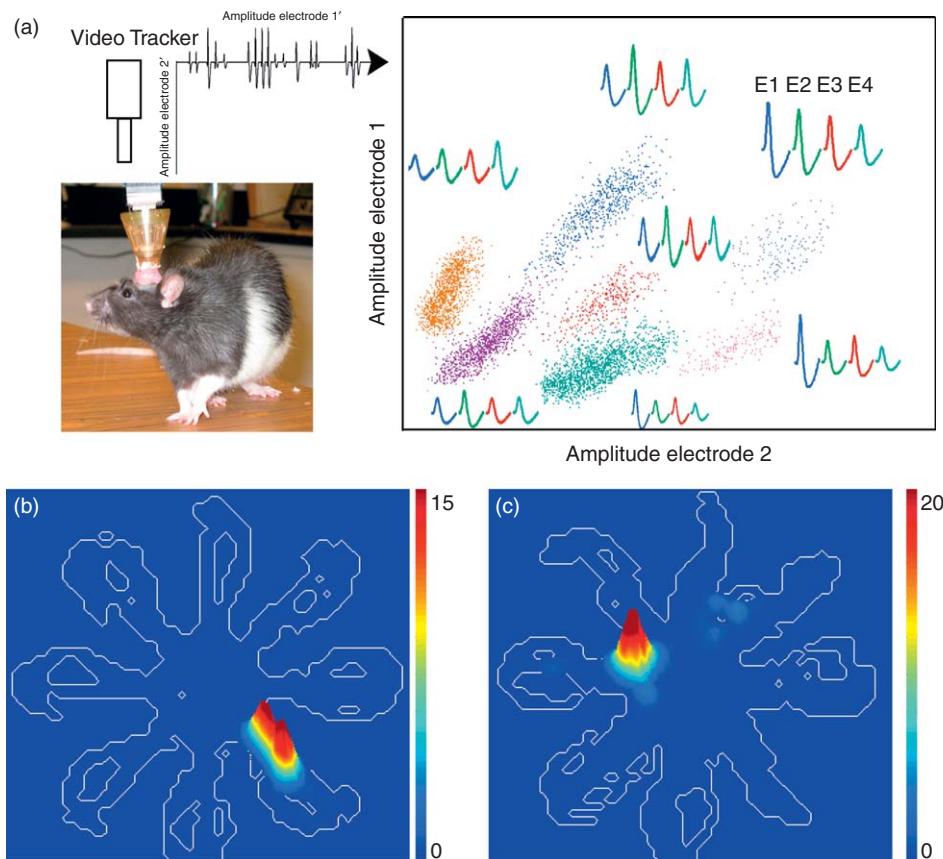

Figure 1 (a) An illustration of recordings from freely behaving rats. Position information recorded from a video tracker is synchronized with neural signals recorded from tetrodes. The neural data are separated into signals from individual cells using a cluster analysis that compares values for spike parameters across four electrodes of a tetrode. Spike-amplitude comparisons across electrode 1 (E1) and electrode 2 (E2) are illustrated and seven clusters are isolated as signals from individual neurons. (b, c) Overlay of video tracker data and neural activity from two individual place cells recorded while rats navigated an eight-arm radial maze. White lines represent the areas of the maze the rat visited and the neural firing pattern is overlaid onto these areas. The maximum firing rate for the cell in (b) is 15 Hz and occurred when the rat visited the maze arm on the lower right. On the other hand, when the rat visited other maze arms the firing rate of the cell was close to zero. Similar patterns of neural activity are illustrated in (c) except the place field is in a different location and has a higher firing rate.

thought to result from inherent Hebbian synaptic plasticity mechanisms that ultimately strengthen existing associative connections. What follows is a discussion of how place field characteristics are related to HPC-dependent learning and memory.

Effects of Sensory Manipulations on Place Fields

Relationships between Place Fields and External Sensory Stimuli

Place fields respond to changes in the visual environment. The fields expressed while rats are navigating in an environment surrounded by familiar distinct visual cues will remap or change field locations in accordance with the rotation of visual cues. For example, when a constellation of cues is rotated by 45°, some place fields will shift their locations by 45°. In addition, place fields respond to

changes in the geometric features of the environment as well as to changes in other nonvisual features of the external environment such as olfactory, somatosensory, and auditory cues. This suggests that place fields provide a representation of the general external sensory environment that is not limited to spatial information. However, place fields also endure after the removal of external sensory cues and exist in blind rats, suggesting that other variables, such as internal sensory information, contribute to the place field when external sensory cues are not available.

Relationships between Place Fields and Internal Sensory Stimuli

Place fields are sensitive to idiothetic (or self-motion) information. For example, the firing rates of place fields are correlated with the animal's velocity and place fields are influenced by vestibular input. In addition, place fields

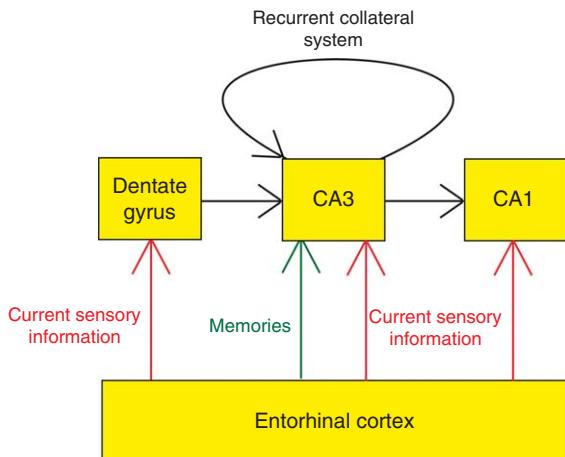

Figure 2 Schematic of HPC circuitry. Entorhinal cortex input to dentate gyrus is comprised of current sensory information. This information is orthonormalized by pattern separation processes that dominate dentate gyrus function. CA3 receives current sensory information and already encoded memory representations from neocortical structures via entorhinal cortex. The CA3 recurrent collateral system is thought to sustain memory representations. Both pattern completion and pattern separation processes in CA3 are involved in determining whether current features of the environment provided by dentate gyrus and entorhinal cortex match expected features of the environment that are maintained by the recurrent collateral system. CA1 is also in a position to mediate pattern completion and separation using current sensory information from entorhinal cortex and information from CA3.

tend to be less specific and reliable when rats are passively moved through a place field either by being held by the experimenter or placed on an electronic moveable device. Under normal circumstances, these data indicate that idiothetic information serves to enhance external representations of the environment. The combination of external and internal cues represented by place fields suggests that place cells contribute to both egocentric and allocentric information processing. Idiothetic information represented by place fields can be used to facilitate path integration processes, that is, the integration of linear and angular motion to keep track of spatial location within an environment, and this allows rats to navigate environments in which external cues are sparse or become unreliable.

Effects of Learning-Related Manipulations and Conditions on Place Fields

Relationships between Place Fields and Synaptic Plasticity

Long-term potentiation (LTP) and long-term depression (LTD) are predominant models of HPC-dependent learning-induced synaptic changes. LTP and LTD

inductions modify synaptic strengths, which should produce changes in spatial representations of place cells. Indeed, induction of LTP produces increases in in-field firing rates and remapping. LTP is dependent on N-methyl-D-aspartic acid (NMDA) receptors and NMDA receptor antagonists impair spatial navigation. In agreement with behavioral deficits, NMDA receptor antagonists also decrease the stability of place fields. Furthermore, genetically engineered mice that lack NMDA receptors exhibit poor spatial learning and have less specific place fields. Temporal properties of place fields are also influenced by NMDA-mediated plasticity mechanisms. Backward expansion is disrupted by NMDA receptor antagonism, suggesting that this place field property is mediated by LTP-like mechanisms. These data provide compelling evidence for similar underlying biological mechanisms that support both HPC-dependent learning and stable place fields.

Place Fields and Sequence Learning

Sequence learning has been shown to be dependent on HPC and may be an integral component of episodic memory formation. As rats traverse a portion of an environment, populations of place cells will fire in a temporal order that reflects the trajectory of the animal. This temporal sequence of place field expression may contribute to HPC-dependent sequence learning since place cells recorded in rats traversing a linear track replay the order in which they fired along a trajectory during subsequent rapid eye movement (REM) sleep. In addition, when a rat reaches the goal location on a linear track, place cells will fire in a reverse temporal order relative to the order in which they fired on the linear track. These replay mechanisms may be related to memory consolidation of the temporal components of the behavioral experience.

Backward expansion and phase precession are two mechanisms that are thought to contribute to encoding and recall of temporal aspects of memory by taking advantage of plasticity mechanisms that are considered necessary for HPC-dependent learning. Backward expansion of place fields may reflect asymmetric Hebbian strengthening of synapses (the presynaptic cell must fire before the postsynaptic cell in order for plasticity to take place) and computational models suggest that backward expansion leads to predictive firing of place cells that can enhance recall of sequences of information. Phase precession can lead to more efficient sequence encoding because it generates temporally compressed sequences of partially overlapping place fields within individual theta cycles (**Figure 3**). This sequence of overlapping representations is also repeated during successive theta cycles. The compression allows the spiking activity of cells, with overlapping fields, to occur within an optimal time

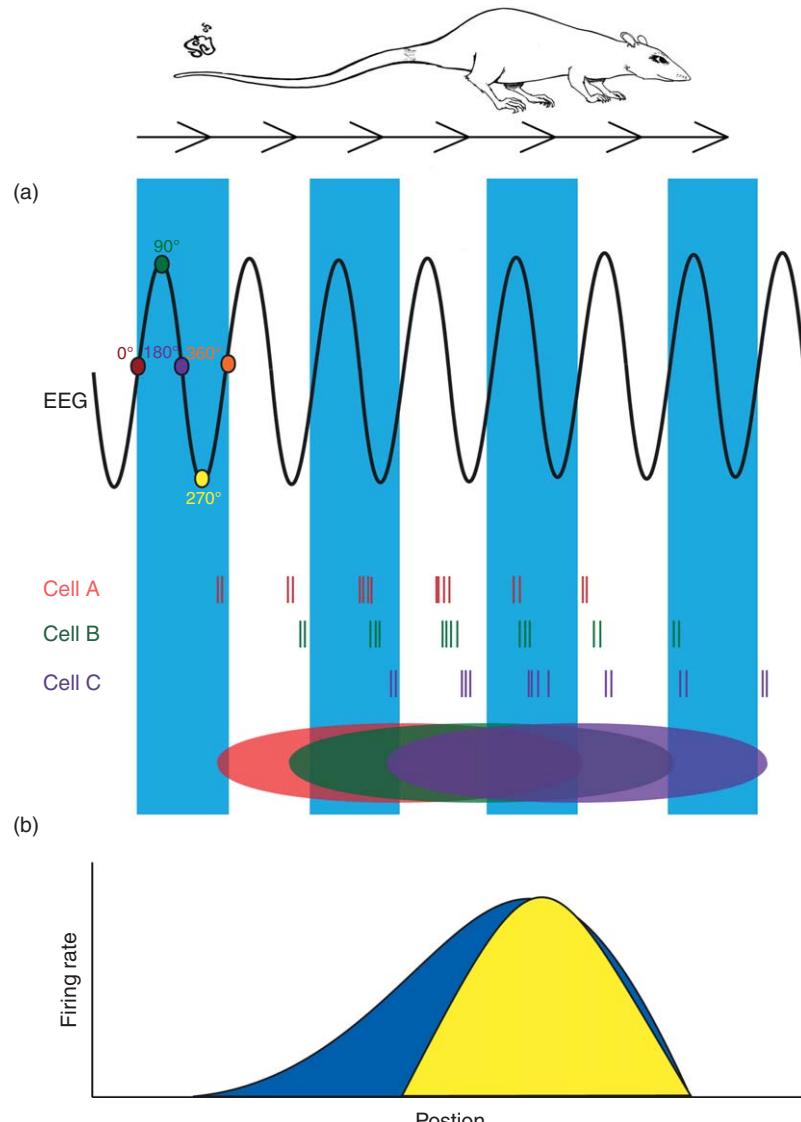

Figure 3 (a) Illustration of theta phase precession. The EEG theta signal is represented by the black sinusoidal function and a complete theta cycle is highlighted in blue. Each short vertical line below the theta waveform represents individual spikes from three place cells with overlapping fields. As the rat enters a place field from left to right the first spike of the first burst occurs late in the theta cycle, as the rat leaves the field the first spike of the last burst occurs early in the theta cycle. Information from the three overlapping place fields is temporally compressed within individual theta cycles such that the ABC sequence is repeated several times across multiple theta cycles during a single pass through the location. (b) Illustration of backward expansion of a place field as a rat makes several passes through the field. The firing-rate distribution of a place field as a rat is moving from left to right during the first pass through the field is shown in yellow. The distribution during the last pass through the field is shown in blue. After the rat passes through the field several times, the place field expands backward and becomes negatively skewed.

window for synaptic plasticity, and repetition could be used to reinforce the associations.

Computational models also suggest that theta rhythm regulates memory encoding and retrieval. The trough and peak phases of theta rhythm are thought to enhance memory encoding and retrieval, respectively. During trough phases of theta, input from entorhinal cortex is strong and HPC synapses show LTP, which allows for encoding of entorhinal representations of the current environment. During peak phases of theta, CA3 activity

(representing retrieval of previously encoded memories) is strong while entorhinal input is weak and synapses show strong LTD, ensuring that the retrieved memory is not encoded as a new memory.

Place Field Comparisons across Animals with Different Learning Capabilities

Place fields have been compared across groups of young and aged rats. Aged rats are often impaired in

their spatial memory abilities and show deficits in LTP induction. To date, the effects of aging on place field properties, such as reliability and specificity, are unclear and somewhat contradictory. Place fields can be just as reliable and specific in aged rats as they are in young rats, but this result can differ depending on the task used at the time of recording. However, place fields tend to be smaller in size and the magnitude of backward expansion is attenuated in aged rats. These results indicate that synaptic plasticity mechanisms are impaired in aged animals, and this impairment may contribute to findings of poor stability of place fields and poor spatial memories of old rats.

Place Field Changes during New Learning

Spatial learning is presumed to occur when an animal is exposed to a novel environment and HPC is known for its involvement in rapid encoding of new information. Disruption of HPC activity results in deficits in one-trial learning, and HPC lesions made immediately after acquisition, but not later, impair contextual fear conditioning. Place-specific firing is evident upon initial exposure to a novel environment or novel portions of a familiar environment. The in-field firing rate and stability of place fields initially increase over time but, as more time is spent in the novel environment, these changes cease such that field properties eventually resemble those found in familiar environments. Place cells have also been recorded while rats are learning HPC-dependent tasks. Under these conditions, place fields become more specific as learning progresses. These fields also tend to move toward new goal locations when rats are tested in familiar environments. In addition to changes observed in spatial tasks, place field responses change after fear conditioning. More specifically, HPC-dependent contextual fear conditioning leads to more place field remapping than cued fear conditioning, which is not dependent on an intact HPC. These results indicate that the stability of the place field and the degree of remapping are related to learning new spatial information. However, these changes may also be related to changes in the behavior of the animal such as movement, emotion, and attention that are associated with new learning.

Place Field Responses to Changes in Cognitive Demand

A different approach to elucidating the role of place cells in learning and memory is to examine the place field when an animal is exposed to changes in cognitive demand. In this behavioral paradigm, sensory, movement, and motivational variables are held constant across

conditions, thus eliminating these explanations for differential responses of place cells. Using this approach, place cells have been recorded while animals perform a HPC-dependent plus-maze task during which animals learn that reward is always located on a particular arm of the plus maze. When the well-learned reward location is relocated to a different area of the maze, place fields undergo remapping, reflecting a memory influence for the previous goal location on the place cell. Place cells have also been recorded while rats are required to shift from an HPC-dependent strategy (e.g., always go to the same location for reward) to a striatum-dependent strategy (e.g., always turn right for reward) to solve a plus-maze task. This explicit manipulation of cognitive demand induces a new place field organization that presumably reflects the newly activated memory that underlies the use of a different strategy to solve the task.

Place cells also exhibit conditional firing that depends on the impending or previous behavior of the animal. Place cells recorded during asymptotic performance on a plus-maze task will fire differentially depending on the trajectory the animal must take to reach the goal location (prospective coding) or depending on what trajectory the animal took to reach the goal location (retrospective coding). In addition, the prospective signal is severely degraded during error trials, suggesting an important role for this signal in accurate performance of a HPC-dependent task. In sum, these signals illustrate a strong memory influence on place fields. They also provide a link between information represented by place cells and episodic memory functions attributed to HPC by illustrating a temporal component in place cell rate coding that is required in defining episodic memory formation.

Effects of Context Manipulations on Place Fields

Although the described features of place fields are consistent with current views of HPC-dependent learning and memory functions, their precise contribution is still far from being understood. Until very recently, many of the behavioral paradigms did not permit assessment of place fields during the performance of HPC-dependent tasks, and they did not consider the responses of place cells within a context-processing theoretical framework. The following describes recent attempts to consider the various dynamic place field responses within a broader context-processing view.

Context Discrimination Hypothesis

The context discrimination hypothesis (CDH) proposes that HPC contributes to complex forms of learning and memory by discriminating meaningful contexts. HPC

place fields are thought to represent spatial contexts and perform match–mismatch comparisons to determine the extent to which a particular context has changed. The results of these comparisons provide a context code propagated by the combined activity of a population of place cells that can be used to distinguish distinct contexts in which significant events or episodes occur. The context code includes several types of contextual information, including spatial information, reward, movement, external nonspatial information, motivation, and memory. What follows is a discussion of how place fields represent contextual information and how this information is relevant to learning and memory.

Place Field Responses to Changes in Context

Some place fields remap in response to changes in context, while other place fields remain stable (Figure 4). The fields that reorganize are thought to represent current contextual features of the environment, while the

fields that remain stable may represent expected contextual features. If there is a mismatch between the current and expected contextual features, then an appropriate message signaling the change may be sent out of HPC to update cortical memory structures. Detected mismatch signals are sent to cortical structures to be used to alter active memory systems and the subsequent selection of behaviors. If the context does not change, the stable place fields can be used as a signal to reinforce ongoing behavior and add to the persistence of the currently engaged memory system. Next is an account of computational models and empirical studies of context processing that reveal the importance of the HPC network in match–mismatch processing.

Pattern Separation and Pattern Completion in HPC Subfields

According to computational theories, HPC function can be characterized as an interaction between pattern

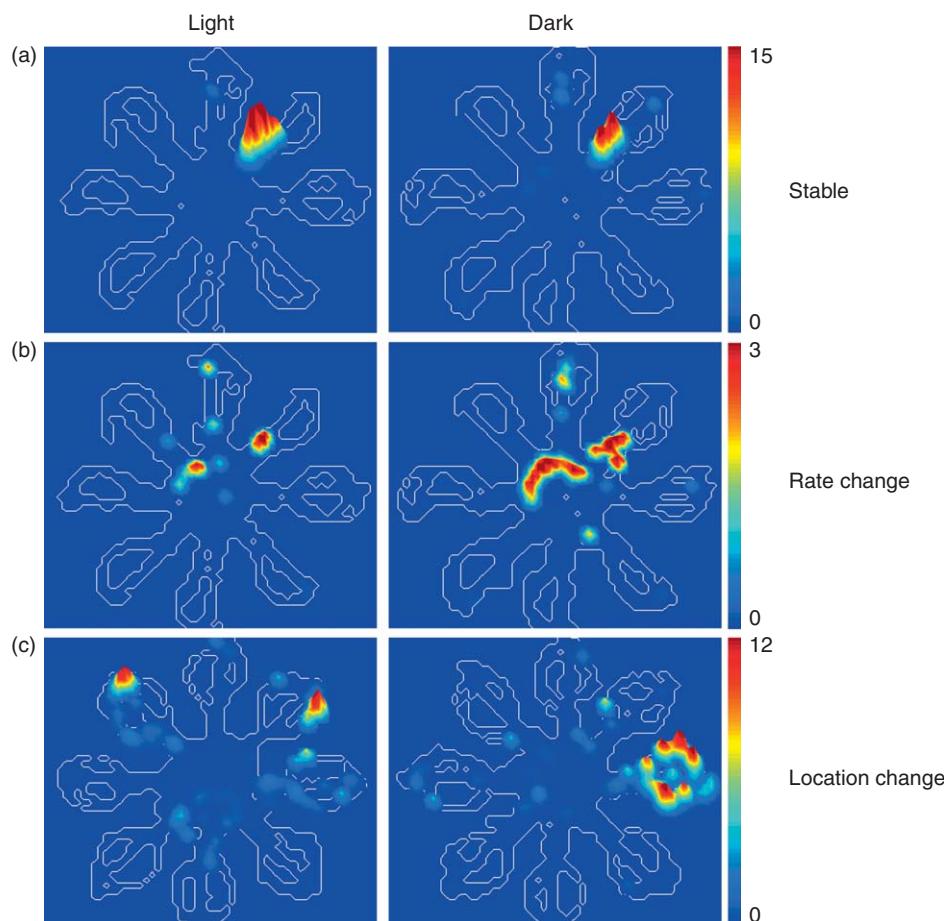

Figure 4 Place field remapping to changes in context. (a, b) Two simultaneously recorded place cells before and after maze lights were extinguished. The place field in (a) did not remap during darkness, whereas the place field in (b) showed robust rate remapping in that the location of the field was still stable but the in-field firing rate increased. (c) A place cell recorded during a different behavioral epoch shows both rate and global remapping in response to imposed darkness. The in-field firing rate on the right maze arm increased and two fields disappeared during darkness.

separation and pattern completion processes. Pattern separation refers to the ability of a network to disambiguate similar input patterns. Pattern completion refers to the ability of a network to retrieve a stored representation of information to generate a whole representation from degraded or sparse inputs. Based on anatomical differences, the dentate gyrus subfield of HPC (**Figure 2**) is proposed to provide a mechanism for pattern separation, whereas the CA1 and CA3 subfields mediate both pattern completion and pattern separation processes. Cells in layer II of entorhinal cortex project directly to the granule cells of dentate gyrus via the perforant path. This pathway is highly plastic and computational models propose that dentate gyrus orthogonalizes (i.e., pattern separates) inputs from cortex. CA3 receives direct projections from layer III of entorhinal cortex as well as strong synaptic connections from the granule cells of dentate gyrus. CA3 is well known for its recurrent collateral fiber system through which the principal cells of CA3 project back onto themselves. The recurrent collateral system is thought to sustain memory representations of the environment, while input from the entorhinal cortex and dentate represent features of the current environment. Interactions between the recurrent collateral fiber system, entorhinal cortex, and dentate gyrus are thought to mediate competition between pattern completion and pattern separation processes in CA3. CA1 receives projections from CA3 via the Schaffer collaterals and projections from layer III of entorhinal cortex. Thus, CA1 is also in a position to mediate pattern completion and separation processes using direct input from entorhinal cortex and CA3.

Comparisons between CA1 and CA3 Place Field Responses to Changes in Context

Based on the unique patterns of connectivity across CA1 and CA3, HPC models propose that CA1 is more involved in novelty detection given its strong direct connections with current environmental information relayed from layer III of entorhinal cortex and memory representations from CA3, whereas CA3 is more involved in rapid encoding (regardless of novelty) via dentate gyrus connections and retrieval of memory-based associations as a result of the recurrent collateral system. Lesion and pharmacological manipulations of CA1 and CA3 have confirmed these predictions, and electrophysiological studies reveal differences in firing patterns of CA1 and CA3 place cells in response to changes in context that support this view.

Place fields in CA3 tend to reorganize more readily during large changes in context, such as placing an animal in a novel testing room, than place fields in CA1. These

results persist regardless of the type of task the animal is performing, although different results can be found depending on the extent to which the context is changed. Slight changes in the expected context, such as rotation of distal cues, cause place fields in CA1 to reorganize more extensively relative to those in CA3. In addition, fields that reorganize in CA3 tend to be more consistent with cue rotations, whereas the location of the fields that change in CA1 cannot be predicted by the cue rotation. The differential responses by CA3 and CA1 place fields during exposure to varying levels of contextual manipulations can be explained by competition between pattern completion and pattern separation processes. When the environment is changed dramatically, pattern separation processes dominate CA3 responses and more remapping is seen in CA3 relative to CA1. When there are subtler changes in the environment, place field responses in CA3 are directed by pattern completion mechanisms and less reorganization is seen in CA3 relative to CA1. It appears that competition between pattern separation and pattern completion in CA3 is mediated by a threshold mechanism such that the CA3 network is very tolerant to small changes in input patterns; however, if the change in input patterns is great enough, the system will switch from expressing information relayed by the recurrent collateral system to signals relayed by entorhinal cortex. In contrast, CA1 place fields may reorganize in response to changes in context in a more linear fashion. More significant reorganizing by CA1 place fields relative to those of CA3 in situations where there are small changes in context indicates that some degree of pattern separation may be occurring in CA1, regardless of the level of change in context. Together, these findings indicate that CA1 is more optimally suited for novelty detection, whereas CA3 may be more involved in determining whether the current features of the context match memory stores of expected contextual features. The combination of output from these two areas is thought to inform neocortical algorithms that select adaptive behaviors.

A Systems Perspective of the Contribution of Place Cells to Learning and Memory

In order to fully understand HPC place cell contributions to learning and memory, one must also consider the role of place cells in other neural systems that underlie learning and memory. Studying afferent and efferent systems associated with HPC has made significant contributions to our understanding of mnemonic functions of place cells.

HPC Interactions with Afferent Cortical Structures

HPC receives a large number of inputs from entorhinal cortex. Grid cells in dorsal medial entorhinal cortex are thought to make a significant contribution to the spatial firing properties of place cells in HPC. These cells show elevated firing at regularly spaced locations within an environment. The grid fields of these cells are arranged in a repetitive, triangular, grid-like pattern. Grid fields are thought to be established by motion-derived information as they maintain their spacing frequency in new environments and in the dark. Unlike place fields, grid fields do not remap in response to contextual variables; instead, they appear to code a more strict spatial representation of the environment. In familiar environments, grid fields will rotate in the direction of cue rotations and if a familiar environment is made to be larger or smaller (by widening or narrowing walls), their spacing frequency will resize in accordance with the environmental change. These small shifts in firing patterns may contribute to some of the remapping seen in place cells to changes in familiar contexts. Therefore, a primary role of entorhinal cortex may be to pass on a spatial framework to HPC within which contextual information can be organized.

HPC also receives input from perirhinal cortex. Following lesions to perirhinal cortex, HPC place fields have been found to be more likely to remap after being returned to familiar environments and are more likely to maintain their positions when visual cues are rotated. Lesions to perirhinal cortex impair context discrimination; therefore, lesioned rats may rely more on olfactory and local cues than on global spatial cues, and slight changes to a familiar environment, such as cleaning, may cause HPC place fields to inappropriately remap, whereas movement of spatial cues would no longer be processed. Given the role of perirhinal cortex in context processing and its direct connections with HPC and entorhinal cortex, this brain region is thought to be a primary source of context-related information to HPC.

HPC Interactions with Efferent Cortical Structures

Although HPC is necessary for establishing new memories, its involvement is temporary and consolidation processes gradually establish memories in cortical areas outside of HPC. HPC is therefore thought to prepare information for integration into neocortical circuits. HPC has a strong monosynaptic projection to medial prefrontal cortex (mPFC) and disruption of this connection produces deficits in spatial learning and memory. More specifically, lesions of HPC produce deficits early on in learning, while lesions of mPFC produce deficits in later learning stages. Activity of individual mPFC

neurons is phase-locked with HPC theta rhythm, and phase precession in mPFC neurons is observed when the local field potential between HPC and mPFC is more coherent. In addition, mPFC phase precession is most robustly observed when rats are making decisions during spatial working memory tasks. Phase locking to HPC theta rhythm has also been observed in cingulate cortex, entorhinal cortex, and visual cortex. Together, this suggests that theta rhythm may be a predominant mechanism by which HPC information becomes incorporated into cortical networks. Future studies need to elucidate how these efferent systems use contextual information from HPC to facilitate the selection of behaviors appropriate for a given context and how HPC place cells contribute to these processes.

Conclusions

The study of place cells in HPC illustrates the importance of studying neural correlates of learning and memory from a broad perspective. One has to consider a broad range of neural responses with a broad range of behaviors that tap into HPC function. Place cells contribute to learning and memory by utilizing a variety of signals, from fine detailed temporal information embedded within the dynamic responses of place fields to more global signals such as local field potentials. The output of these place cell signals can also change depending on what behavior the animal is engaged in. Therefore, interpretations of the significance of these signals are complex, as they should be. With more refinement and expansion of levels of analysis, our understanding of the mnemonic contribution of HPC place cells will become clearer.

Glossary

Dysconnection syndrome – A hypothesis suggesting that cognitive dysfunctions and clinical symptoms of brain disorders arise out of a disconnection between brain regions.

Frequency bands – Neural oscillations have been classified into different frequency bands (delta, 1–3 Hz; theta, 4–7 Hz; alpha, 8–13 Hz; beta, 14–30 Hz; gamma, 30–80 Hz; fast, 80–200 Hz; ultra fast, 200–600 Hz).

Neural oscillations – Refer to periodic variations in the recordings of neural activity. Activity measures are related to the membrane potential of single neurons or populations of neurons and thereby encompass action potentials (APs) and local field potentials (LFPs).

Phase locking – Time locking of brain oscillations to (sensory) stimuli or (motor) responses.

Psychosis – Refers to distortions in inferential thinking, such as delusions (fixed, false beliefs that are firmly held in the face of contradictory evidence), and perceptual disturbances, such as hallucinations. Auditory hallucinations, usually experienced as voices distinct from one's own thoughts, are most common in schizophrenia.

We focus this review on these diseases and exclude epilepsy and Parkinson's disease because several recent reviews have covered the obvious involvement of abnormal rhythms and synchronization in these disorders.

Neural Synchrony during Normal Brain Functioning

Transient synchronization of neuronal discharges has been proposed as one possible mechanism to dynamically bind widely distributed sets of neurons into functionally coherent ensembles that represent the neural correlates of a cognitive content or a motor program. The first indications for a functional role of gamma-band oscillations for information processing in cortical networks was obtained by Gray and Singer in studies investigating the relations between stimulus-induced synchronization of gamma-oscillations and feature binding in cat primary visual cortex (V1) at the Max-Planck Institute for Brain Research in 1987. This relationship was then confirmed in a series of studies with electroencephalography (EEG) and magnetoencephalography (MEG) that found robust support for the role of gamma oscillations in the grouping of stimulus elements into coherent object representations. Synchronization in these studies was consistently associated with an oscillatory patterning of neuronal responses, most often in the beta (15–30 Hz) and gamma (30–80 Hz) frequency range. Subsequent research has indicated that such high-frequency oscillations are particularly effective in supporting precise synchronization of neuronal discharges.

Further research has found a close relationship among attention, oscillations, and synchrony in the gamma-band range. Recordings of neurons in the cortical area V4 while macaque monkeys attended to behaviorally relevant stimuli and ignored distractors revealed increased gamma synchronization (35–90 Hz) compared with neurons at the nearby V4 sites activated by distractors. Consistent evidence for the relationship between attention and gamma-band activity during both visual and auditory perception has been also found in human EEG- and MEG-recordings. Taken together, these findings suggest that gamma-band oscillations have a general computational role in dynamically selecting neurons that

Introduction

Most of the brain's cognitive and executive functions are based on the coordinated interactions of large numbers of neurons that are distributed within and across different specialized brain areas. A fundamental yet unresolved problem of modern neuroscience is how this coordination is achieved. Integration and segregation of neural activity need to occur at various spatial and temporal scales and these scales must be dynamically adjusted depending on the nature of the respective cognitive tasks.

In contrast to the large number of studies that investigated the role of synchrony in a wide range of cognitive and executive processes, relatively few investigations have examined the possible relevance of neural synchrony in pathological brain states, such as schizophrenia, autism, and Alzheimer's disease.

communicate information about sensory inputs effectively.

Gamma oscillations have been also implicated in higher cognitive functions, such as working memory. In EEG-studies, induced gamma-band activity was observed during the delay over frontal and parietal electrodes, indicating that gamma oscillations are involved in the maintenance of information in working memory. Additional evidence for the role of gamma oscillations during working memory has been obtained from intracranial recordings as well as from studies that examined the relationship between auditory working memory and gamma oscillations in MEG-data. Finally, gamma oscillations may also be involved in long-term memory as there is a relationship between the amount of gamma-band activity during the encoding of information and the subsequent recall.

Recent data suggest that synchronized gamma-band activity may also be related to consciousness as a large body of evidence suggest that consciousness has to be understood as a function of numerous interacting systems that require a mechanism that transiently synchronizes a number of widely distributed neural assemblies.

Measures of Oscillatory Activity and Synchrony

Recording methods that assess the activity of large populations of neurons such as microelectrode recordings of local field potentials (LFPs) or EEG and MEG registrations can only detect neuronal activity if it exhibits some degree of synchrony. Entirely uncoordinated activity would not be detectable because the currents of synaptic events, which are the major sources of the measured signals, would cancel out.

In most cases, the signals recorded from neuron populations consist of oscillations that cover a broad-frequency spectrum and are usually quantified by computing the relative power in distinct frequency bands. Until a decade ago, the most frequently applied technique for this spectral decomposition was the Fourier analysis. This classic method has recently been complemented by wavelet-based techniques and multitaper analyses, which are better adapted for the spectral decomposition of nonstationary time series.

In addition to analyzing the frequency spectrum of spontaneous oscillations, it is of interest to determine the time course of stimulus- or task-related oscillations. Two forms of stimulus-related oscillatory activity need to be distinguished: (1) evoked and (2) induced oscillations. Evoked oscillations are strictly phase-locked to the onset of a stimulus and, therefore, can be measured by stimulus-triggered averaging of responses. By contrast, induced oscillations appear in association with stimulus triggered cognitive processes but reflect self-paced temporal coordination of neuronal responses. They are not phase-

locked with external events, and therefore abolished by averaging. These induced oscillations typically occur in the beta- and gamma-frequency range and appear in association with a large variety of cognitive and executive processes.

Although the amplitude of LFP, EEG, or MEG signals correlates with the degree of synchrony of neuronal responses, there are numerous confounding variables that make it difficult to draw firm conclusions on synchrony by considering only amplitude measures. Among these are the size and the alignment of the dipole fields of the contributing neurons, the fraction of synchronously active neurons in the population of cells contributing to the signal, and, above all, the degree of precision with which the neuronal discharges are synchronized. The latter variable is particularly critical when neurons engage in high-frequency oscillatory activity. In this case, the precision of synchrony needs to be in the millisecond range in order to permit effective summation of synaptic currents and to yield a measurable signal. Therefore, methods have been developed which permit assessment of synchrony independently of amplitude.

These measures need to be distinguished from measures of coherence, which determine the covariance of the amplitude of oscillations recorded from different sites for the various frequency bands. Both phase synchronization and coherence have been used to assess functional coupling among distributed neuronal populations.

Neuronal Synchrony: Anatomical Substrate and Neurotransmitters

Studies based on lesions, developmental manipulations, and simulations indicate that neuronal synchronization in the high-frequency range (beta- and gamma-band) is mainly mediated by cortico-cortical connections that link, reciprocally, not only cell populations situated in the same cortical area but also cells distributed across different areas and even across the two hemispheres. Accordingly, synchronization probability between neurons partly reflects the anatomical layout of excitatory cortico-cortical connections.

The generation and synchronization of cortical beta and gamma oscillations involves several neurotransmitter systems. The network of reciprocally coupled γ -aminobutyric acid (GABA)ergic neurons plays a pivotal role in the primary generation of high-frequency oscillations and their local synchronization, whereas glutamatergic connections appear to control their strength, duration, and long-range synchronization. Recent evidence indicates that cholinergic modulation plays a crucial role in the fast, state-dependent facilitation of high-frequency oscillations and the associated response synchronization. In addition to chemical synaptic transmission, direct

electrotonic coupling through gap junctions between inhibitory neurons also contributes to the temporal patterning of population activity and, in particular, to the precise synchronization of oscillatory activity.

Neuronal Synchrony in Brain Disorders

Schizophrenia

Schizophrenia is a severe mental disorder with an estimated lifetime prevalence of 1%. The disorder is characterized by psychotic symptoms (e.g., delusions and hallucinations), negative symptoms (e.g., flattening of affect and apathy) and disorganization of thought and behavior. Cognitive dysfunctions are prominent throughout the course of schizophrenia and have been shown to be a better predictor for outcome than the overt symptoms, suggesting that cognitive deficits represent the core pathology of the disorder.

Current theories of schizophrenia emphasize that core aspects of the pathophysiology are due to deficits in the coordination of distributed processes that involve multiple cortical areas and that are associated with specific cognitive deficits. Some of the deficits concern functions such as working memory, attention, and perceptual organization that have been proposed to involve synchronization of oscillatory activity in the high-frequency band (beta and gamma).

A substantial body of EEG studies supports the hypothesis that schizophrenia is related to impaired neural synchrony. Examination of auditory and visual steady-state responses to repetitive stimulation has revealed a specific reduction in the power of the stimulus-locked response (entrained oscillations) in the beta- and gamma-frequency range but not for the lower frequencies. This could be due to reduced synchronization of stimulus-evoked high-frequency oscillations and/or to an inability of neurons to follow high stimulation rates. Moreover, there is evidence for a reduction of evoked stimulus-locked oscillatory activity, again in the high-frequency range, following auditory and visual stimuli. Reductions in evoked oscillatory activity have been reported for tasks involving visual binding, for backward masking, and an auditory oddball paradigm. Furthermore, there is also preliminary evidence for a reduction of induced non-stimulus-locked oscillations in the gamma-band range during the processing of visual stimuli. These results suggest selective deficiencies in the ability of cortical networks or cortico-thalamo-cortical loops to engage in precisely synchronized high-frequency oscillations.

In addition to these analyses of spectral power of evoked oscillatory activity, several studies have examined phase-synchrony between distributed neuronal populations while patients performed cognitive tasks. In a recent study, we provided evidence for a close relation between

impaired neural synchrony in schizophrenia and specific cognitive deficits using Mooney faces as stimuli (see Figure 1). Schizophrenia patients exhibited a deficit in the perception of Mooney faces and reduced phase-synchrony in the beta-band while the power of induced gamma-band oscillations was in the normal range. This suggests that large-scale synchronization is crucially impaired in patients with schizophrenia while local synchrony in the gamma band is largely intact.

Impairments in the ability of distributed networks to establish precise synchronization of neuronal assemblies oscillating at high frequencies can have many reasons. These comprise both a host of local factors that determine the time constants of interactions within the oscillating microcircuits as well as the properties of long-distance connections that mediate interareal synchronization. Abnormalities have been identified for some of these candidate mechanisms in schizophrenia patients. *In vivo* anatomical examination with diffusion tensor imaging (DTI) has revealed white-matter anomalies that might be related to deficiencies in long-range synchronization. Cortico-cortical connections were reduced in the frontal, temporal, and parietal lobes and between the two hemispheres. However, there is also evidence for locally increased connectivity that is related to productive symptoms, such as auditory hallucinations. One interpretation of these seemingly paradoxical findings is that hyperconnectivity between higher- and lower-order cortical areas favors back-propagation of oscillatory activity generated in higher sensory areas during visual and auditory imagery to the respective primary sensory cortices, thus generating activation patterns that resemble those induced by sensory stimulation. This interpretation receives some support by the finding that hallucinations are associated with increased gamma oscillations and enhanced hemodynamic responses (blood-oxygen-level-dependent (BOLD) signals) in the corresponding sensory areas of the cerebral cortex. For several reasons, this increased BOLD signal is likely to reflect the entrainment of neurons in the primary areas into synchronized, high-frequency oscillations: first, it is improbable that neurons in primary sensory areas exhibit major increases in discharge rates in the absence of sensory stimulation. Second, top-down effects, such as those associated with focused attention, cause an entrainment of selected neuronal populations into well-synchronized gamma oscillations without enhancing the discharge rates. Third, increases of the BOLD signal correlate well with the entrainment of neurons into synchronized high-frequency gamma oscillations.

Further candidate mechanisms for deficient synchronization in the high-frequency range are abnormalities in the rhythm-generating networks of inhibitory interneurons and in the glutamatergic neurons mediating long-distance synchronization. Abnormalities in te

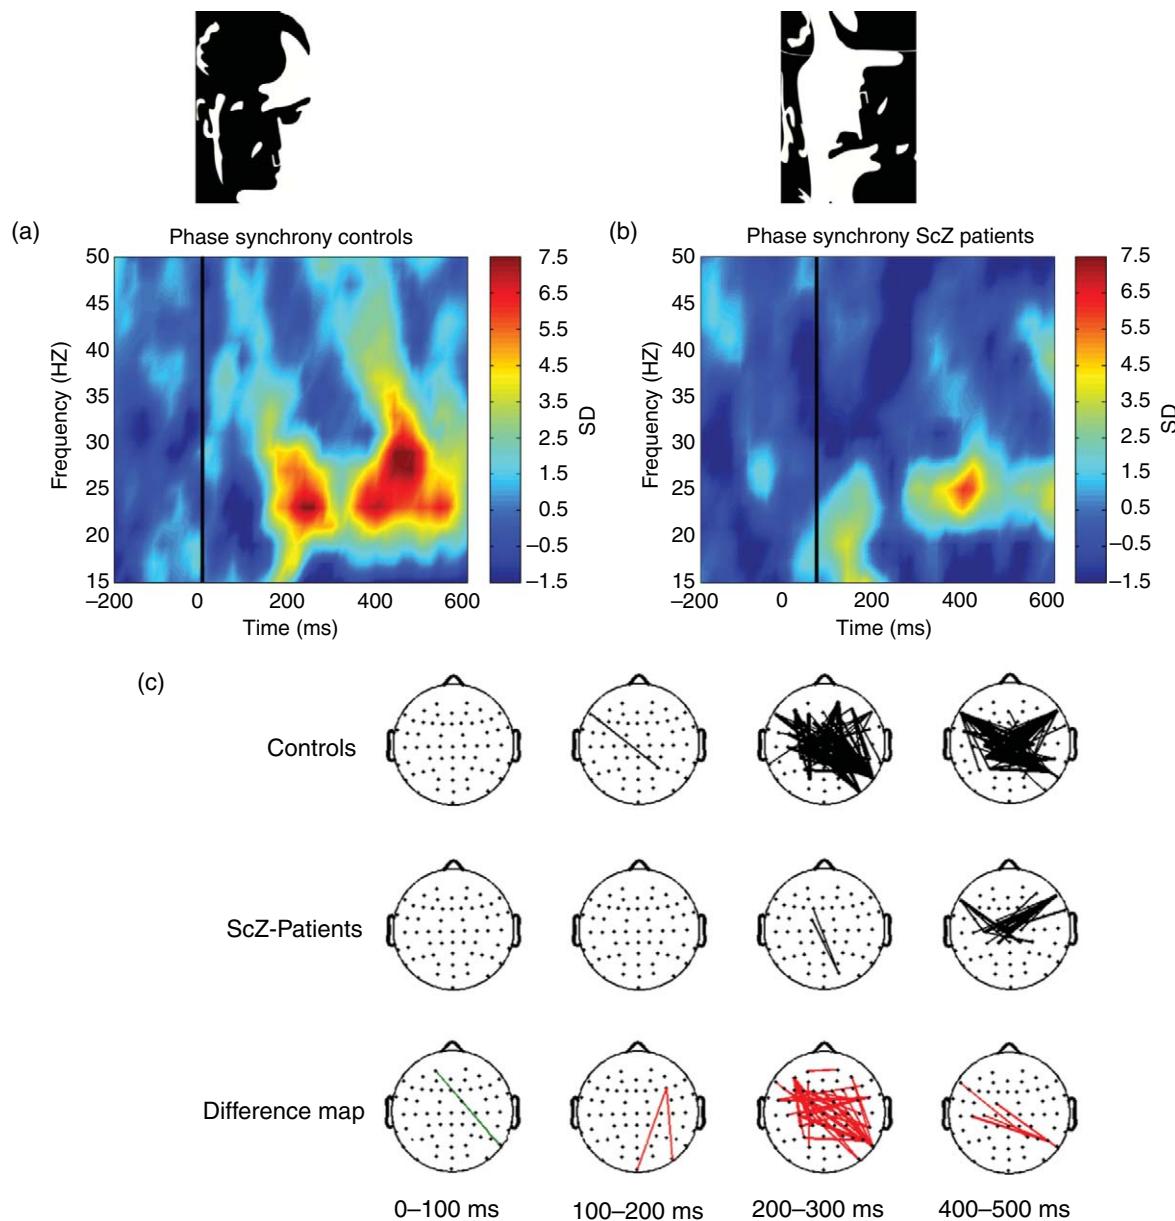

Figure 1 Neural synchrony during Gestalt perception in schizophrenia. Group average of phase synchrony for all electrodes and for correct trials during a Gestalt perception task in controls ((a) and (b)). Phase synchrony during Gestalt perception in controls exhibited two maxima over an average frequency range of 20–30 Hz (a). The increase in phase synchrony between 200 and 300 ms has been related to the construction of coherent object representations, whereas the second peak indexes the preparation and execution of the motor response. In patients with schizophrenia (b), the onset of the first peak in the face condition was delayed and occurred between 350 and 400 ms in the frequency range of 20–25 Hz (Figure 1c). In addition, a second, weaker peak was found around 600 ms. Compared with controls, the reduction in phase synchrony in the frequency range of 20–30 Hz was significant (frequency range: 20–30 Hz, time interval: 200–280 ms, $t(36) = 2.96$, $p = 0.005$). (c) The topography of phase synchrony between 20 and 30 Hz. Synchrony between electrodes is indicated by lines, which are drawn only if the synchrony value is beyond a two-tailed probability of $p < 0.0005$. Differences between groups are displayed in the bottom row. Black lines indicate a decrease in synchrony in schizophrenia patients compared with controls. Green lines indicate increase in synchrony for patients with schizophrenia relative to controls. The decrease in phase synchrony between 200 and 300 ms indexes a deficit in the long-range synchronization during Gestalt perception in schizophrenia. Reproduced with permission from Uhlhaas PJ, Linden DEJ, Singer W, Haenschel C, Lindner M, Maurer K, and Rodriguez E (2006) Dysfunctional long-range coordination of neural activity during Gestalt perception in schizophrenia. *Journal of Neuroscience* 26: 8168–8175.

GABAergic inhibitory neurons and *N*-methyl-d-aspartic acid (NMDA) receptor dysregulation have both been found in patients with schizophrenia. The possible role

of NMDA receptors in the pathophysiology of schizophrenia is supported by the acute effects of NMDA antagonists, such as ketamine or phencyclidine (PCP),

on healthy volunteers. For example, subanesthetic doses of ketamine produce an acute psychosis that includes many of the symptoms and characteristic cognitive dysfunctions of schizophrenia. Because the typical and atypical neuroleptics interfere with dopaminergic and serotonergic neurotransmission, respectively, abnormalities in these transmitter systems are thought to play a central role in the pathophysiology of schizophrenia. How these systems modulate neural synchrony has not been investigated yet.

In Parkinson's disease, reduced dopamine leads to enhanced beta oscillations in the subthalamic nucleus (STN) and decreased gamma-band oscillations in cortical and subcortical networks. In schizophrenia, dopaminergic dysfunctions could affect neural synchronization through established effects on GABAergic interneurons.

So far, direct evidence for a link between high-frequency oscillations and neuromodulators is available only for the cholinergic system. Cortical networks can only engage in synchronized, high-frequency oscillations when muscarinic receptors are activated. Further studies need to clarify whether this finding can be related to the emerging evidence that deficits in cholinergic transmission may be involved in abnormal cortical information processing in schizophrenia.

In summary, there is consistent evidence that neural synchrony is impaired in patients with schizophrenia. This impairment is particularly pronounced for oscillatory activity in the beta- and gamma-frequency ranges and for the synchronization of these high-frequency oscillations over longer distances. Because synchronization of oscillatory activity in this frequency range is associated with cognitive functions that are disturbed in schizophrenia patients, it is conceivable that the relation between impaired synchrony and the symptomatology of schizophrenia is not merely correlative. Data on anatomical connectivity and neurotransmitter systems in schizophrenia suggest several potential causes for impaired neural synchrony, but more focused studies are required to distinguish between cause and effect. Synchronized oscillator activity plays a crucial role in guiding the development of neuronal networks. Therefore, abnormal connectivity could be both cause and effect of abnormal synchrony.

Neuronal Synchrony in Autism

Autism is a developmental brain disorder characterized by a triad of impairments that affect social interaction, verbal and nonverbal communication, and the repertoire of interests and activities. Similar to recent work in schizophrenia, theories that account for the pervasive cognitive dysfunctions associated with autism have highlighted a deficit in the integration of cognitive mechanisms. A number of studies have demonstrated superior performance in tasks requiring recognition of

details and directing attention to small elements as, for example, in visual search and in the identification of hidden figures. This reduced ability to integrate components into coherent representations is not only confined to visual perception but has also been found in the processing of auditory information, linguistic context, and social cues.

Current theories and experimental data converge on the notion that dysfunctional integrative mechanisms in autism may be the result of reduced neural synchronization. Recent functional magnetic resonance imaging (fMRI) and EEG studies have supported this view through demonstrating reduced connectivity during sentence comprehension in high-functioning individuals with autism. Compared with controls, subjects with autism are characterized by a marked reduction in functional connectivity throughout the cortical language system that was most pronounced during comprehension of sentences.

In analogy to the findings in schizophrenia patients, these data predict that autism should be associated with reduced neural synchrony. However, so far, only few studies have examined this possibility. Induced gamma-band activity was examined in EEG data in individuals with autism and in a matched control group during the perception of face stimuli. In controls, an increase in induced gamma power differentiated responses to face from no-face stimuli, while subjects with autism showed no difference between the two experimental conditions. Analysis of auditory steady-state responses indicates that, similar to patients with schizophrenia, there is a reduction in the power of the stimulus-locked responses in the gamma-band range.

Several authors have recently proposed that in autism cortical networks may be characterized by an imbalance between excitation and inhibition, which leads to hyperexcitability and unstable cortical networks. This hypothesis is consistent with abnormalities in GABAergic- and glutamatergic-transmitter systems. Indications for reduced GABAergic inhibition have been derived from the evidence that autism is associated with mutations of genes encoding subunits of the GABA(A) receptor, reduced expression of GAD 65 and GAD 67 and synthesis of abnormal isoforms of these enzymes. Abnormal glutamatergic neurotransmission is supported by polymorphisms in genes that encode both metabotropic and ionotropic glutamate receptors, and a postmortem study has reported reduced alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionate (AMPA) receptors in the cerebellum. In addition, the serotonergic system may be dysregulated in autism. To date, it is unclear how these abnormalities relate to the cognitive deficits in autism, whether they play a role in the hypothesized disruption of integrative processes and whether there are electrographic correlates of reduced large-scale synchronization in this disorder.

Neuronal Synchrony in Alzheimer's Disease

Alzheimer's disease (AD) is the most common form of dementia that affects approximately 11% of the world population older than 65 years. AD is associated with a wide range of cognitive dysfunctions that typically start with characteristic memory impairment, followed by deficits in visuo-spatial and executive processes. These differential impairments in cognitive domains reflect the spread of cortical pathology from medial-temporal to parietal association areas. Patients with AD show pronounced deficits while performing tasks that require interhemispheric transfer of information, executive processing, and episodic memory consistent with a disconnection syndrome.

A hallmark of the resting-state EEG in patients with AD is a relative increase in the theta- and delta-band activity that co-occurs with a reduction in activity in the alpha and beta band. The reduction in alpha-band activity correlates well with the severity of the disease and the cognitive deficits. These power changes in distinct frequency bands are associated with impaired synchrony. Patients with AD show reduced coherence of oscillations in the alpha- and beta-frequency band both for distant and nearby recording sites.

Supportive evidence comes from studies that have utilized direct measures of synchrony, such as synchronization likelihood (SL) that is sensitive to linear and nonlinear interdependencies between EEG channels. Topographically, the reduction of synchrony is particularly pronounced for long-range synchronization. In addition to lowered synchronization in the alpha and beta bands, patients with AD are also characterized by a reduction in gamma-band synchronization in the resting state. Thus, there is substantial evidence for reduced neural synchrony during the resting state, but relatively little research has been performed so far to link reductions in neural synchrony directly to impaired cognition by analyzing task- and performance-related changes of synchronization.

The hypothesis that impaired neural synchrony underlies some of the cognitive deficits in AD is compatible with data suggesting that the degenerative processes caused by AD lead to a neocortical disconnection syndrome. Neurofibrillary tangles (NFTs) and neuritic plaques (NPs) are particularly prominent in brain areas that give rise to long cortico-cortical tracts. Accordingly, DTI studies disclosed disintegration of white-matter fiber tracts. Furthermore, neural synchrony in the high-frequency range is expected to be reduced because AD leads to a pronounced degeneration of the cholinergic projections to the cerebral cortex that originate in the basal forebrain and have been shown to be a necessary prerequisite for the generation of beta- and gamma-band oscillations and response synchronization in this

frequency range. The evidence that muscarinic antagonists, such as scopolamine, induce a pattern of memory and cognitive deficits characteristic of elderly subjects and shift EEG power toward lower frequencies is compatible with this hypothesis.

Finally, there is evidence for alterations in glutamatergic neurotransmission that may also effect neuronal synchronization in AD. It has been demonstrated that NPs produce a persistent depression of NMDA-evoked currents in cortical neurons. Moreover, neurons from a genetically modified mouse model of AD expressed reduced amounts of NMDA receptors. These findings suggest that AD-related alterations of cellular functions can cause depression of NMDA-receptor-mediated synaptic transmission.

Taken together, these data suggest that the cognitive disturbances associated with AD may not solely be due to the loss of neurons but also to impairments in the temporal coordination of distributed neuronal activity. So far, studies have concentrated on neural synchrony in the lower frequency bands, especially in the alpha band, and more investigations are required to examine the expected deficits of long-range synchrony in the higher frequency bands.

Conclusion

The evidence reviewed suggests that schizophrenia, autism, and AD are characterized by changes in neural synchrony that are likely to play an important role in the pathophysiology of the disorders. There is consistent evidence across studies that these disorders are associated with a reduction of both local as well as long-range synchronization. In addition, the cognitive functions that are impaired have all been shown to be associated with neural synchronization, suggesting that abnormal synchrony could be one of the causes of the cognitive dysfunctions.

The impairments of neural synchrony in schizophrenia, autism, and AD are consistent with current theories that emphasize a disconnection syndrome as the underlying pathophysiological mechanism. Cognitive dysfunctions are thought to arise from a dysfunction in the coordination of distributed neural activity between and within functionally specialized regions of the cerebral cortex. Reduced neural synchronization can be a consequence of disconnection, but it can also be the cause of impaired coupling between brain areas because synchronization of neural responses is essential for their propagation across sparsely connected networks. At present, it is difficult to differentiate between these possibilities.

The pathophysiological role of neural synchrony in schizophrenia, autism, and AD is likely to be different

however. Both schizophrenia and autism are developmental disorders whose symptoms manifest early during development, whereas AD is a neurodegenerative disease that typically begins after >60 years of age. Thus, neural synchrony is likely to be causally involved in the early developmental alterations in autism and schizophrenia whereas in AD, changes in neural synchrony result from progressive neurodegeneration that are a core feature of the disease.

Evidence suggests that the cognitive deficits correlate particularly well with disturbances of long-range synchrony, in agreement with the hypothesis that higher cognitive functions require large-scale integration of distributed neural activity. In schizophrenia, AD, and autism, large-scale integration was found to be more impaired than was local synchronization, as reflected by the amplitude of local oscillatory activity and BOLD activation. Furthermore, cognitive dysfunctions were particularly pronounced for tasks requiring interactions between widely distributed brain areas, such as integration of polymodal stimulus attributes, dynamic perceptual grouping, working memory, and executive processes. This agrees with the proposals of several authors that complex cognitive processes, such as attention, memory, dynamic grouping, and awareness, require large-scale integration of activity.

Future Perspectives

The data reviewed here suggest that measures of neural synchronization may be of importance for the diagnosis of neuropsychiatric disorders. As measurements of neural synchrony are noninvasive and quantifiable in an objective way that is largely immune against observer bias, advanced methods of time series analysis may provide valuable diagnostic tools for the assessment of disease progression and the efficiency of therapeutic interventions. For example, aberrant large-scale integration of neural activity may also turn out to be a predictor of incipient AD. A recent study examined patients with mild cognitive impairment and showed that the covariance of BOLD responses during a face-matching task was a more sensitive measure for impaired functions than behavioral performance or the amplitude of regional brain activation, suggesting that reduced functional connectivity might represent one of the earliest markers of changes in brain functioning in AD. Prospective longitudinal studies of phase synchronization with EEG and preferably MEG methodology are required to examine whether changes of synchrony in the high-frequency bands can be used as an early predictor of AD.

Impaired neural synchrony may also guide further research into the pathophysiological mechanisms underlying neuropsychiatric disorders. For example, there is increasing interest in the role of GABAergic

neurotransmission in schizophrenia and autism. These efforts have already led to the investigation of therapeutic effects of GABAergic modulators in these disorders. We believe that further research into neurotransmitter systems and other mechanisms involved in the generation of oscillatory activity and its synchronization could ultimately help develop more precise pharmacological interventions for these disorders.

Neural synchrony is also of relevance for several other disorders not reviewed here such as epilepsy, Parkinson's disease, and most likely also multiple sclerosis. In the latter case, it is to be expected that axonal damage and demyelination interfere with the temporal coordination of neuronal activity. In particular, long-distance synchronization is likely to be impaired by prolongation of conduction times.

The possibility may also be considered to use measures of neural synchrony rather than just the power of EEG or MEG signals, in particular, frequency bands as biofeedback signals. Evidence indicates that biofeedback can be used to modify brain states in neuropsychiatric disorders. So far, the therapeutic effects of this approach have been variable, but it is conceivable that more advanced measures of the temporal coordination of distributed activity will be more effective in helping the patients to bring aberrant activity under voluntary control.

Short-Term Memory: Psychological and Neural Aspects

S M Courtney, Johns Hopkins University, Baltimore, MD, USA

Glossary

Capacity – The limit on the amount of information or the number of items that may be processed, encoded, or maintained in working memory simultaneously.

Chunking – The process of grouping items in working memory according to presented or discovered relationships, resulting in a more efficient representation and the ability to remember more items.

Interference – Any irrelevant information that overwrites or degrades the relevant information being maintained in short-term memory, or reduces the effectiveness of the relevant information in driving behavioral response.

Memory load – The number of items or amount of information currently being maintained in short-term memory.

Recoding – The process of changing information that is to be remembered into a form which is easier to hold in memory. Chunking is one type of recoding, but there are many other ways that information can be recoded, such as using verbal descriptions or remembering only certain features of an image.

Rehearsal – The process of actively and repeatedly thinking about the information in short-term memory in order to protect it from decay and interference. The most common example is silently saying a list of words over and over during the memory period, but other kinds of information can be rehearsed in other ways, such as repeatedly imagining making a series of eye movements to the remembered locations.

Reverberating circuit – Reciprocally connected neurons that form a loop providing positive feedback, which enables their neural signals to maintain their level of activity without additional input from sensory or other sources.

Sustained activity – Neural activity containing information about an item held in short-term memory that persists for several seconds after the item to be remembered is no longer available in the sensory input.

active rehearsal and sustained attention, but will eventually succumb to decay and interference. Short-term memory is often studied with either change detection or delayed recognition tasks. In a change detection task, a display with multiple items is presented briefly and, then a short time later, another display is presented in which one or more of the items may have changed according to one of its features, such as its color. The research participant's task is to indicate whether anything in the display changed from the first to the second presentation. To succeed in the task, short-term memory must maintain a representation of the first display during the delay until the second display is presented. Delayed recognition is a similar task, but the test after the memory delay is usually a single item and the participant is to indicate whether or not this test item matches one of the items in the preceding display. The memory delays in these tasks usually vary from 1 to 20 s.

The concept of short-term memory lies between those of iconic memory and working memory. Iconic memory is an automatic, very brief (less than 1 s) memory for a sensory stimulus, presumably due to persistence of the neural activity arising from that stimulus. Working memory is a combination of short-term memory and the goal-driven manipulation and use of the information maintained in short-term memory. The manipulation and use of the remembered information is often considered to be a process, referred to as 'the central executive' or 'cognitive control,' that is psychologically and neurally distinct from the storage and maintenance of the information. However, even without explicit manipulation and use of the information, maintenance in short-term memory requires executive-like control processes, such as selecting the most important information to be maintained and protecting it from interference. Thus, the distinction between short-term memory and working memory is often blurred.

Behavioral Properties

Capacity

Unlike long-term memory, which given sufficient conditions seems to have unlimited capacity, short-term memory can hold a relatively very small amount of information at one time. This is often looked upon as a problem to be overcome. However, the limited capacity of short-term memory is actually beneficial to the individual. The information maintained in short-term memory

Definition of Short-Term Memory

Short-term memory involves the maintenance of a limited amount of currently relevant information. This information may be maintained indefinitely through

influences sensory attention and goal-directed behavior. Without this influence, sensory processing is driven by stimulus salience (the loudest or brightest), while behavior is driven by habit. Flexible, goal-driven behavior depends on the ability of short-term memory to select information for the task at hand and to allow that information to have the greatest influence on perception and action. Thus, a limited capacity imposes priority so that only the most important information is maintained, and therefore only the most important information drives perception and action.

While it is universally agreed that short-term memory is capacity limited (only a small amount of information may be maintained at any one time), there is much disagreement regarding what the capacity is and the units by which capacity should be measured. The amount of information that may be maintained in short-term memory ultimately depends on several factors, and therefore the apparent capacity can vary greatly, according to the parameters of the task used to measure it. As the definitions of short-term memory and capacity have evolved, the ways of measuring capacity have changed. Answers to the question "How much can be stored in short-term memory?" depend on (1) how the task parameters influence the constraints, (2) how much information can be encoded into short-term memory, and (3) how much information can subsequently be maintained.

Number of items

Estimates of the number of items that may be stored in working memory have ranged from 1 to 7, depending on the type of information (such as auditorily presented words vs. visually presented objects) and the demands of the task. Researchers who use tasks that involve very brief visual displays to present the information to be remembered almost always conclude that short-term memory in healthy adults is approximately three or four objects. When people are given ample time to encode the items, however, estimates of capacity increase. This increase has been attributed to peoples' ability to recode information into a different form that may be easier to remember and to rehearse. People may use inherent relational structure in the presented information, or draw on long-term memory knowledge to recognize or impose structure on the information. This process has been called 'chunking.' For example, the string of numbers 945826734 can be remembered more accurately if one groups these numbers as $(9-4=5)$, $(8-2=6)$, and $(7-3=4)$. Nine items become three chunks. If these chunks can be considered as items, then the capacity of short-term memory again appears to be approximately 3.

Amount of information

While short-term memory capacity appears to be limited to approximately three items (or chunks), there has been

debate over whether the information complexity of those items further limits capacity. In other words, can we remember three simple items but only two complex items? If so, then short-term memory capacity might better be measured in terms of amount of information, rather than number of items, in that the total amount of information to be remembered would be the amount of information per item times the number of items. Again, the answer seems to depend on the nature of the task and the type of information that must be maintained. If the item is complex by way of having multiple low-level visual features (such as color and orientation of an object) that can be quickly and easily bound together, then it does not seem to matter if the items contain a single feature or multiple features. If items are complex in ways other than the combination of low-level features, such as tasks that require memory for abstract shapes, then the increasing complexity of the individual items does decrease the number of items that can be maintained in short-term memory. These constraints on capacity come into play primarily in tasks that involve memory for briefly presented visual material.

Maintenance, Decay and Interference

When the task allows for longer encoding time and performance is more dependent on sustained attention and rehearsal of the information in order to maintain it in memory for several seconds, a different set of factors affects how many items can be maintained. It is these constraints that have led to estimates of approximately seven items for short-term memory or working memory capacity. Most of the research on this aspect of short-term memory has used verbal information, usually lists of words. The number of words that can be maintained in short-term memory depends on, among other factors, the word lengths and how similar they are to each other.

Theories on the word length effect generally posit that there is a fixed amount of time that a given item can be maintained in short-term memory unless its representation is refreshed through rehearsal. In the case of verbal information, it is thought that this rehearsal is achieved through covert speech (i.e., saying the list of words silently, one at a time, and repeating the list as long as required by the task). Thus, the longer it takes to say each word in the list, the longer will be the time to say the entire list before you get back to repeating a word. If too much time elapses between repetitions, the representation of that word would have decayed while you were saying the rest of the list. Researchers have debated as to whether time alone is sufficient to cause decay or if it is only when other information interferes with the representation of the remembered information that decay occurs. However, since other information is always present and the more time passes, the more interfering

information accumulates, it is difficult to behaviorally isolate the effects of the passage of time from that of interference from other information.

Interference comes from multiple sources. The interference that usually is confounded with the delay effect is the presence of completely irrelevant information during the memory delay that can cause distraction from and interruption of the rehearsal process. Sometimes, this information is purposefully introduced by the experimenter to study its effect, but distracting information is present even when not explicitly introduced, such as the presence of an itch during performance of a visual memory task. Thus, it may be more useful to think of the amount of known sources of distracting information rather than the presence or absence of distraction from interfering information.

The item similarity effect is another type of interference. It is more difficult to remember the letter string BDCV than XCKH, because the sounds we use to name B, D, C, and V all have the same ‘ee’ end sound. This effect is most consistent regarding phonological similarity of items in verbal memory. Semantic or visual similarity can sometimes increase short-term memory performance, perhaps because of facilitation of chunking or other organizational strategies. Representations of items in short-term memory are flexible and appear to depend on the representations of other items simultaneously held in memory and the expectations for the upcoming test items. At least regarding phonological rehearsal of verbal information, however, the more overlap there is in the long-term memory representation of the items to be held in short-term memory, the more difficult it is to keep them distinct from one another. Likewise, the more similar a nonmatching test item is to the remembered items, the more difficult it will be to reject that item as a potential match. Similarity between items necessitates a more finely tuned representation of the items to be remembered.

‘Proactive interference’ is a term used to refer to the detriment to performance on the current memory test caused by information that was recently held in short-term memory but is now no longer relevant. For example, you initially try to remember and are tested on a list of five words: apple, banana, pear, cherry, and lemon. Now you are given a new list of words: mango, orange, plum, strawberry, and grape. After a few seconds I give you a test that asks “Was lemon a word on the most recent list?” You will be slower and less accurate in responding “No, it was not on the list,” than if you had not just recently been trying to remember lemon as part of the previous list. Previous experience with an item will facilitate processing of that item when it is presented at test for the new list, resulting in a sense of familiarity and thus a tendency to give a match response rather than the correct nonmatch response. If that particular item was not only on the

previous memory list, but was also a previous test item that required a match response, this previous stimulus-response association will add to the difficulty in now responding nonmatch to the same item.

Neural Basis

Sustained Activity

Long-term memory is instantiated by structural changes in the brain that change how information is processed. Short-term memory, on the other hand, is instantiated by spatiotemporal patterns of neural activity, as is perception of current stimulus information. The key property of neural activity that enables short-term memory is the ability to maintain sustained patterns of activity in the absence of any current, related stimulus input. Sustained activity during the delay period of short-term memory tasks has been observed through single cell recordings in primates and other animals and through functional magnetic resonance imaging (fMRI) and other neuroimaging techniques in humans. Such sustained activity is present in many different brain areas. Different brain areas and different populations of cells within those brain areas demonstrate sustained activity that differs in its robustness to interference and its selectivity for different types of information required for the task. These differences suggest different roles for these brain areas and cell populations for the different components of short-term memory tasks, such as encoding the items, remembering those particular items, remembering the task rules, and preparing to process and respond to an expected test stimulus.

Prefrontal Cortex

The prefrontal cortex is defined as all of the cortex that lies anterior to the premotor cortex in the precentral sulcus. Many of the cells in the prefrontal cortex demonstrate sustained activity during the delay period of short-term memory tasks. Unlike sustained activity observed in perceptual processing areas, in prefrontal cortex it is generally resistant to interference from irrelevant perceptual stimuli and correlates strongly with performance on the task.

Functional organization of prefrontal cortex

The prefrontal cortex contains multiple functionally dissociable subareas. The boundaries between these areas, however, are less distinct in terms of the differences in cellular anatomy across areas and the functional distinctions among these areas have been the subject of much debate. The clearest distinction in humans is between medial and orbital frontal areas versus the lateral prefrontal cortex. Medial and orbital frontal areas appear to be

more involved in the reward, motivation, and social aspects of short-term memory tasks, whereas the lateral frontal areas are more involved in memory for the specific item and rule information for the particular task at hand.

The lateral prefrontal cortex contains further subdivisions that appear to process and maintain different types of information. Within the posterior part of lateral prefrontal cortex, the dorsal areas seem to be more involved in spatial information, such as the posterior part of the superior frontal sulcus in humans playing a role in short-term memory for spatial locations. The ventral areas of posterior lateral prefrontal cortex, on the other hand, appear to be more involved in remembering nonspatial information, such as verbal information and many stimulus aspects related to object identity. The types of information represented by sustained activity in more anterior parts of prefrontal cortex are less well understood, but appear to involve memory for task rules, relationships among items to be remembered, and relationships between items and anticipated responses. It is thought that the patterns of activity in all of these regions interact, perhaps in a hierarchically organized network. Thus, sustained activity representing short-term memory for task rules influences which particular objects or locations will be held in short-term memory, and ultimately these remembered items provide specific feedback to other brain areas that influence perception and behavior.

Interactions between prefrontal cortex and other brain areas

While the prefrontal cortex plays a vital role in short-term memory behavior, it can do so only by interacting with other brain areas. Short-term memory is not a process or a storage area localized to any particular brain area. It is an ability of the animal that arises from the properties of the entire neural system. Sustained activity is thought to be made possible through reverberating circuits in which two populations of cells reinforce the activation patterns in each other through rapid, cyclical interactions. These circuits may exist for two populations of cells within an area of the prefrontal cortex, across separate areas within the prefrontal cortex, or they may exist for interactions between a cell population in the prefrontal cortex and one in a different part of the brain.

Basal ganglia

The neural mechanisms of short-term memory must be able to sustain patterns of activity related to the items currently held in short-term memory and protect them from all sources of interference for as long as those items are important for the current task. At the same time, these mechanisms must be able to very quickly change those patterns of activity to represent new items when the new information becomes more important than the previously remembered information. This balance

between maintenance and updating appears to be controlled in part by interactions between the prefrontal cortex and the basal ganglia, a group of subcortical structures that appear to be also involved in changing current patterns of neural activity governing motor behavior.

Motor and premotor cortex

Early studies of sustained activity in frontal cortex used delayed response tasks in which an animal made an eye movement toward a remembered location after a delay. This task confounds neural activity related to short-term memory for the spatial location of a previously viewed stimulus and neural activity related to anticipating a future motor response directed toward that location. Recent research, however, has demonstrated that both pieces of information are reflected in sustained neural activity and the patterns relating to each are dissociable, with separate neural populations and different time courses. Recordings from cells in prefrontal and premotor cortices suggest that interactions between prefrontal cortex and premotor cortex transform the pattern of sustained activity from a representation of the stimulus-to-be-remembered to the anticipated motor response. Of course, this can happen only when the task demands are such that a particular anticipated motor response can be deduced from the nature of the remembered stimulus and the task rules.

Perceptual cortical areas

Similar interactions are thought to occur between prefrontal cortex and perceptual cortical areas. In this case, the prefrontal cortex appears to enhance the activity or sensitivity of cells in perceptual areas that are selective for the anticipated stimulus that would be a match-to-the-remembered information. This interaction results in a greater neural activation in both prefrontal and perceptual areas for a test stimulus that matches the remembered stimulus than for a test stimulus that does not match.

Relationship to Attention

This interaction between prefrontal cortex and perceptual areas in order to maintain stimulus-specific information in short-term memory and influence processing of anticipated matching stimuli is one way in which short-term memory and attention interact. Perceptual selective attention is the ability to enhance the neural activity of one stimulus, spatial location, or stimulus feature over others. Short-term memory and perceptual selective attention interact when the information being attended is selected based on remembered task rules and short-term memory for the particular stimulus item or feature information to which those rules apply. For example, a classic task used to test selective attention is the visual search task in which the participant is instructed to

respond according to whether a particular item is present in a scene or within an array of multiple other items. The target of the search must be maintained in short-term memory. Attention and eye movements are drawn earlier and more often to items in the array that are most similar to the remembered target item. The contents of working memory can also influence the locations or objects that are selectively attended even when the contents of working memory are irrelevant for the perceptual selective attention task.

The neural mechanisms of perceptual selective attention may apply more generally to enhance the neural activity related to one item held in short-term memory over the neural activity of another remembered item. Thus, both items continue to be maintained in memory, but one is prioritized for more immediate manipulation, response, or comparison to anticipated stimuli. Thus, there appear to be two levels of prioritization. First, there is the limited capacity of short-term memory which dictates that only the top few pieces of information are actively maintained. Second, only the most important of these maintained pieces of information will have an immediate impact on perceptual selective attention and behavioral choice.

Neural Basis Helps Explain Behavioral Properties

As with all psychological abilities and behaviors, what is observed during measurements of short-term memory is the result of the entire, interactive, and interdependent neural system. Constraints on behavior may arise from the properties of any one or a combination of brain areas that comprise the neural system responsible for that behavior. Understanding how each cognitive component of a task depends differentially on various levels or aspects of the neural system makes the complex properties of short-term memory behavior more tractable.

Population Coding and Capacity

There are three components of most short-term memory tasks: (1) encoding of the material to be remembered, (2) maintenance of that information, and (3) comparison of the remembered information to the information presented during the test. Each of these stages can have its own constraints and properties. All three stages require representation of information, which must be accomplished by the spatiotemporal patterns of activity in populations of neurons. The information representation capacity of a population of neurons depends on the number of patterns of activity that sufficiently represents the relevant properties of the items in such a way that each can be distinguished from the other items when all are

simultaneously present in short-term memory. In other words, if the activity of a population of neurons is representing one item and then the activity representing a second item is superimposed on the activity of the first, can the system decode the independent properties of both items? The more the activity patterns of different items overlap and interfere with one another, the fewer items will be accurately represented. If each stage of processing for a task depends on a different population of neurons (potentially in different parts of the brain), then it is possible for each stage to have a different information representation capacity. The nature of the task will determine which of these stages has the dominant effect on behavioral measures of total short-term memory capacity. Whichever stage has the smallest capacity will set the upper limit for the system.

Visual Attention and the Processing Bottleneck

In tasks where the information to be encoded and remembered is presented very briefly, the capacity of sensory processing and perceptual selective attention serves as a bottleneck for the rest of the short-term memory system. It appears that the limit for this perceptual encoding into short-term memory is approximately three items, where all of the task-relevant features of those items must be capable of being bound together to form an integrated representation of each item at the earliest stages of sensory processing. When items can be encoded into short-term memory serially rather than simultaneously, with sufficient time for detailed encoding of each item, then the capacity of the system will be governed more by the representational capacity of the sustained activity in the reverberating circuits of prefrontal cortex.

Reverberating Circuits Are Susceptible to Decay and Interference

The neural populations of the prefrontal cortex may have a representational capacity that is different from that of the perceptual processing and attention neural populations. In addition, the effective capacity of short-term memory representations in the prefrontal cortex is influenced by the ability of these cortical regions to reorganize and transform the information into more efficient and effective representations. This transformation is primarily achieved through the use of relationships among the items to be remembered or through their relationship to items stored in long-term memory.

The capacity of short-term memory representations in the reverberating circuits of prefrontal cortex is dependent on the ability of these circuits to continue refreshing the representations without degradation. If the activity loses a little bit of signal and/or gains a little bit of noise each time it goes through this cycle, the information will

eventually decay to the point where it will no longer be able to support successful memory task performance. Signal transmission between the two cell populations in the circuit will naturally be imperfect, particularly for circuits that depend on long-range white matter pathways, such as between prefrontal cortex and perceptual areas. Noise can contaminate these representations from multiple sources, including interactions between multiple item representations in short-term memory and input from irrelevant sensory stimuli during the memory delay.

Dependence of Short-Term Memory on Long-Term Memory

The behavioral effects of short-term memory maintenance are most apparent when responses dictated by the contents of short-term memory conflict with those made prepotent from previous experience. Short-term memory enables flexible behaviors that are optimal for the current goals and context. The feedback signals provided by sustained patterns of neural activity, however, are acting on a system whose neural structure has been shaped by a lifetime of experience. These neural structures are influenced by many factors, including both long-term habitual stimulus-response associations and priming of circuits from recent experience. These structural changes provide their own bias that affects the individual's response to a given test stimulus. The biasing of behavioral and perceptual selection by short-term memory neural activity patterns must be able to override these structural influences on perceptual processing and responses. This constraint on the influence of short-term memory on behavior helps explain some of the apparent interference effects in short-term memory, including proactive interference and observations that short-term memory capacity for familiar stimuli is greater than for unfamiliar stimuli.

Summary

Short-term memory is an ability of the mind that is both enabled and constrained by the function and structure of neural circuits and systems. Prefrontal cortex plays a vital role in establishing the sustained patterns of neural activity that represent information in short-term memory, and the functional organization of prefrontal cortex provides

valuable information regarding the nature of those representations. However, short-term memory is not localized to the prefrontal cortex. Many of the psychological aspects of short-term memory, including capacity limits, effects of interference, and its relationship to attention and long-term memory, can be best understood by considering the properties of the multiple, interacting components of these circuits and systems.

Glossary

Adrenocorticotrophic hormone (ACTH) – A peptide hormone released from the anterior pituitary gland that mediates the production and secretion of hormones of the adrenal cortex.

Allostasis – The process of maintaining homeostasis through active means, such as the secretion of stress-related hormones in response to a stressor.

Allostatic overload – The wear and tear on the brain and body produced by chronic engagement of allostatic mediators, such as stress-related hormones.

Corticosterone – A steroid hormone released by the adrenal cortex of rodents that plays a major role in homeostatic/allostasic processes and acts throughout the body, including the brain.

Corticotropin-releasing hormone (CRH) – A peptide hormone that participates in the release of stress-related hormones, such as ACTH. This hormone is also referred to as ‘corticotropin-releasing factor (CRF).’

Cortisol – A steroid hormone released by the adrenal cortex of primates that plays a major role in homeostatic/allostasic processes and acts throughout the body, including the brain.

Dendrite – Branching neurites that emanate from the neuronal cell body.

Glucocorticoid receptor (GR) – A low-affinity steroid hormone receptor for the glucocorticoids, such as corticosterone or cortisol.

Hypothalamic–pituitary–adrenal axis (HPA axis) – The major neuroendocrine axis that mediates the hormonal stress response.

Mineralocorticoid receptor (MR) – A high-affinity steroid hormone receptor for the glucocorticoids, such as corticosterone or cortisol.

Paraventricular nucleus of the hypothalamus (PVN) – A nucleus in the hypothalamus that contains CRH neurosecretory cells that regulate the release of stress-related hormones.

with the immediate internal and external demands imposed by the stressful event. This response attempts to restore homeostasis, a process termed ‘allostasis.’ However, prolonged or more chronic exposures to stress and stress-related hormones can lead to allostatic overload, resulting in a number of negative effects, particularly in regard to neurobiological and behavioral function. This article highlights the effects of chronic stress on the structure and function of the hippocampus, prefrontal cortex (PFC), and amygdala, brain areas vitally important in various cognitive abilities, and emotional reactivity.

Stress and the Hypothalamic–Pituitary–Adrenal (HPA) Axis

The hypothalamic–pituitary–adrenal (HPA) axis is the major neuroendocrine axis that controls the hormonal stress response. In response to a stressor, neurosecretory cells in the paraventricular nucleus of the hypothalamus (PVN) release corticotropin-releasing hormone (CRH) into the hypophyseal portal system, which in turn causes the release of adrenocorticotrophic hormone (ACTH) from the anterior pituitary gland. ACTH then induces the secretion of the glucocorticoids, such as cortisol in primates and corticosterone in many rodent species, from the cortex of the adrenal gland. The hormones secreted by the HPA axis control their own release through a negative-feedback loop, specifically the glucocorticoids feedback on the PVN and pituitary to inhibit the release of CRH and ACTH, respectively ([Figure 1](#)).

In addition to the hypothalamus and pituitary, the glucocorticoids also regulate their secretion by acting on the hippocampus, PFC, and amygdala. Through projections to the PVN, the hippocampus and PFC largely contribute to the glucocorticoid-dependent negative feedback on the HPA axis. Conversely, the amygdala can activate the PVN, initiating the hormonal cascade that leads to glucocorticoid release. It is important to note that the balance between each part of this neural–pituitary network that regulates HPA function is dependent upon many modulatory factors, such as age, sex, time of day, and experience.

The mineralocorticoid receptor (MR) and the glucocorticoid receptor (GR) mediate the actions of the glucocorticoids. The MR has a high affinity for the glucocorticoids and thus is typically saturated at basal

Introduction

Stress induces a host of physiological and behavioral responses. The hormones released in response to stress are essential for survival, as they allow an animal to cope

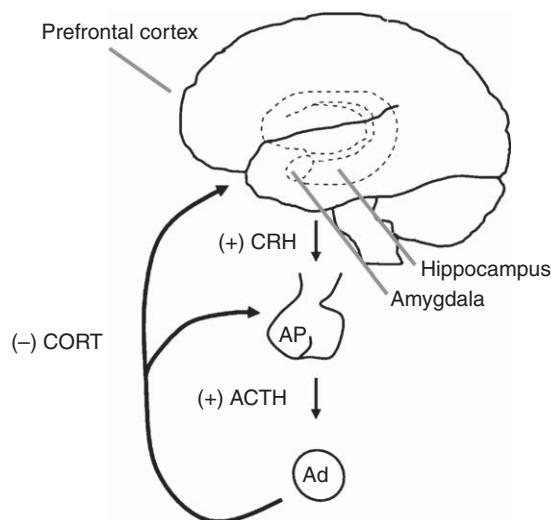

Figure 1 Schematic of the hypothalamic–pituitary–adrenal (HPA) axis and the hormonal cascade induced by stress and the relative anatomical position of the prefrontal cortex (PFC), amygdala, and hippocampus in the human brain. The dotted lines represent the approximate anatomical location of the amygdala and hippocampus within the brain. glucocorticoid levels. Conversely, the low-affinity GR is primarily occupied only when elevated concentrations of glucocorticoids are present, such as in response to stress. In the brain, these receptors are found in the highest concentrations in areas associated with HPA regulation and cognitive and emotional functions. These areas, such as the hippocampus, PFC, and amygdala (Figure 1), also show substantial stress-induced structural remodeling, which is the focus of the next section.

Stress and the Brain

Chronic exposure to stress and stress-related hormones has been shown to affect the gross morphology and size of the brain. For instance, it has been reported that humans exposed to recurring physical and mental abuse demonstrate significant cortical thinning, while animals treated neonatally with high doses of corticosterone show reduced brain weight. Though the brain is clearly sensitive to the glucocorticoids, some regions of the brain appear to be more sensitive to the effects of stress than others, that is, stress does not necessarily affect the structure of the brain uniformly. In fact, different regions of the brain can show diametrically opposed responses to prolonged exposure to stress, with some areas showing stress-induced atrophy, while others hypertrophy.

Hippocampus

The effects of stress on the structure and function of the hippocampal formation have been well studied. The hippocampal formation includes both the hippocampus and dentate gyrus, areas critically important in spatial and episodic learning and memory. The hippocampus contains a prominent layer of pyramidal cells called ‘Ammon’s horn’ (*cornu ammonis* or CA), which is usually subdivided into CA1, CA2, and CA3, while the dentate gyrus is composed of granule cells. The dentate gyrus is also one of the two major neurogenic zones in the brain and is capable of producing new neurons throughout an organism’s lifespan. The hippocampal formation expresses very high levels of both MR and GR, and thus is exquisitely sensitive to the effects of the glucocorticoids.

In humans, magnetic resonance imaging (MRI) studies have demonstrated that individuals reporting high levels of perceived chronic stress show reduced hippocampal volumes. A decrease in hippocampal volume is also observed in patients with Cushing’s syndrome, an endocrine disorder marked by high cortisol secretion (e.g., hypercortisolism). Interestingly, hippocampal volumes return to normal after successful treatment of Cushing’s syndrome that reduces the abnormally high cortisol levels. Together, these data suggest that prolonged exposure to the glucocorticoids can lead to hippocampal atrophy in humans.

Not only have animal studies produced similar results, but they have also been able to delve deeper into the regional specificity of the effects of stress on the structure of the hippocampus and the cellular mechanisms that may mediate stress-induced hippocampal atrophy. For instance, in adult male rats, chronic restraint (6 h of restraint stress per day for 3 weeks) or social stress significantly reduce branching of the dendrites of the CA3 pyramidal cells (Figure 2), and to a lesser extent the CA1 pyramidal cells and granule cells of the dentate gyrus. This stress-induced remodeling of the hippocampus is dependent on corticosterone as administration of cyano-ketone, a corticosterone synthesis inhibitor, blocks the stress-induced atrophy of the hippocampal dendrites, while chronic injections of corticosterone mimic the stress-induced atrophy. Activation of the N-methyl-D-aspartic acid (NMDA) receptor also plays a role in these effects of stress, as NMDA receptor antagonists block stress- and corticosterone-induced dendritic atrophy.

It is important to note that these effects of stress on hippocampal morphology are reversible. Specifically, if animals are allowed to recover from chronic physical and/or social stress, then neuronal branching patterns can return to prestress levels within 10 days (Figure 2). Thus, similar to the human imaging studies with

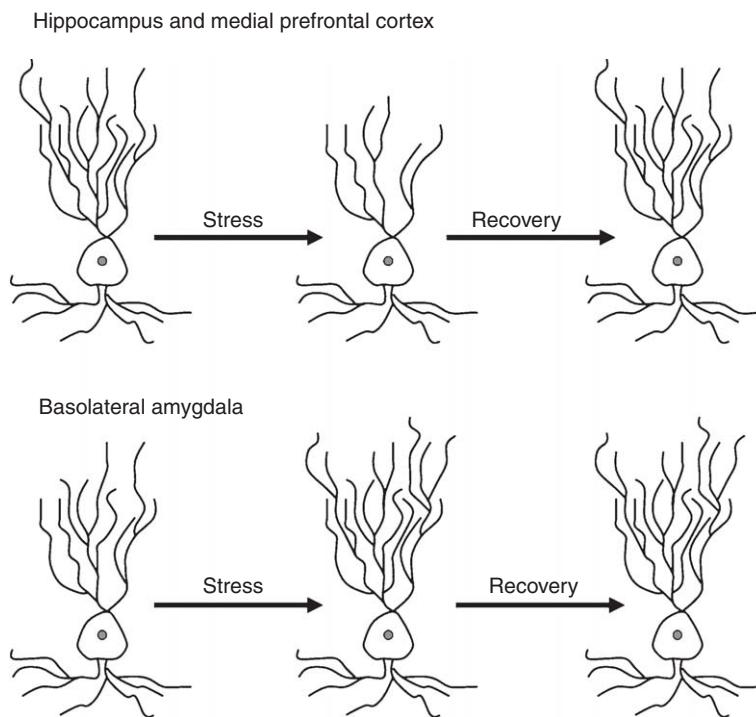

Figure 2 Diagrams of dendritic remodeling in the hippocampus, medial prefrontal cortex (mPFC), and basolateral nucleus of the amygdala in adult male rats. Note that the dendritic atrophy of the hippocampus and mPFC is reversible, while the basolateral amygdala dendritic hypertrophy is longer lasting, and perhaps permanent.

Cushing's patients, it appears that once glucocorticoid levels are reduced, hippocampal atrophy can be reversed.

As mentioned above, the hippocampal formation is integral in many types of learning and memory. In both human and animal studies, chronic stress is associated with impairment of spatial and episodic memory. Interestingly, studies have shown that if stress-induced CA3 dendritic atrophy is blocked pharmacologically, chronic stress does not result in deficits in spatial memory. For example, chronically stressed animals pretreated with tianeptine, an antidepressant that blocks stress-induced hippocampal atrophy, show spatial abilities similar to nonstressed controls. These data suggest that dendritic remodeling of hippocampal pyramidal cells may mediate the decrease in learning and memory observed during extended periods of stress.

It should be noted that chronic stress has also been shown to inhibit neurogenesis in the dentate gyrus of adult animals. Similar to the morphological changes, this suppressive effect of stress on neurogenesis appears to be reversible. Although methods are in development, it is presently difficult to measure hippocampal neurogenesis in living humans. It is therefore not possible to follow men and women in a longitudinal fashion to establish the role of, or recovery from, chronic stress on neurogenesis. Regardless of the unknown relationship between stress and human neurogenesis, it is possible that the stress-induced reduction in hippocampal volume observed in

both human and animal studies is due, at least in part, to the decreases in the birth of new neurons in this brain area.

Prefrontal Cortex

The PFC is essential in the regulation of emotional behaviors, executive function, and fear extinction. Though reports on the effects of chronic stress on the adult PFC are more limited than those which exist for the hippocampus, an emerging literature suggests that the PFC, especially the medial portion of the PFC (e.g., anterior cingulate and prelimbic cortices), is very sensitive to stress-induced neuronal remodeling.

Neuroimaging studies on the volume of the PFC in humans reporting chronic stress are lacking. However, human studies have shown reduced PFC volumes in depressed individuals. As depression can be associated with elevated cortisol levels, these data suggest that the human PFC may demonstrate glucocorticoid-dependent atrophy. Again, animal studies have greatly contributed to our understanding of stress-induced structural remodeling in the PFC. Recent experiments have shown that chronic restraint stress (6 h of restraint stress per day for 3 weeks) or even shorter periods of restraint stress (1 week), lead to significant reductions in dendritic branching of medial prefrontal cortex (mPFC) neurons (**Figure 2**). As chronic exposure to corticosterone mimics

the effects of chronic stress, it appears that stress-induced release of the glucocorticoids is involved in the mechanism(s) that lead to these morphological changes in the mPFC. Analogous to the hippocampus, the remodeling of the mPFC in response to chronic stress is reversible, such that animals allowed to recover for 3 weeks after exposure to stress show a dendritic morphology similar to unstressed controls (**Figure 2**).

In addition to these morphological changes, behaviors mediated by the PFC are also compromised in response to chronic stress. For example, tasks that require an animal to shift its attention, which is dependent on an intact mPFC, are greatly impaired in chronically stressed rats that demonstrate dendritic atrophy in the mPFC. It is presently unknown whether these changes in behavior show similar reversibility as the stress-induced structural remodeling of the mPFC.

Though more research is clearly needed, a growing body of literature suggests that the mPFC and hippocampus are similarly affected by chronic stress in the context of dendritic atrophy and its reversibility. As mentioned earlier, however, the brain is not uniformly affected by stress. Next, we turn to the amygdala, a brain region that shows a very disparate pattern of stress-induced morphological plasticity compared to the mPFC and hippocampus.

Amygdala

The amygdala is composed of many subregions, including the medial, central, and basolateral nuclei, all of which have relatively high GR (but lower MR) expression levels in the rat. Generally, the amygdala plays an important role in emotional memory and fear conditioning. Among other projections, the medial nucleus projects to hypothalamic nuclei relevant to reproductive behavior, the central nucleus (via the bed nucleus of the stria terminalis) to the PVN to mediate HPA activity, and the basolateral to the caudate, accumbens, and cortex to modulate the encoding of emotionally arousing events. Similar to the mPFC, a nascent literature has begun to emerge regarding the structural remodeling of the amygdala in response to long-term stress exposure.

In humans, overall amygdalar volume is reduced in individuals receiving chronic corticosteroid treatment for asthma or rheumatic illnesses compared to unmedicated controls. It has also been reported that people suffering from major depressive disorder have smaller amygdalar volumes than nondepressed individuals. Animal studies, however, indicate that exposure to chronic stress (2 h of immobilization stress per day for 10 days) can lead to increases in neuronal branching, specifically within the basolateral nucleus (**Figure 2**). It is unclear why the human studies report decreases in amygdala volume in individuals experiencing a chronic stress condition or

long-term corticosteroid therapy, whereas animal studies report stress-induced increases in neuronal elaboration. However, as the amygdala is such a complex and heterogeneous structure, it is possible that the human neuroimaging data, which quantify the volume of the entire amygdala, are missing morphological changes in the discrete subnuclei of the amygdala.

Animal studies have shown that behaviors known to be mediated, at least in part, by the amygdala are affected by chronic stress. For example, anxiety-like behaviors are augmented after prolonged exposure to stress, and fear conditioning has been reported to increase following glucocorticoid treatment. Unlike the reversibility of the effects of chronic stress on the dendritic structure of hippocampal and mPFC neurons, chronic stress-induced changes in the amygdala appear to be long lasting. That is, the dendritic hypertrophy in the basolateral amygdala and increases in anxiety-like behaviors remain even after 3 weeks of recovery from chronic stress (**Figure 2**). Although future studies will need to determine whether these stress-induced changes in the structure and function of the amygdala are permanent, it is clear that the neurons within the basolateral nucleus of the amygdala respond very differently to stress than the pyramidal cells of both the hippocampus and PFC.

Stress-Induced Neuronal Remodeling and Psychological and Physiological Dysfunction

Numerous studies have reported that exposure to chronic stress is correlated with the development and exacerbation of various psychological and physiological dysfunctions. It is presently uncertain how stress leads to these dysfunctions. However, stress-induced neuronal remodeling in the hippocampus, PFC, and/or amygdala may be a mechanism through which stress affects these aspects of mental and physical health. Though stress has profound influences on myriad psychological disorders and physiological functions, this section focuses specifically on the role that stress-induced neuronal remodeling in the hippocampal formation may play in major depressive disorder and HPA dysregulation.

Major Depressive Disorder

In addition to severe changes in mood and anhedonia, major depressive disorder is typically marked by a hyperactive HPA axis. For instance, individuals suffering from depression have higher concentrations of CRH in their cerebrospinal fluid, increased production of CRH in the PVN, and higher levels of circulating cortisol, compared to healthy controls. As alluded to in the section above (see sections ‘Prefrontal cortex’ and ‘Amygdala’), major

depression is also associated with changes in the structure and function of key brain regions involved in emotionality, which may be related to this HPA hyperfunction (see section ‘HPA dysregulation’).

Numerous empirical studies and meta-analyses have found a significant decrease in hippocampal, PFC, and/or amygdala volume in depressed men and women. Prospective studies are lacking, and thus, it is difficult to establish whether the depressive episode(s) result in these structural changes in the brain, or whether differences in brain structure lead to depression. Interestingly, upon successful treatment of major depressive disorder some, but not all, studies have found a reversal of these volumetric reductions. As successful treatment of depression is often associated with a normalization of HPA function, these data suggest an important interactive relationship between HPA reactivity, structural changes in brain, and major depression.

Along with structural changes, major depression is also associated with functional alterations in the brain. Depending on both the stimulus used and brain region examined, fMRI studies examining subjects with major depression have reported altered brain activity in hippocampus, PFC, and/or amygdala compared to non-depressed subjects. For example, depressed subjects presented with pictures of sad facial expressions or pictures that evoke negative emotions show higher activity in the amygdala and mPFC compared to control subjects. Again, whether these functional differences exist prior to depression, or conversely, are the result of depression, is uncertain.

HPA Dysregulation

The hippocampal formation is not only a target of the glucocorticoids, but is also intimately involved in modulating the output of the HPA axis (see section ‘Stress and the hypothalamic–pituitary–adrenal (HPA) axis’). Thus, it is not surprising that stress-induced alterations in the hippocampus can lead to changes in HPA reactivity. In addition to dendritic atrophy and suppressed neurogenesis, long-term exposure to high levels of glucocorticoids (e.g., chronic stress or exogenous application) can lead to hippocampal cell death, particularly in the CA3 pyramidal layer. Together, these structural insults and cell loss can compromise the ability of the hippocampus to participate in glucocorticoid-dependent negative feedback on the HPA axis. This reduction in negative feedback then sets the stage for greater secretion of the glucocorticoids, which in turn may result in further hippocampal damage.

The feedforward nature of compromised negative feedback makes it difficult to discern whether increased HPA function in situations such as major depression (see above) is the cause or the effect of elevated glucocorticoid levels. Moreover, it is unclear whether the neuronal

remodeling associated with chronic stress in areas, such as the mPFC and amygdala, contribute directly to HPA dysregulation. It is becoming more clear, however, that stress-induced changes in the morphology of cortical and limbic brain regions can affect the balance between HPA output and negative feedback.

As the effects of chronic stress on the hippocampal formation can have such profound effects on psychological disorders and physiological functions, it would be helpful to determine what factors may insulate, or even prevent, stress-induced changes in the hippocampus. It appears that if the hippocampus is continually engaged, such as in complex spatial situations or enriched environments, then structural and functional parameters of the hippocampus can be enhanced. For instance, imaging studies have demonstrated that taxi cab drivers in London, who have to frequently navigate the labyrinth-like streets of London, have larger hippocampal volumes than their nontaxi driving counterparts. Animal experiments have also shown that voluntary exercise and being exposed to environmental enrichment (e.g., larger housing, toys, and cage mates) can lead to enhanced neurogenesis in the dentate gyrus. Taken together, these data suggest that actively engaging with the environment prior to, or concomitant with, stress exposure may mitigate some of the adverse effects of chronic stress on the structure and function of the hippocampus.

Conclusions and Future Directions

Though a substantial amount of progress has been made regarding the effects of stress on the brain, many questions remain unanswered. Majority of animal studies addressing the role of stress in altered hippocampal, prefrontal cortical, and amygdalar morphology have been conducted on adult male rats. However, several stress-induced physiological and psychological dysfunctions show sex differences in their onset, severity, and/or recovery. For instance, depression occurs at nearly twice the rate in women compared to men, and heightened stress sensitivity in females has been posited as a key underlying factor. Therefore, it is imperative that future studies include females in experimental designs to assess the role of sex in the neurobehavioral consequences of chronic stress. Experiments have already begun to show significant differences in how the male and female brain responds to chronic stress. For example, when male and female rats are exposed to chronic restraint stress, only male rats show dendritic atrophy of hippocampal CA3 pyramidal neurons, though both sexes demonstrate stress-induced decrements in spatial memory.

In addition to sex differences, the stage of an organism’s development also appears to significantly alter the effects of stress on the brain and an organism’s sensitivity

to allostatic overload. For example, an interesting and emerging body of data suggests that the effects of stress during pubertal development may be longer lasting or more dramatic compared to the effects of stress on the adult brain. Recent studies have shown that adolescent animals exposed to chronic physical or psychosocial stress display long-term changes in the size of hippocampal cell layers and decreases in structural proteins (e.g., synaptophysin) in the mPFC well into adulthood. This developmental shift in stress sensitivity of the brain is not just limited to adolescence. In fact, studies have demonstrated differential stress sensitivity in the fetal, neonatal, and aged brain.

Obviously, additional research is needed to more fully appreciate the role of factors, such as sex and development in modulating stress-induced changes in brain structure and function. However, our understanding of stress and brain morphology continues to grow. As reviewed above, numerous studies have convincingly shown that chronic stress, or long-term exposure to stress-related hormones, has significant effects on the brain, particularly in areas critical in cognitive and emotional functions. It is also clear that the stress-induced changes in neuronal structure and function are brain-region dependent. Though the exact relationship between stress, brain morphology, and psychological dysfunction remains to be elucidated, it is encouraging to know that despite the pervasiveness of stress in modern life, many aspects of stress-induced changes in brain structure are reversible, and perhaps even preventable.

Glossary

Conditioned taste aversion – A form of associative learning in which a neutral or palatable taste becomes an aversive stimulus as a result of its association with the symptoms of a malaise-inducing drug.

Coolidge effect – Restoration of mating behavior in males that have reached satiety with one female, but show renewed mating behavior when presented with a new female.

Delayed non-matching-to-sample – A visual object-recognition task. First, a subject is presented a sample object and is trained to pick it up and reveal the reward. After a delay, a new object and the sample object are presented simultaneously. The subject is reinforced for picking up the new object. Performance depends on object-recognition memory.

Face recognition – The process by which a subject can recall that a face has been previously encountered.

Object recognition – Successfully remembering that an object has been previously encountered.

Spontaneous object recognition – A nonappetitive object-recognition task developed for rodents. In the first part of each trial, the animal is allowed to explore two identical sample objects, while in the second part the animal is presented one sample and one new object. Rats with intact object-recognition memory spend more time exploring the novel object.

Introduction

Impressive progress has been made towards understanding the neurobiology of object-recognition memory – a cognitive function that is absolutely essential to animal survival. Object recognition is now known to depend critically on temporal-lobe function. This article focuses on four parts of the temporal cortex that have been implicated in object-recognition memory. These include the inferotemporal cortex (IT), perirhinal cortex (PR), insular cortex (IC), and the hippocampus (HC). The role of these structures is shown to depend partly on the type of measurement of object recognition, which in turn depends on the definition of objecthood. Irrespective of these considerations, the PR consistently emerges as a key player in object-recognition memory.

Expanded Concept of Objecthood

Traditionally, the explicit or implicit understanding of objecthood has tended to be restricted to entities that have certain visual-stimulus attributes. According to one definition, an object is a visible entity that is relatively stable in form. However, it is possible to challenge this visuo-centric perspective. Some investigators have expanded the concept of objecthood to include perceptual entities in the auditory modality. The list might be enlarged to include tactile, olfactory, or gustatory, and multimodal objects. The article skirts the interesting issue of the concept of objecthood by defining object recognition based on tasks that might be used to measure it. This approach leaves the reader free to accept or reject any particular task as being pertinent to object-recognition memory. Finally, certain parts of the temporal lobes turn out to be consistently important across several tasks.

Measurements of Object Recognition

Among the following tasks, some depend entirely or partly on vision and some depend on nonvisual-stimulus attributes.

Delayed (Non)-Matching-to-Sample

In the delayed-matching-to-sample (DMS) paradigm the subject is first presented with a sample object that is covering a baited food well. The subject is trained to pick up the sample object to reveal and obtain the reward. Later, a delay interval is introduced between the visual observation of the object and the opportunity to make a choice between the observed object and a novel one. In the DMS version of this task, the novel object always covers the food reward (hence, ‘non-matching-to-sample’). The DMS task varies this rule by always hiding the food reward under the sample object so that the subject must learn to ignore the novel object. The location of the sample and novel objects is always counterbalanced to ensure that the subject does not perform based on the location of the reward. In addition, each trial contains new pairs of sample and novel objects. In primate versions of this task, performance depends on visual recognition of the sample object. In another version of this task, developed for rodents, performance depends on olfactory-recognition memory.

Spontaneous Object Recognition

The spontaneous object-recognition (SOR) task is a non-appetitive variation of the DMS task. When rats are presented with a novel and familiar physical object, their natural tendency is to spend more time exploring the novel one. The SOR task takes advantage of this tendency by measuring the time spent exploring the novel object. This task eliminates the need for a food reward. In the first stage, a rat encounters and explores two novel objects. After a delay period – during which the objects cannot be seen or touched – the rat is presented with one of the former objects plus a novel object. The rat demonstrates object-recognition memory by spending more time exploring the novel object. Depending on the details of this task, it is possible that both visual- and tactile-recognition memory control performance.

Face Recognition

Face recognition has been studied exclusively in humans and other primates. It is unclear whether rodents can visually recognize faces. In the human, face-recognition studies are often carried out using brain-imaging techniques such as functional magnetic resonance imaging (fMRI). Participants are shown images of faces and non-faces such as simple shapes or complex scenes. The dependent variable is activation in parts of the brain as measured, for example, by a blood-oxygen-level-dependent response in the case of fMRI. In monkeys, single-unit recordings commonly serve as the dependent variable. A subject is presented with conspecific faces that are varied in size or orientation as well as nonface stimuli such as bars or textures. The goal is to identify brain regions in which cells change their firing pattern or firing frequency in response to the presentation of faces.

Coolidge Effect and Conspecific Recognition

The so-called Coolidge effect is defined as the restoration of mating behavior in males that have reached sexual satiation with one female but show a restoration of mating behavior if presented with a novel female. A typical paradigm begins by allowing a male to mate with a female to satiety, as indicated by the absence of mating behavior for several minutes. Next, the familiar female is removed, and a novel female is introduced. Mating behavior is measured by counting the number of mounts, intromissions, and/or ejaculations until satiation. The Coolidge effect has been demonstrated in rats, sheep, rams, guinea pigs, and golden hamsters, and is starkly absent in monogamous species such as prairie voles and old-field mice. Since rats are nocturnal, live in burrows, and have relatively poor vision, one expects olfaction, not vision, to play a prominent role in the Coolidge effect. In fact,

conspecific recognition in rats is known to depend on olfaction.

Taste Recognition

There are two common measures of taste-recognition memory in rodents. Both are based on strong biological predispositions toward food. The first measure, called conditioned taste aversion (CTA), is a type of classical conditioning in which a neutral or palatable taste becomes aversive as a result of its temporal association with subsequent symptoms of malaise. The latter can be experimentally induced by a prior injection of lithium chloride. If the food-to-malaise timing is right, the animal will develop an aversion to the taste. Interestingly, rats do not learn to associate malaise with stimuli in other modalities. CTA is highly adaptive because it trains the organism to avoid potentially life-threatening substances within one trial and because it is long lasting. The second measure of taste recognition, called attenuation of neophobia (AN), relies on the fact that rats are innately neophobic toward food. With repeated exposures, neophobia toward food normally decreases, provided that the food is not followed by malaise.

Neuroanatomy of the Essential Temporal Cortex

Four regions of the temporal lobes have been implicated in object-recognition memory, as defined by the tasks defined in the section entitled ‘Measurements of object recognition.’ These include the IT, PR, HC, and IC. The entorhinal cortex (EC) is also included below because it furnishes essential input to and output from HC. **Figures 1** and **2**, respectively, illustrate the relevant neuroanatomy in the rat and primate cortex.

Inferotemporal Cortex

The IT is a high-level visual-information-processing area. In the human, IT occupies the lingual and fusiform gyri. In nonhuman primates, it occupies the ventral temporal gyrus (**Figure 2**). There is no apparent IT homolog in rodents.

IT is classified as a neocortex because it is organized into six layers. Layer I – the molecular layer – mainly contains the dendrites of pyramidal neurons from other layers. Layer II – the external granule cell layer – contains densely packed small-granule and pyramidal cells. Layer III – the external pyramidal cell layer – contains medium-sized pyramidal neurons. Layer IV – the internal granule cell layer – contains closely packed spiny-stellate and granule cells as well as myelinated fibers. Layer V – the internal pyramidal cell layer – contains medium- and

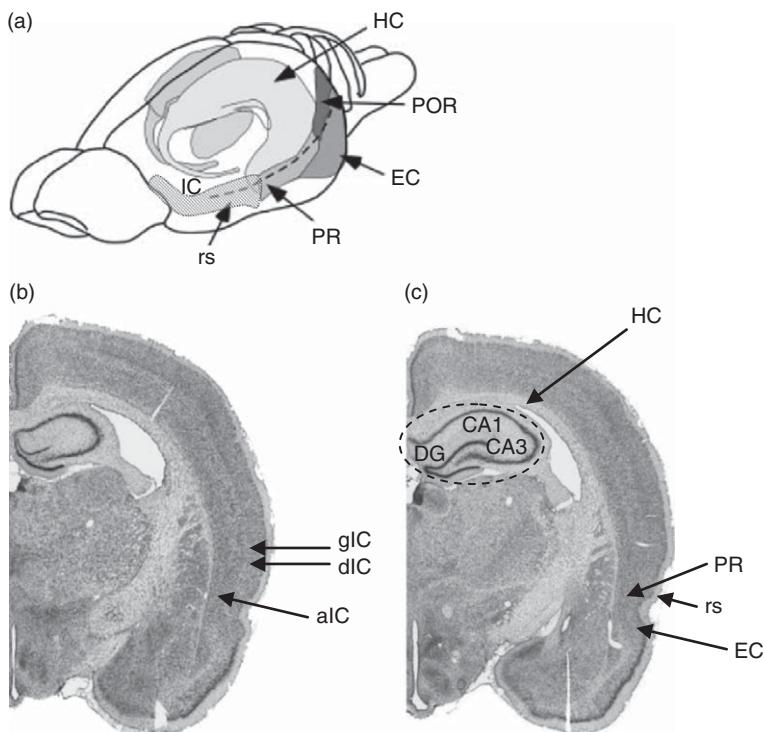

Figure 1 Rat temporal cortex. (a) Location of the temporal lobe cortex in the rat brain. Shading indicates location of the hippocampus (HC), postrhinal (POR), entorhinal (EC), perirhinal (PR), and insular (IC) cortices. POR, EC, PR, and IC are situated along the rhinal sulcus (rs). POR is termed as the parahippocampal cortex in primates. (b) Coronal section of rat (*rattus norvegicus*) brain showing granular, dysgranular and agranular insular cortex (gIC, dIC, aIC, respectively). Figure 3 Ventral visual pathway. The structures within the ventral visual stream are shown in gray. Visual information from the primary visual cortex (V1) reaches the inferotemporal cortex (IT) via V2 and V4. The perirhinal (PR) and entorhinal cortices (EC) are reciprocally connected to the IT. The amygdala (AM) receives input from the IT. The hippocampus (HC) is indirectly connected to the IT via the EC. The PR is also reciprocally connected to the AM.

large-pyramidal cells as well as intrinsic granule cells. Layer VI – the multiform or fusiform layer – contains small-pyramidal neurons, spindle-shaped cells, granule cells, and a variety of stellate neurons.

Visual information from the primary visual cortex (V1) reaches the IT via its projections through V2 and V4. This network – referred to as the ventral visual stream – is illustrated in **Figure 3**. The ventral stream is sometimes termed the ‘what’ pathway. By contrast, the dorsal visual stream, not shown in **Figure 3**, is sometimes termed the ‘where’ pathway. IT is reciprocally connected to the PR and EC and also projects to the prefrontal cortex, the amygdala, and the basal ganglia.

Perirhinal Cortex

The PR is a high-level, polymodal, association cortex. In rodents, it consists of a strip that occupies the dorsal and ventral banks of the rhinal sulcus (**Figure 1**). The PR is distinguishable from neighboring areas based on its extraordinarily low level of myelin and laminar distribution of neuronal cell types. At least 15 neuroanatomical categories of neurons have been discovered in the rat PR using the Golgi-staining method. One striking characteristic of the PR is a much larger proportion of cell types that are less common in other cortices – a fact that creates the visual impression of enormous morphological diversity.

The PR is classified as the periallocortex because it is organized into five layers. Layer I – the most superficial layer – contains axons and dendrites, but no cell bodies. Layers II and III are counted as two layers even though they are difficult or impossible to distinguish from each other in the rat PR. Layers II/III and V contain many

upright pyramidal cells, large spiny stellates, and numerous smaller cell types. Layer VI is uniquely characterized by the fact that the dendrites are aligned parallel to the external capsule and pial surface.

The neuroanatomical connections to and from the PR can be subdivided into three broad categories: cortical, hippocampal, and subcortical connections. The PR receives massive input from all unimodal sensory and polymodal association cortical areas, and is reciprocally connected to the IC and IT. The PR also receives afferents from the piriform cortex and is strongly connected to the hippocampal formation through its reciprocal connection with the EC. Furthermore, the PR is reciprocally connected to the lateral and basal nuclei of the amygdala (LA and BA, respectively) and also receives afferents from the thalamus (dorsal nucleus and medial geniculate body).

Hippocampal Formation

The HC proper is an elongated structure within the medial temporal lobes (**Figure 1**). Throughout its length, HC consists of three subfields, designated CA1, CA2, and CA3. The hippocampal formation includes, in addition to the HC, the dentate gyrus (DG) and the subiculum complex (subiculum, presubiculum, and parasubiculum).

The HC is typically classified as archicortex or allocortex because the CA fields are organized into three prominent layers: the stratum oriens, the stratum pyramidale, and stratum radiatum/stratum lacunosum-moleculare. Stratum oriens contains the basal dendrites of pyramidal cells. Stratum pyramidale contains the cell bodies of pyramidal neurons. Stratum radiatum and stratum lacunosum-moleculare contain the apical dendrites of pyramidal cells. DG also has a trilaminar organization,

with the molecular layer being the most superficial, followed by the granule cell body layer, and finally, the polymorphic layer.

Entorhinal Cortex

The EC furnishes an essential part of the input to and output from HC. Much of the higher-level sensory input to EC originates in the PR and IC. The medial and lateral parts of the EC have different types of connections. The medial EC receives afferents from the postrhinal cortex, whereas the lateral EC receives inputs from the PR and the IC. These cortical afferents (among others) reach layers II–III of the EC. From there, activity traverses the internal circuitry of HC. Information from the HC is projected back to layers IV–VI of the EC, which projects to the PR and the IC. In summary, the HC is extensively connected to the PR and IC via the EC. The HC is also reciprocally connected to the IT via the EC and PR (**Figure 3**).

Insular Cortex

The IC is important for integrating high-level gustatory, olfactory, and visceral information. In rodents, the IC is a broad strip, situated anterior to the PR along the rhinal sulcus (**Figure 1**). In primates, the IC is situated deep within the lateral sulcus of the brain (**Figure 2**). The IC is reciprocally connected to both the PR and the EC. Based on cytoarchitecture, one can distinguish three subdivisions of the primate IC: agranular IC (aIC), dysgranular IC (dIC), and granular IC (gIC). The aIC occupies the anterior portion, dIC occupies the middle portion, and gIC occupies the posterior portion of the IC. The aIC is further divided into dorsal aIC and ventral aIC. The ventral aIC is classified as allocortex because it has three layers: II/III, V, and VI. The three layers are easily distinguishable because they are segregated by cell-free zones called the *lamina dissecans*. The dorsal aIC, classified as proisocortex, has only two layers: II/III and V/VI. Layers V and VI are not distinguishable because the dorsal aIC region lacks the *lamina dissecans*. Layer II/III contains pyramidal cell bodies. Layers V and VI contain pyramidal cell axons that project to regions near the rhinal sulcus.

The IC is connected to several structures in a topographically specific fashion: only aIC projects to the mediodorsal thalamic nucleus; only dIC projects to the presupplementary motor cortex; and only gIC is reciprocally connected to the somatosensory cortex. The differences in connectivity suggest that the three divisions of IC may be functionally dissociable. All three divisions are connected to the PR, EC, and the amygdala. PR is reciprocally connected to the aIC and receives input from the dIC. The EC is reciprocally connected to aIC and dIC

and projects to the gIC. The lateral (LA), basolateral (BLA), and central (Ce) nuclei of the amygdala receive input from the aIC and dIC. The LA and BLA project to the gIC. Finally, the gustatory thalamic nucleus is reciprocally connected to the gIC and receives input from the dIC. In summary, the IC is well connected to the PR, EC, the gustatory thalamus, and the amygdala.

Temporal Cortex and Object Recognition

Each of the four regions of temporal cortex described in the section titled ‘Neuroanatomy of the essential temporal cortex’ has been linked to one or more of the object-recognition tasks described in the section titled ‘Measurements of object recognition.’

Inferotemporal Cortex

The IT is implicated in face recognition and, more generally, in recognition of complex stimulus patterns. In the 1970s, Pribram and Mishkin discovered that removal of IT in monkeys severely impaired visual-object recognition. In the human, damage to the IT leads to prosopagnosia – a condition in which a person is unable to recognize faces. Damage to the IT can also impair discrimination among colors (achromatopsia), animal species, and categories of manmade objects.

Human fMRI studies suggest that the fusiform gyrus (FFA), a part of the IT, is particularly responsive to faces. The FFA is also activated when participants are asked to discriminate among bird species, types of cars, or complex nonsense shapes called Greebles. The evidence to date suggests that the FFA is involved in face recognition, and also plays a role in discriminating complex nonface visual objects.

The involvement of the IT in face recognition has been investigated in large part via electrophysiological studies in monkeys. Some neurons in the IT seem to be selectively tuned to faces. These cells are responsive irrespective of whether the faces are real or plastic, human, or monkey. They are also responsive irrespective of the size or orientation of the faces. Importantly, these cells are not responsive if the components of the face are rearranged. They are also relatively unresponsive to simple stimuli such as gratings, or complex stimuli such as food or snakes.

Some cells within the IT are highly responsive to components of the face, such as the eyes, mouth, or hair. One implication of this fact is that the IT may support face recognition based on a distributed network of cells that individually encode particular aspects of faces. This possibility stands in contrast to the alternative that so-called gnostic or dedicated face cells are responsible for representing different faces. A distributed encoding

mechanism may be more economical. The modern consensus is that the IT supports face recognition through distributed networks of neurons that are individually tuned to simpler shapes, colors, and textures. Face-responsive cells have also been reported in the amygdala. This is not surprising given that the IT projects directly to the amygdala (**Figure 3**). However, amygdalar cells appear to be selective for certain facial expressions, rather than face recognition. It is unclear whether the PR, HC, or IC play important roles in face recognition.

Perirhinal Cortex

The PR is essential for the performance of four different categories of object-recognition tasks. No other temporal-lobe region has been demonstrated to have this task- and modality-independent relationship to object recognition. The four general categories of tasks are discussed under separate headings below.

Delayed (non)-matching-to-sample

Abundant evidence demonstrates that damage to the PR produces the largest deficits in visual object-recognition memory. Seminal studies in the late 1980s compared the effects of the PR and parahippocampal (PHC) cortical lesions with lesions of the HC and amygdala. The PR-PHC lesions severely impaired DMS performance in monkeys even when the HC and amygdala were intact. Studies by Elizabeth Murray and colleagues show that damage restricted to the PR is necessary and sufficient for severely impairing DMS performance in monkeys. Combined PR and EC lesions drastically impair DMS and DMS performance, but lesions limited to the EC produce only a mild and transient deficit. Thus, the PR is strongly implicated as being the most critical structure in the medial temporal lobe (MTL) for visual object recognition.

Decreased neuronal responding to familiar stimuli may be one mechanism by which the PR supports familiarity-based object recognition. Approximately 25% of the PR neurons show attenuated responses to familiar stimuli. Importantly, neuronal responses in the PR have been shown to attenuate in as little as one stimulus repetition, a finding that is consistent with object-recognition memory, which can form in a single trial. Attenuated responding in the PR occurs even when several objects are presented simultaneously or serially, suggesting that this mechanism has a large capacity. Given that unique stimuli are presented on each trial in DMS, it is possible that object recognition of multiple familiar stimuli is supported by attenuated neuronal responding in the PR. In this way, attenuated PR responding may encode stimulus familiarity.

Performance on DMS and DMS tasks depends on muscarinic receptor activation. Systemic injections of

scopolamine or atropine, which are cholinergic muscarinic receptor antagonists, impair performance in the human and rats. Intra-PR infusion with scopolamine disrupts DMS performance in monkeys. Interestingly, performance on the DMS task has been reported to enhance the release of acetylcholine in the PR. Systemic injections of the acetylcholinesterase inhibitor, physostigmine, enhances recognition memory in monkeys and the human.

Spontaneous object recognition

The PR plays a prominent role in SOR. Inactivation of the PR via lidocaine infusion impairs SOR performance across a wide spectrum of time points, which suggests that the PR may be necessary for the encoding, maintenance, and retrieval of object-recognition memory. The cholinergic system in the PR is implicated in SOR because intra-PR infusion of scopolamine impairs SOR. Finally, single-unit recordings in the PR reveal attenuated neuronal responses during presentations of familiar objects in SOR. Both SOR and DMS may be tapping a common PR function.

Coolidge Effect and conspecific recognition

The PR also plays a critical role in the Coolidge effect. Ibotenic acid lesions of the PR and the EC (but not of the HC) abolish the Coolidge effect. In one study, male golden hamsters were mated with a female until satiation. The males were then presented with both the familiar female and a novel one. Both females were anesthetized. Investigatory and copulatory behavior was measured. A control test confirmed that lesioned males do not differ from control animals in terms of general investigatory behavior. PR-EC-lesioned males (but not HC-lesioned males) failed to demonstrate the Coolidge effect. Other studies have similarly reported that combined PR-EC lesions (but not fimbria-fornix lesions) impair discrimination between novel and familiar conspecific odors. Similarly, PR-EC lesions (but not HC lesions) impair recognition of juvenile conspecifics. Both PR and EC appear to play fundamental roles in the recognition of conspecifics.

Taste recognition

The PR is strongly implicated in taste-aversion tasks. The disruption of the cholinergic system in the PR impairs taste recognition as assessed by AN and CTA. More specifically, infusion of scopolamine into the PR impairs AN and CTA. Pretraining, but not pretesting, inactivation of the PR blocks CTA, implicating the PR in CTA learning but not retrieval.

Hippocampus

The role of the HC in object recognition has been a subject of intense debate since the 1970s. Early studies suggested that the HC and the amygdala were critical for object-recognition memory. Specifically, combined lesions of the HC and the amygdala impaired visual- and tactile-recognition memory, but lesions restricted to either structure did not. Combined HC and amygdalar lesions also impaired DMS performance, retention of object discrimination at long delays, and concurrent object discrimination. In some or all of these studies, the PR may also have been damaged. Indeed, subsequent research found that attempts to ablate the HC and the amygdala only resulted in impaired DMS performance when the surrounding PR and PHC were also damaged. Furthermore, lesions that were restricted to the PR and PHC produced an equally severe impairment. These studies collectively suggest that the PR plays a greater role in DMS than does the HC.

In the 1990s, the DMS task was adapted for use in rats. Although some studies reported that damage to the HC or to the fornix impairs DMS performance, an equal number of studies failed to find this impairment. It is thought that HC lesions only impair DMS performance when the delay period between the sample and choice phase is sufficiently long. In fact, HC-lesion deficits in DMS performance are evident at 10 min, 1 h, and 24 h, but not at 10 s and 1 min.

Physiological studies reveal that attenuated neuronal responding to familiar stimuli is not common in the HC. Although one study reported attenuated responding in the HC, this occurred in only 2% of HC neurons, as opposed to 25% of PR neurons. Enhanced neuronal responding has also been observed in the HC, but this is less common. Relative to the PR, it appears that the HC plays a much more limited role in object-recognition memory.

Insular Cortex

The IC is implicated in CTA and AN. Early studies reported that electrolytic lesions of the amygdala impair CTA and AN. However, it was unclear whether the impairment was due to damage to amygdalar neurons, or to fibers of passage within the amygdala. A double-dissociation study tested this confound by comparing the effects of ibotenic and electrolytic lesions of the amygdala and IC on CTA and AN. Electrolytic, but not excitotoxic, amygdalar lesions impaired CTA and AN. Excitotoxic IC lesions severely impaired CTA and AN. Given that axons to and from the IC pass through the amygdala, the results suggest that the IC is more critical than the amygdala for taste-aversion tasks. The physiological and chemical mechanisms underlying the function of the IC in CTA remain to be unraveled. One might expect the IC to also

be critical for the Coolidge effect and conspecific recognition, but we found no evidence to support this possibility.

Synthesis

The concept of an object commonly conjures up visually identified features that have essential spatial relationships to each other. Recently, however, the concept of object-hood has been extended to include auditory, olfactory, or gustatory, and multimodal objects. Here we consider a wide range of object-recognition tasks, some of which do not depend on visual or spatial stimulus attributes. Evidence to date suggests that the PR is critical for object recognition, irrespective of the stimulus modality. We anticipate that the PR will also play a critical role in multimodal object-recognition memory.

Glossary

Ablation – Surgical removal.

Adipose – Of, or relating to fat.

Caudal – Situated in, or toward the hind end of the body.

Comorbid – Pertaining to two diseases occurring together.

Countercurrent – Materials flowing in opposite directions.

Cytokine – One of several intercellular proteins that mediate an immune response.

Dorsomedial – Located toward the back and near the midline.

Pyrogen – A fever-producing substance.

Rostral – Situated in, or toward the front end of the body.

Sepsis – A toxic condition resulting from the spread of bacteria from a site of infection.

Vaso- – Of, or relating to blood vessels.

Ventromedial – Located abdominally and near the midline.

systems mitigate heat escaping through the extremities, by transferring heat from outgoing arterial to incoming venous blood. Metabolic adaptation includes the ability to store metabolic energy in the form of fat. Through thermogenesis, energy can be released rapidly (e.g., shivering) or gradually (e.g., liver). Furthermore, evolutionary pressures also select for advantageous anatomical features, such as shortened extremities, or increased body size to more easily facilitate a steady core body temperature.

As thermoregulators, humans have successfully adapted to a diverse set of climates. In cooler conditions, the human body engages in thermogenesis (e.g., liver processes and muscle contractions) to produce heat, and vasoconstriction to retain heat. In warmer environments, humans engage in vasodilation and sweating to transfer excess heat through evaporation. In addition to physiological mechanisms, humans also employ other social (e.g., huddling), cultural (e.g., clothing), and technological adaptations to produce or retain heat.

Thermometers provided the means to accurately measure temperature in animals. Because rates of heat loss and heat production vary in different parts of the body, local temperature readings may differ considerably. Although circulating blood tends to standardize body temperature, the identification of body parts that closely match those of the internal organs have proven useful in ascertaining core temperature. These body parts include the rectum, uterus, bladder, mouth, ear, and groin.

Behavioral Physiology

Homeostasis involves the dynamic interaction between an organism's internal processes and its external environment to maintain physiological stability. One such homeostatic process is thermoregulation. Among animals, there are thermoconformers and thermoregulators. A thermoconformer's body temperature changes based on external temperature. A thermoregulator, however, maintains its body temperature within a particular range, while still being responsive to various external, environmental stimuli. Among thermoregulators, failure to achieve thermoregulatory balance may result in physiological damage, metabolic irregularities, or even death.

In order to maximize heat loss in warm environments, mammals typically employ a number of adaptations. These include physiological strategies such as evaporative cooling (i.e., panting and perspiration), highly vascularized extremities, and compartmentalized fat storage to reduce insulation (e.g., camels). Other strategies involve behavioral adaptations such as daytime burrowing and increased nocturnal activity. Conversely, mammals utilize a variety of strategies to retain heat in cold environments. Physiologically, vascular countercurrent exchange

Heat Loss

When environmental temperature is above core body temperature, humans lose heat through evaporation by secreting sweat. Furthermore, dermal hairs lie flat to prevent air retention between them, and thus complement convective heat loss. Vasodilation is another mechanism by which humans lose heat. Relaxation of smooth muscle in arteriole walls increases arterial blood flow. By redirecting blood to distal parts of the body, such as the skin, heat is lost through radiation and convection. In contrast to humans, only few other mammals lose heat primarily through sweating (e.g., horses). Rats, mice, cats, and dogs possess sweat glands exclusively on their foot pads. Instead, many mammals (e.g., dogs) pant to cool their bodies. Highly vascularized lungs, with a large surface area, facilitate heat exchange between the air and their bodies.

Heat Retention/Production

In contrast to heat loss, humans apply the opposite mechanisms to retain heat whenever environmental temperature dips below core body temperature. Sweat pathways are deactivated. Vasoconstriction is achieved by constricting subdermal capillaries and thus, shunting blood away from the skin and the body's periphery. In extremely cold conditions, prolonged rerouting of blood away from the extremities causes numbness and cellular damage (e.g., frostbite). To augment heat retention, humans contract minuscule subdermal muscles (erector pili) to erect dermal hair follicles. These erect hairs form an insulating layer capable of trapping heat. Furthermore, humans and some animals produce heat in an exothermic process called thermogenesis. Effector signals from the hypothalamus reach peripheral muscles to cause shivering. Humans engage in short-term shivering, where heat is produced through high-intensity glucose metabolism in a relatively short period of time. Other animals, such as hibernating bears, are capable of long-term shivering, often for months, by gradually and steadily metabolizing fat stores.

Circadian Rhythm
