Daily variations in body temperature have been observed in mammals, particularly humans and rats. The daily peak of body temperature rhythm in rats was found to consistently follow the daily peak of heat production rhythm and to precede the daily peak of heat loss rhythm. Furthermore, the daily rhythm of heat balance is 180 degrees out of phase with the rhythm of body temperature. Animals with lesions in the dorsomedial nucleus of the hypothalamus (DMH) maintained a normal circadian variation, though body temperature remained 0.5°C lower. Rat studies have shown that the circadian rhythm may be inverted by restricting food access to daylight hours. When only permitted to eat during the latter half of the light period, these animals awaken and increase body temperature a few hours before food administration. Lesion studies have determined that, the ability to alter rhythms in body temperature, as well as the wake–sleep cycle, feeding, activity, and corticosteroid rhythms, correlate with DMH activity.

Sleep

Mammals sleep to conserve energy, during most of which, decreased body and brain temperatures are observed (exception: rapid eye movement (REM) cycle). Small mammals tend to sleep the most, since they also have higher energy demands for thermoregulation and locomotion, while possessing relatively lower energy reserves. Disruption of normal sleep cycles has been associated

with thermoregulatory irregularities. For example, chronically sleep-deprived rats show increased preference for cooler ambient temperatures ($\sim 10^{\circ}\text{C}$), which suggests that sleep has cooling function. Conversely, rats sleep-deprived for 2 weeks show a significant decrease in body temperature despite a doubling in metabolic rate, suggesting sleep's role in heat retention. In humans, increased hypothalamic temperature induces sleep, and body heating prior to sleep increases subsequent slow wave sleep.

Mechanism

Hypothalamus

Found in all mammalian brains, the hypothalamus is located ventral to the thalamus, where it coordinates certain metabolic processes and various autonomic nervous system activities, as well as synthesizes and secretes particular hormones. Stimulation and ablation studies have determined that the preoptic anterior part of the hypothalamus (PO/AH) is crucial for thermoregulation. Approximately, 40% of PO/AH neurons are temperature sensitive, while the rest are insensitive. Local warming of PO/AH neurons evoked heat loss responses, whereas local cooling induced heat production. This observation led to the idea that the PO/AH is an area responsible for thermoregulatory control, that is, the body's central thermostat.

Neuroanatomical Correlates

Observed heat loss behavior includes vasodilation, panting, and sweating, while heat production behavior involves vasoconstriction, shivering, breakdown of brown adipose tissue, and huddling. Further studies have determined that heat loss and production are triggered by the actual ambient temperature, and not by the rate of change in temperature, since no burst of neuronal firing rates was detected during rapid temperature change. Hypothalamic temperature does not vary considerably (range: $\pm 1^{\circ}\text{C}$) even when ambient temperature is changed drastically. However, drops in hypothalamic temperature below this range often induce a coma and other neuroprotective mechanisms.

Changes in the activity of neurons in the PO/AH have been correlated with initiation of thermoregulatory mechanisms. Nearby areas, such as the DMH, may include thermoeffector neurons. Electrical stimulation of the DMH induced an increase in heat production behavior. Retrograde labeling shows dye beads transported to the lateral hypothalamus (LH), PO/AH, ventromedial preoptic (VMPO), and paraventricular area (PVN). It is thought that the PO/AH may have direct control of the DMH.

Neuronal Thermosensitivity

Various *in vivo* and *in vitro* electrophysiological studies have identified four types of thermoregulatory neurons: warm-sensitive, cold-sensitive, temperature-insensitive, and silent. Among these types, the vast majority of the PO/AH neuronal population comprise warm-sensitive (~30%) and temperature-insensitive (~60%) neurons. One main difference between these two types is that warm-sensitive neurons not only inherently respond to local thermal input, but also to hypothalamic, skin, and/or spinal temperature. Conversely, temperature-insensitive neurons do not exhibit temperature-related changes in activity.

Thermal Classification

Historically, temperature sensitivity has been ascertained in one of two ways: either through the determination of a Q_{10} thermal coefficient, or through calculation of the neuronal firing rate regression line slope. The slope reflects the number of action potentials (APs) as a function of hypothalamic temperature.

Using the latter criteria, temperature-sensitive neurons can be divided into two subgroups: warm- (35% PO/AH) and cold-sensitive (5%). Warm-sensitive neurons fire at ≥ 0.8 impulses/s/ $^{\circ}\text{C}$, when the PO/AH temperature is changed by $\pm 2\text{--}3$ $^{\circ}\text{C}$. These neurons respond to both direct changes in hypothalamic temperature and peripheral thermal stimulation. They also have a distinct lateral/medial orientation in dendritic morphology, which is consistent with their roles as integrators of thermal information. Cold-sensitive neurons, on the other hand, fire at ≤ -0.6 impulses/s/ $^{\circ}\text{C}$ when PO/AH temperature is changed by $\pm 2\text{--}3$ $^{\circ}\text{C}$. Unlike warm sensitivity, cold sensitivity is not an inherent property, and may be a result of synaptic input from nearby warm-sensitive and -insensitive neurons.

In contrast, temperature-insensitive neurons show little change in firing rate when temperature deviates from the normal physiological condition (~ 37 $^{\circ}\text{C}$). Temperature-insensitive neurons fire at ≤ 0.79 impulses/s/ $^{\circ}\text{C}$ and ≥ -0.6 impulses/s/ $^{\circ}\text{C}$ when the PO/AH temperature is changed by $\pm 2\text{--}3$ $^{\circ}\text{C}$. Essentially, this range is between the firing rates of warm- and cold-sensitive neurons. Unlike their warm-sensitive counterparts, temperature-insensitive neurons extend their dendrites in rostral/caudal directions, consistent with their roles as indicators of baseline of hypothalamic activity.

The characterization of physical differences between temperature-sensitive and -insensitive neurons is an active area of research. These differences in firing rates may be determined by various ionic conductances, such as tandem-pore K⁺ leak channels (TWIK-related acid-sensitive K⁺ (TASK), TWIK-related K⁺ (TREK), and TWIK-related arachidonic acid-stimulated K⁺ (TRAAK), transient K⁺ A-current channels, hyperpolarization-activated cyclic

nucleotide-gated channels (HCNs), and vanilloid transient receptor potential (TRP) channels. The proportion of these channels within the hypothalamus may explain the difference among warm-, cold-sensitive, and temperature-insensitive neurons. It has been observed that increased temperature positively correlated with both firing rate thermosensitivity and A-current inactivation, resulting in a higher probability of reaching firing threshold.

Hammel's Model

In the 1960s, the six-neuron Hammel's model (see Figure 1), named after its developer, proposed that set-point temperature was determined by the integration of afferent signals with neuronal interactions within PO/AH. The model proposed that warm-sensitive neurons positively synapse on warm effector neurons, whereas temperature-insensitive neurons inhibit them. The temperature where excitation equals inhibition determines the set point. Above the set-point temperature, warm effector neurons receive more stimulation than inhibition, thus leading to heat loss behavior. Conversely, temperature-insensitive neurons positively synapse on cold effector neurons, whereas warm-sensitive neurons inhibit them. Below the set-point temperature, cold effector neurons receive more stimulation than inhibition, thus initiating heat retention/production behavior.

Medical Implications

Fever, General Pathology

Several studies estimate that the average core temperature for healthy adults is approximately 98.2 $^{\circ}\text{F}$ or 36.8 $^{\circ}\text{C}$. When presented with an immunological challenge, the human body undergoes a cascade of factors that signal the brain. The resulting rise in body temperature of 1–4 $^{\circ}\text{C}$ is defined as a fever. Metabolically, specific cytokines cause production of prostaglandin (PGE₂) in the brain, which in turn affects neuronal activity in the ventromedial preoptic (VMPO). Introduction of PGE₂ to this region or stimulation of afferent pathways causes significant rise in body temperature (>1 $^{\circ}\text{C}$). According to Hammel's model, an increase in the firing rates of temperature-insensitive neurons and/or a decrease in the firing rates of warm-sensitive neurons result in a new, higher set point. The presence of PGE₂ causes warm-sensitive neurons to decrease their firing rates and temperature-insensitive neurons to be unaffected or increase their firing rates.

Fever, Evolution of

Endotherms and ectotherms (both vertebrates and invertebrates) initiate a febrile response when challenged with endotoxins or pyrogens. This widespread occurrence

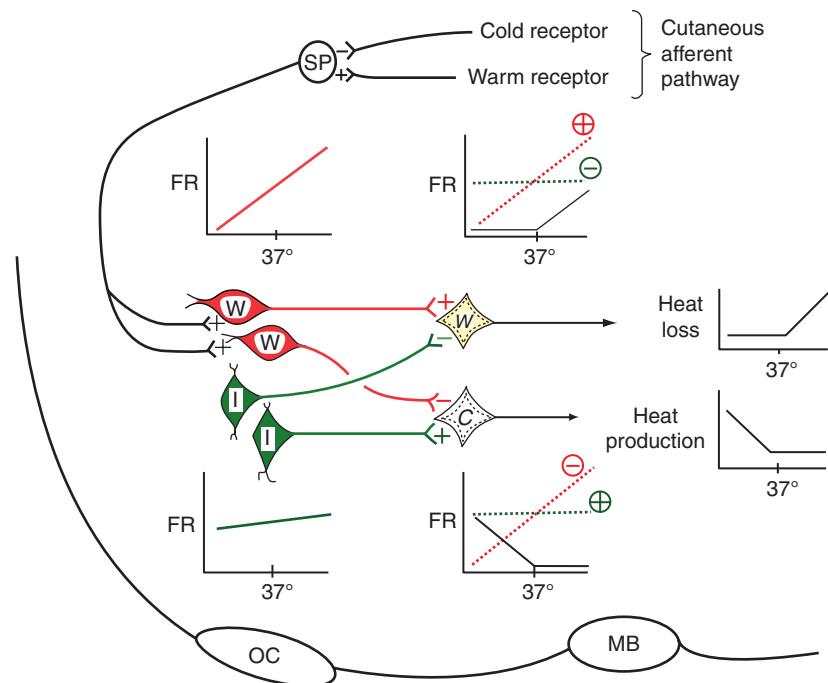

Figure 1 Hammel's model. A modified six-neuron model explaining the hypothalamic determination of set-point temperature. Key: FR, firing rate; W, warm-sensitive neuron; I, temperature-insensitive neuron; w, heat loss effector neuron having synaptically derived-warm sensitivity; c, heat production effector neuron having synaptically-derived cold sensitivity; SP, dorsal horn spinal neuron; OC, optic chiasm; MB, mammillary body. suggests that, fever most likely evolved hundreds of millions of years ago.

There has been some debate as to whether the febrile response is evolutionarily beneficial or maladaptive. For example, in endotherms, such as birds and mammals, maintenance of body temperature at 2 or 3°C above set-point levels often results in an increase in energy consumption by at least 20%. Despite this metabolic expenditure, several studies have shown that suppression of the febrile response in many species resulted in increased mortality, while artificial inducing fever increased resistance in others. However, adverse effects through pyrogenic cytokines (such as interleukin-1, tumor necrosis factor, interleukin-6, and interferons) have been shown to add to an infection's pathophysiological burden on the host, and, in some instances, even induce sepsis.

Despite the risk, it is unlikely that such an energetically expensive process would have persisted for millions of years, among diverse groups of organisms, if fever did not have an adaptive function. One evolutionary explanation proposes that, fever may lead to a sacrifice of the host, if that individual poses a threat to the species as a whole. From this perspective, the febrile response might have evolved as a mechanism for facilitating the recovery of infected individuals with localized, or mild to moderate systemic infections, while simultaneously accelerating the

demise of hopelessly infected individuals, who pose an epidemic threat to the species.

Thermal Dysregulation

Because of the hypothalamus' importance in thermoregulation, injuries, tumors, genetic abnormalities, and its exposure to pyrogenic and other exogenous compounds may cause thermal dysregulation. Because the PO/AH can be influenced by factors besides temperature (e.g., glucose levels, testosterone, estrogen, and osmotic balance), dysfunctions in maintenance of these factors may be comorbid with thermal dysregulation. Furthermore, metabolic and physiologic conditions, such as hormonal imbalance and poor blood circulation, may contribute to abnormal body temperature.

Conclusion

To summarize, thermoregulation is a dynamic, homeostatic interaction between an organism's internal processes and its thermal environment. To maintain physiological stability, many organisms employ processes such as heat loss, retention, and production. These thermoregulatory mechanisms influence other aspects of life, such as sleep and circadian rhythms. Among mammals,

the hypothalamus (located deep within the brain) coordinates certain metabolic processes, regulates various autonomic nervous system activities, and synthesizes/secretes particular hormones critical to thermoregulation. Through thermal dysregulation and protective mechanisms like fever, we are reminded of thermoregulation's importance in maintaining life.

Glossary

Diffusion-weighted (magnetic resonance) imaging (DWI) – A technique that measures the diffusive motion of water molecules in biologic tissue. It is commonly used in clinical practice for early detection of cytotoxic edema due to ischemia (water moves from the less restricted extracellular environment to the more restricted intracellular one). This phenomenon results in reduced extracellular water motion (random displacement of the molecules), leading to an attenuation of analog-to-digital converter (ADC) signal and a hyperintensity on DWI sequences.

Episodic memory – A term introduced by Endel Tulving within the context of the fractionation of memory. It is the memory of personal events, as opposed to the memory of knowledge (semantic memory). Episodic memory makes mental time travel possible in the sense that it allows the reexperiencing of a situation. It is defined through three important clues: the sense of subjective time, autonoetic awareness, and self.

Lexical–semantic priming – A semantic paradigm allowing the assessment of semantic memory implicitly. The lexical–semantic priming effect is attested by a faster reaction time and/or greater accuracy when a target item (giraffe) is preceded by a semantically associated prime (zebra) rather than an unrelated one (table).

Wechsler Adult Intelligence Scale – An individually administered adult scale measuring general intelligence through 15 subtests dealing with both verbal and performance abilities.

Working memory – A limited-capacity and short-term memory system that temporarily stores information in view of its manipulation. According to Baddeley and Hitch's model, it is a multicomponent system comprising two slave systems (the phonological loop and the visuospatial sketchpad) devoted to the maintenance of verbal and visuospatial information, respectively, which are supervised by a coordinating system called the central executive.

Introduction

Among the variety of amnestic disturbances, transient global amnesia (TGA) remains one of the most enigmatic syndromes. Reasons for this may lie in the fact that TGA has a relatively low incidence (3–10 per 100 000 per year) and that it may have long been immersed in the psychiatric literature and once viewed as an atypical case of psychogenic/hysterical amnesia. In fact, its definition as a distinct entity is relatively recent, with its first descriptions appearing in 1956: Guyotat and Courjon reported 12 cases of *ictus amnésique idiopathique* in France, while Bender described the “syndrome of isolated episode of confusion with amnesia” in the US. Fisher and Adams subsequently published an account of 17 cases and discussed the possible etiologies. Although these authors were specific in their description, the diagnosis of TGA was still applied to a wide variety of clinical situations that only shared with TGA an acute and dense memory loss as their core feature, which resulted in persistent heterogeneity in the subsequent publications. It was not till 1990 that Hodges and Warlow established the following criteria, which are still unanimously accepted for the diagnosis of TGA:

1. attacks must be witnessed and information available from a capable observer who was present for the most part of the attack;
2. there must be clear-cut anterograde amnesia during the attack;
3. clouding of consciousness and loss of personal identity must be absent, and the cognitive impairment limited to amnesia (i.e., no aphasia, apraxia, etc.);
4. there should be no accompanying focal neurological symptoms or functionally relevant focal signs;
5. epileptic features must be absent;
6. attacks must resolve within 24 h; and
7. patients with recent head injury or known active epilepsy (i.e., remaining on medication or one seizure in past 2 years) are excluded.

From a group of 114 patients diagnosed with these criteria, Hodges and Warlow found that TGA most commonly occurs in middle-aged or elderly people (mean age 62.3, most patients between 50 and 80 years) and that amnesia lasts 4.2 h on average. Regarding the behavioral manifestations during the attack, Hodges and Warlow observed repetitive questioning, disorientation in time; they also noticed that a number of subjects were perplexed, anxious, or agitated. None had neurological symptoms, such as ataxia, limb weakness, or sensory disturbance, and all were able to perform complex tasks (e.g., driving a car). The only commonly noted nonfocal symptoms were headache, nausea/vomiting, and dizziness that might occur at any time from the onset of the attack. One conspicuous feature noted in their report is the frequent presence of precipitants of the attacks. In the previous 24 h, a number of subjects had faced an emotionally stressful event (e.g., learning that a close relative had cancer, witnessing a severe car accident, being involved in a gas cylinder fire, being told that a close friend had had a heart attack, attending the grave of a deceased spouse, or having a violent family argument), or experienced physical pain, or performed some physically straining action (e.g., having sexual intercourse, swimming in cold water, undergoing a medical procedure, or doing vigorous exercise). Hodges and Warlow concluded that TGA is a heterogeneous clinical syndrome and considered that there is little support for a cerebrovascular etiology in pure TGA defined according to their criteria. They also raised the role of physical and emotional stress in the etiology of TGA. Once Hodges and Warlow's criteria were fully accepted, TGA reports became more frequent with time and the nosological concept of TGA was better and better delineated. However, as the knowledge of the syndrome spread, questions initially tackled by Hodges and Warlow emerged. First, even though neuropsychological assessment of patients in the acute phase is difficult to carry out because of the suddenness and the short duration of the attack, TGA is an interesting model for testing the memory organization. This syndrome represents an interesting approach to understand the episodic memory disorders, especially in the light of the recent theoretical development of this concept. Second, although the psychopathological aspects have been reported in the first cases, they remain almost unexplored, highlighting the need for a comprehensive investigation. Third, the etiology of TGA is still unknown. These issues are successively discussed in the subsequent sections of this article.

Neuropsychology of TGA

TGA comprises, on the one hand, a massive anterograde amnesia that expresses itself chiefly by repetitive questioning, and, on the other hand, a variable retrograde amnesia that may extend back from a few hours to several months prior to the onset of the attack. Only a few group studies of patients examined during TGA have been published because TGA patients often access medical care only when the attack is already over. This fact may contribute to the heterogeneity of the findings. However, a general survey of the publications suggests that during a TGA attack some memory functions appear to be completely lost, while others are only partially lost or impaired and some others are preserved.

It must be stressed, in the first place, that TGA patients have no impairment of intelligence or of cognitive functions other than memory, such as attention, language, praxia, or visuoconstructive abilities. Speech is spontaneous, coherent, and fluent. Patients also correctly perform the copy of complex geometrical figures and score within the normal range at general intelligence tests such as the Wechsler Adult Intelligence Scale.

The leading feature of TGA is total anterograde amnesia and all observers agree that learning into episodic memory is completely suppressed, whatever the type of information (numbers, letters, faces, figures, objects, stories, paired associated lists, or spatial locations) format (verbal, visual, or tactile) or testing procedure (recall or recognition). The issue of whether anterograde amnesia in TGA is caused by encoding or storage impairment has stirred considerable interest and it seems that both patients with preferential storage disorders and those with preferential encoding deficits may be observed. This distinction may be closely related to the time of testing, that is, impaired encoding is more likely to be found in the early phase of the attack.

The next most important aspect of memory impairment during TGA is retrograde amnesia, which affects past memories to a variable extent, from days to months, sometimes even more. There is a gradient between recent and remote memories, with recent memories being more affected than remote ones. However, not only is there a gradient, but retrograde amnesia during TGA is also patchy in nature, depending on the type of memory involved. This is because, of all memories we have of the past, some pertain to the semantic system, while others still remain episodic in nature, being closely linked to episodes of our personal life. This may be sorted out through neuropsychological testing paradigms specifically designed to evaluate the episodic load of one particular remote memory. It has thus been demonstrated that the more episodic an ancient memory is, the higher the likelihood for it to

be missing or altered during TGA, while the semantic components are spared, so that in its retrograde as well as in its anterograde component, the amnesia of TGA mainly affects the episodic memory system. Retrograde amnesia completely recovers after the attack, and the patient is only left with a lacunar amnesia that covers most of the time of the episode.

Semantic memory includes conceptual knowledge (knowledge about common objects), knowledge of famous people and public events, and personal autobiographical knowledge. It has been mostly investigated during the acute phase of TGA through explicit tasks such as giving an object's name, definition, or category but seldom through implicit tasks assessing the lexical–semantic priming effects. Reduced verbal fluency has sometimes been observed, and ascribed to impaired retrieval strategies, but conceptual knowledge is spared. Regarding lexical–semantic priming, it has been shown that despite their absolute anterograde episodic amnesia, patients are still able to acquire new conceptual semantic information such as learning how to solve sentence puzzles during the very acute phase of TGA attack. The dissociation between sparing of semantic memory and episodic amnesia impairment is such that patients who have just learned how to solve sentences puzzles have no explicit memory of the learning phase that took place a few minutes before. Performances at tests assessing the knowledge of famous people and public events fall below the normal range. Errors affect exclusively the most recent knowledge and suggest difficulties in the retrieval process, as further supported by the better scores in recognition than in free recall tasks. Impairment in personal autobiographical knowledge also involves the most recent period of time rather than earlier memories, extending at most back to 1 year before the attack.

Procedural memory has been explored in two ways showing that, during the attack, patients were able (1) to remember already-learned procedures as complex as driving a car, conducting an orchestra, or even taxiing an airplane for takeoff, and (2) to learn new cognitive procedures, such as perceptual-verbal and perceptual-motor skills (e.g., Tower of Toronto, mirror reading, or copy of complex geometric figures). Similarly, long-term perceptual priming (as studied with word completion or fragmented-picture identification tasks) can occur during TGA.

Working memory consists of two slave systems, the phonological loop and the visuospatial sketchpad, and of a supervisory system called the 'central executive.' The slave systems function normally during the acute phase of TGA. The integrity of the central executive is still a matter of debate, but its impairment, if any, is probably limited.

Psychopathology of TGA

That TGA may be triggered by emotional stress and that patients display emotional changes during the attack has prompted the hypothesis that TGA could have some relationship to psychogenic amnesia. Regarding emotional triggers, however, they do not appear to bear any specificity, and they only stand among a number of other possible events that have long been known to be classical TGA triggers for TGA as well. Similarly, there is no evidence so far that emotionally triggered TGA attacks have a specific clinical profile as compared with the remaining cases. It seems clear, however, from group studies, that TGA patients who suffered the attack after an emotional precipitant have, more often than not, a personal history of anxiety. This may mean that, in such people, a stressful event is more likely to have physical consequences than in others, as is true for various psychosomatic diseases. As far as TGA is concerned, it is possible that the physiological disturbances resulting from the stress reaction impinge on the brain chemistry in such a way as to modify the concentration of one or another of the molecules involved in the metabolism of the limbic system. To date, however, the mechanism by which such interference might occur is still a matter of pure speculation.

The emotional changes that occur during the acute phase of TGA may be more relevant to the present discussion, because triggers, which may or may not exist, and which vary from one patient to another, occur in all patients. Again, anxiety is the core feature of these changes, with associated symptoms of depression sometimes, as demonstrated by examinations carried out during attacks by means of specific scales. The emotional state interferes with memory processes, and it is common knowledge that, for example, depression impairs episodic memory, or that emotional items are processed differently than neutral ones. The influence of the emotional state of patients upon memory scores during the acute phase of TGA has been demonstrated, and so has been the relationship between emotional changes during the attack and persistent subtle memory deficits that can sometimes still be observed the day after or even later. The amnesic syndrome of TGA, however, is nowhere near to those of psychogenic amnesia. Hysterical amnesia, for example, is primarily retrograde in nature, predominantly affects personal memories such as identity or significant autobiographical events of the past, and usually lasts from days to months; however, no such clinical profile has been shown so far to result from a demonstrable brain lesion or dysfunction. While hysterical conversion does occur in anxious and depressed subjects, the significance of behavioral and emotional changes in this setting is thus completely different from that of TGA patients.

Episodic memory is primarily dependent on the integrity of well-identified cerebral structures, located within the limbic system, which also supports the expression and experience of emotions. It is thus tempting to speculate that any dysfunction of this system severe enough to cause a total episodic amnesia could have some impact on the emotional state as well. Further, the repetitive and anxious questioning of patients about time during the acute phase, as well as the questions invariably asked the day after about what they may have done during the period of which they have no memory, may somehow reflect the feeling of losing their personal identity, insofar as it is episodic memory that supports the perception of someone's life continuity.

Pathophysiology of TGA

TGA is a completely transient disorder that leaves no trace except for a memory gap. To find (1) the nervous structure the dysfunction of which causes TGA, and (2) the cause and mechanism of this dysfunction, are thus particularly demanding tasks.

As far as the location of the brain dysfunction is concerned, there is growing evidence that this could be the hippocampal cortex. The hippocampus is located on the medial aspect of the temporal lobe, within the fifth temporal gyrus, and is a key element of the brain memory circuitry. Other parts of this circuitry (the so-called Papez loop) are equally important, but the clinical profile of TGA episodic amnesia is closer to that of amnesic syndromes resulting from hippocampal damage than to any other type of amnesia. Unfortunately, material evidence is still lacking. Conventional morphological brain imaging (computed tomography (CT) and 1.5-T magnetic resonance imaging (MRI)) are always normal in TGA, and the results of the few studies using functional imaging such as positron emission tomography (PET) or single-photon emission tomography (SPECT) have been too inconsistent to allow any definitive conclusion. Recent studies with 3T-MRI seem more promising in that small hippocampal hyperintensities on diffusion-weighted sequences have been found in some patients but their meaning is still uncertain.

When faced with a transient dysfunction of the central nervous system, the neurologist always thinks of either epilepsy or transient ischemia. None of these mechanisms is at work in TGA. Transient amnestic epilepsy does exist but its duration is shorter than that of TGA, and epilepsy is generally a chronic disease such that seizures recur frequently, which is not the case of TGA, although as many as 20% recurrence may exist.

Electroencephalographic tracings done during TGA attacks are usually normal. Regarding transient ischemia, it is more a matter of differential diagnosis. A few cases of

acute and transitory amnesia associated with stroke (mainly anterior thalamic ischemia or hemorrhage) but then the lesion is demonstrated by the CT or MRI examination. On epidemiological grounds, the only common factor between transient ischemic accidents (TIAs) and TGA is the age range of the patients. Otherwise, TGA patients share neither the vascular risk factors nor the poor vascular prognosis of TIA patients. Finally, unlike in TIAs, there is no such permanent purely episodic and isolated cerebral vascular syndrome that would be the stroke equivalent of TGA. Thus, while, on an individual basis, an episode of TGA may lead to the disclosure of hypertension or diabetes, there are no firm grounds to state that TGA is a transient ischemic cerebral syndrome.

The viewpoint that TGA may be triggered by vigorous exercise has led some authors to search for anatomical abnormalities that could predispose to TGA in case of increased intrathoracic pressure. Abnormally high incidences of patent foramen ovale and venous jugular incontinence were found in TGA patients versus control subjects, which might carry an increased risk of paradoxical cerebral embolism and venous cerebral ischemia, respectively. No evidence for either of these phenomena has been gathered to date and the significance of these findings should probably be reassessed. The time course, duration, reversibility, and the frequent occurrence of headache at sometime during or immediately after TGA have suggested that there could be some pathophysiological connection with migraine. A number of experts think that the migraine aura, which consists of reversible cerebral symptoms (paresthesiae, visual disturbances, and/or aphasia) that usually last from 15 to 60 min occurring before headache, is associated with cortical spreading depression (SD). This phenomenon has been described experimentally in animals and can be triggered by a variety of stimuli directly applied on the brain cortex (electrical, chemical, mechanical, etc.). It consists of a depolarizing wave that extends on the brain cortex and induces local electrical changes. While its relevance to human pathology is unknown, SD could account for acute, relatively lasting, and reversible phenomena such as those seen in the migraine aura or in TGA. To explain the clinical homogeneity of the TGA syndrome, it can be hypothesized that the same neuronal mechanism (SD) is at work in all cases during the attack. This, on the other hand, could be triggered by a variety of causes, either external such as physical or emotional stress, or individual such as cerebral circulatory disturbances, in combination with any possible predisposing physical or psychological factor. This would account for the apparent heterogeneity found in all studies of TGA patients, with such different subgroups as anxious people, migrainous individuals, and subjects with vascular risk factors of any type, as demonstrated recently in a large group study.

Glossary

- Cognitive control** – The organization of thoughts, behaviors, and emotions to achieve selected goals.
- Conflict** – The cognitive state that arises from competition between different behavioral options when only one option may be selected.
- Dorsolateral prefrontal cortex** – An area of the prefrontal cortex that comprises Brodmann's areas 9 and 46 and that subserves working memory and top-down attention.
- Response inhibition** – Inhibition of behavioral responses that are goal or task irrelevant.
- Self-regulation** – It encompasses cognitive control as well as the selection of goals and their interactions with current and learned parental, social, and cultural influences.
- Striatum** – The major input structure of the basal ganglia, consisting of the caudate nucleus and putamen. Portions of the striatum are important for the encoding of well-learned motor and cognitive tasks.
- Stroop Task** – Cognitive task in which each trial consists of a colored word. In congruent trials, the ink color is the same as the color that the word denotes. In incongruent trials, the ink color differs from the color that the word denotes. The subject's task is to name the ink color. The conflict inherent in incongruent trials causes participants to take longer to respond and make more errors on those trials than on congruent ones.
- Top-down attention** – Goal-driven selection of task-relevant stimuli or features that may not be the most salient and might, therefore, not be attended otherwise.
- Ventrolateral prefrontal cortex** – An area of the prefrontal cortex that comprises Brodmann's area 47 and that is important for response inhibition.

Introduction

Conflict arises from competition between different behavioral options when only one may be selected. Conflict is ubiquitous in everyday life, in that we are constantly pulled in multiple directions. On a given day, we may need to accomplish a task that others are depending on us to complete while we are simultaneously tempted by

more pleasing activities. We may have to finish a review for an employer or pay the bills when a friend calls with an invitation to watch a sporting event. Even choosing not to act may produce conflict, since it involves an assessment of the risks and benefits of not undertaking possible actions.

Appropriate resolution of conflict occurs when the choice among competing behavioral options offers the greatest overall benefit to the individual. Often, this requires the inhibition of automatic or immediately rewarding options in favor of nonautomatic, effortful options that are better aligned with the organism's long-range goals. This requires cognitive control – the goal-oriented organization of thoughts, behaviors, and emotions.

The concept of cognitive control poses the difficult questions of who is doing the controlling and why? Who is controlling the controller? These questions raise the age-old paradox of the homunculus pulling at the strings of thought and action. The paradox boils down to the problem of the origins of goal selection. Why do we choose to pursue certain goals rather than others? These choices are the products of the complex influences and interactions of individual, familial, societal, and cultural values, reinforcements, and other determinants. Cognitive control, in contrast, refers to the mechanisms supporting the coordination of thought and action to achieve given goals; the origin of the goals themselves is beyond the scope of cognitive control.

The term 'cognitive control' comes from cognitive psychology and cognitive neuroscience; a related term that is used in these and a variety of other disciplines is 'self-regulation'. The latter term is, sometimes, used with slightly different meanings across disciplines. For our purposes, the concept of self-regulation is related to, but broader than, that of cognitive control. Whereas cognitive control refers to a set of cognitive mechanisms that allow action to be aligned with internal goals, the concept of self-regulation also includes the origin of those goals and their interaction with current and learned parental, social, and cultural influences. Self-regulation often engages cognitive control mechanisms to achieve goals, but it also includes the broader context and choice of those goals. For example, self-regulation may include a set of internalized moral imperatives according to which an individual seeks to behave, and it may establish goals consistent with those moral imperatives. Cognitive

control can then be engaged to achieve those goals (e.g., a person may inhibit the impulse to buy an expensive material object so as to use the money instead to help a friend in need).

Self-regulation and cognitive control play a central role in normal mental and behavioral functioning, and its impairment is a central sign in many neuropsychiatric and behavioral disorders. We can consider the example of people who suffer from bipolar disorder (BD), who have great difficulty inhibiting their responses to behavioral options that offer immediate rewards, such as sex or spending sprees. At the same time, they may neglect longer-term goals that would produce more rewarding long-term gains, while they simultaneously incur many painful consequences of their impulsive behavior.

Attention in the Service of Cognitive Control

Attention allows an individual to resolve conflict by selecting task-relevant information and ignoring task-irrelevant information. This is best illustrated by a classic example from experimental psychology, the Stroop interference effect, named after its discoverer. Participants are asked to identify the ink color in which words are written. Conflict arises because the words also spell names of colors, which may or may not be the same as the ink color. Each trial consists of a single colored word. In congruent trials, the ink color is the same as the color that the word denotes. In incongruent (conflict) trials, the ink color differs from the color that the written word denotes. Participants take longer to respond and they make more errors on incongruent trials than on congruent

ones. This is one of the most robust and best-replicated findings in all of behavioral neuroscience.

Responding in incongruent trials is slow and prone to error because reading is a highly practiced, automatic task, whereas color naming is not. To name the ink color rather than read the word, participants must, therefore, inhibit the more automatic task in order to correctly perform the less automatic one. This requires the allocation of attentional resources and the resolution of the two competing behavioral tendencies, the naming of colors and word reading. Resolving these two tendencies requires more time to complete the task. Failure to boost activity appropriately in the neural pathways associated with color naming or to suppress activity in the neural pathways associated with word reading produces error, which nearly always is responding with the color that the conflicting word denotes. In contrast, when the ink color is the same as the color that the word denotes, the response tendencies for the two tasks are identical, and the task is much easier and less prone to error. In fact, the presence of a congruent word speeds the naming of the ink color, compared to the naming of the ink color of, for example, a colored patch.

One model of the Stroop task helps to explain how the human uses attention to boost activity in task-relevant neural pathways when faced with competing activation in task-irrelevant pathways. Several versions of this model have been developed over the years, but the basic mechanisms underlying all of them are similar. A typical version of the model is depicted in **Figure 1**. It includes a sensory input layer, an association layer, and a response layer – all of which are connected via feedforward connections. Separate units in the input layer represent the written text and the ink's color of a colored word. These

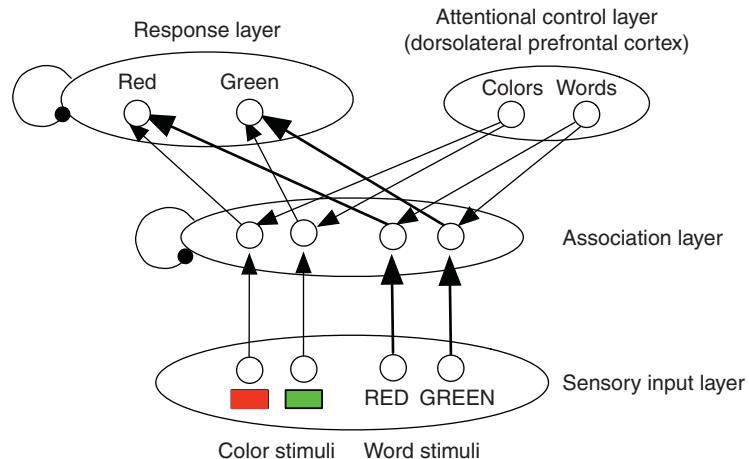

Figure 1 Connectionist model of the Stroop task. The model consists of three layers – sensory input, association, and response layers – that communicate through feedforward connections. Additionally, an attentional control layer provides top-down control to bias either the word-reading or the color-naming pathways. Layers are indicated by ovals; processing units within layers are indicated by circles. Connections between units are indicated by arrows. The width of the arrows represents the strength of the connections.

units project to corresponding units in the association layer, where lateral inhibition introduces competition between the units. Further competition occurs at the response level via lateral inhibition between the units that represent the possible responses. An attentional control layer, representing the dorsolateral prefrontal cortex (DLPFC), projects to the association layer. The role of the attentional control layer is to bias activation in the association layer in a task-relevant way. Such biases are often called ‘top-down’ influences on activity in the association layer, reflecting the common notion that the brain is organized hierarchically, with the DLPFC at the top of the hierarchy controlling activity in areas lower in the hierarchy, such as the posterior cortex and subcortex. We note that the validity of this hierarchical view of the brain is not essential to the validity of the connectionist model. All that is essential to the latter is the capacity to flexibly, but selectively, alter the strength of activity in one pathway compared with activity in another pathway according to task demands.

The strength of connections from one layer to another, indicated by the width of the arrows in **Figure 1**, reflects the degree of automaticity of the competing behavioral tendencies of word reading and color naming. Thus, connections are stronger for the word-reading than for the color-naming pathway. Incongruent stimuli will, therefore, activate the units in the word-reading pathway more strongly and, without top-down attentional control, will produce a response that denotes the written word. The attentional control layer, however, contains units that can provide top-down activation that can differentially boost activity in either the color-naming or the word-reading pathway. Appropriately activating the ‘colors’ unit in the attentional control layer increases responsivity of the color-naming pathway to support color naming, even for incongruent stimuli. Nevertheless, color naming is slower and more prone to errors when responding to incongruent than to congruent stimuli, because incongruent words interfere with the processing and naming of colors via the competitive dynamics present in the association and response layers.

A key question not addressed by the model is how the instructions to name the colors or read the words are translated into appropriate activations in the attentional control layer. This question is even more complicated if one generalizes the model to address the allocation of attention that is required to pursue dynamically changing goals as encountered in everyday life. How are goals translated into the appropriate patterns of activation in the attentional control layer? How are the appropriate connections from that layer to the associative layer formed?

Unfortunately, the model is not yet designed to address fully questions that extend beyond cognitive control and into the broader domain of self-regulation. To

perform appropriately in the Stroop task, for example, participants must have the goal of complying with the task instructions. But what is the origin of that goal? It likely is a product of complex interactions among the participant’s understanding of the desirability of certain types of behavior in given social or academic situations, the desire to perform well, or the motivation provided by external rewards, if available. While these processes of goal selection are taken for granted in most experimental situations, their influence is likely to be even greater, and their interactions more complex in real life. Undoubtedly, the appropriate allocation of attention or inhibition of task-irrelevant responses requires clear goals. In experimental settings, these goals often are clearly defined by the experimenter (but assuming that the participant wants to comply with task instructions). However, in real life, goals themselves are dynamic and often underdetermined. A key component of self-regulation is the ability to select goals consistent with one’s values. Future research on self-regulation should emphasize the process of goal selection, the relation between goals and learned values, and the origin of values themselves.

The degree to which a given task is automatic or requires effort is not fixed but, instead, can be changed by practice. The effects of practice and prior experience on the degree of automaticity of behavioral tendencies may reflect the strengthening of synapses from the input layer to the association layer, and from the association layer to the response layer for the relevant task. As the pathway corresponding to a given behavioral tendency is strengthened, execution of tasks that engage that behavior relies less on top-down control by the DLPFC. Evidence for this claim comes from the finding that activation of the DLPFC decreases with additional training in given tasks.

The prefrontal cortex and basal ganglia are intimately interconnected in cortico-striato-thalamo-cortical (CSTC) loops. At least five such loops have been identified, each involving projections to and from different cortical areas. With extensive training, activity during performance of motor-planning tasks shifts from the CSTC loop that involves the DLPFC to the CSTC loop that involves sensory and motor cortices. Behavioral tendencies that are more controlled and effortful on the one extreme, therefore, lie along a continuum with more automatic behavioral tendencies on the other extreme, with the degree of control and automaticity changing along this continuum as a consequence of prior experience and practice.

Neural Monitoring of Conflict

Discerning the nature of conflicting behavioral tendencies and detecting when they occur is essential to the appropriate resolution of conflict. Conflict can occur when the

processing of two or more stimuli competes or when a response must be selected from among two or more competing behavioral responses. Considerable experimental evidence suggests that the ACC (Brodmann's Area 24) is the neural locus for detecting conflict both at the level of stimulus processing and at the level of response.

The ACC can help to resolve detected conflict only if it signals the presence of the conflict to a neural system, such as the DLPFC, that can then appropriately deploy the attentional resources and control required to resolve the conflict that accompanies the simultaneous presence of conflicting stimulus processing or response tendencies, as occurs in the Stroop effect. The ACC and DLPFC, therefore, cooperate by detecting conflict within the ACC and then deploying the cognitive control systems within the DLPFC that are required for correct, goal-directed responding.

The ACC also seems to participate in detecting the occurrence of errors in responding. Studies using event-related potentials (ERPs), for example, have established firmly that the so-called 'Error Related Negativity,' a peak deflection over the ACC, occurs approximately 100 ms following an erroneous response. Multiple functional magnetic resonance imaging (fMRI) studies also report activity in the ACC following errors. These findings are consistent with those from studies using single-unit recordings in monkeys, which show that increases in activity of ACC neurons signal error when monkeys fail to inhibit a planned, task-guided saccade. The seemingly different conflict-detecting and error-detecting activities of the ACC can potentially be reconciled by considering the detection of errors as a form of conflict, one in which a person recognizes that the actual, erroneous response differs from (and, therefore, conflicts with) the correct response.

Similar to conflict in the Stroop task, which we might designate 'cognitive conflict,' 'emotional conflict' arises when an emotionally salient stimulus competes with task demands. Conflict in the classical color-naming Stroop task activates the dorsal division of the ACC. In the emotional Stroop task – in which conflict is produced by the presentation of words with emotional valence (e.g., 'murder') – conflict, instead, activates the ventral, or affective, division of the ACC. The dorsal and ventral ACC exhibit opposite patterns of activation, with the ventral ACC decreasing and the dorsal ACC increasing activity during cognitive conflict, whereas the dorsal ACC decreases and the ventral ACC increases activity during emotional conflict.

Neural Mechanisms of Control

The DLPFC uses top-down attention to enhance processing along task-relevant neural pathways. Top-down attentional processes should be distinguished from

bottom-up ones. Bottom-up attention is a consequence of the salience of stimulus features (e.g., loud noises) that automatically attract attention. Top-down attention, in contrast, involves the goal-driven selection of task-relevant stimuli or features that may not be the most salient and, thus, would not necessarily be attended using only the bottom-up mechanism. In the connectionist model of the Stroop Task, bottom-up processing is reflected in the strength of connections between the input, association, and response layers. Top-down processing is modeled by the top-down influences of the attentional control layer onto the association layer. In the Stroop task, when naming colors, participants use top-down processing to attend to colors and to override the bottom-up tendency to attend to and read words.

Top-down attention functions similarly irrespective of whether salience is determined by static stimulus features or by the frequency of stimulus presentation. Stimuli that are presented in an unpredictable, oddball fashion have greater salience and are thus more prone to capture attention. If such oddball stimuli are behaviorally irrelevant, greater top-down attentional control must be used to inhibit their processing.

The top-down attentional control exercised by the DLPFC is flexible and can change in the context of changing task goals, task demands, or motivational states. This contrasts with a habit-learning system that is based within the dorsal striatum and that guides action selection via previously learned stimulus-response (S-R) associations. One theory suggests that the prefrontal and dorsal striatal systems balance their control over behavior according to Bayesian principles, such that each system guides behavior when it is likely to be the most accurate of the two (i.e., when the uncertainty associated with its predictions is smaller than that associated with the other system's predictions).

Response Inhibition

In addition to the deployment of attention for selective stimulus processing, cognitive control depends on the inhibition of goal- or task-irrelevant responses. Appropriate development of response inhibition is also critically important for normal development, and impaired maturation of this cognitive ability may produce or predispose to disorders of impulse control. The prefrontal cortex is fundamental for response inhibition, just as it is for attention, consistent with the idea that the prefrontal cortex exerts top-down control over other brain regions and circuits. Top-down control is precisely the type of mechanism necessary to inhibit prepotent responses and responses that have already been initiated. The specific portions of the prefrontal cortex that are involved in response inhibition differ, however, from

those that have been implicated in attentional facilitation. Whereas attention relies largely on the DLPFC (and related, interconnected portions of parietal cortex), response inhibition appears to rely instead on the ventrolateral prefrontal cortex (VLPFC). Different areas of prefrontal cortex seem, therefore, to be specialized for different cognitive control functions.

Response inhibition is often studied using the Go/No-Go task. The participant must perform an action, such as pressing a button, when a given stimulus is presented ('Go' trials), and refrain from performing the action when a different stimulus is presented ('No-Go' trials). If Go trials are much more frequent than No-Go trials, the participant has difficulty inhibiting the response on No-Go trials, producing a higher error rate on the No-Go trials.

Another task commonly used to study response inhibition is the Stop-Signal Reaction Time (SSRT) task. In this task, participants perform a speeded response to a stimulus. On some trials, however, that stimulus is followed after a brief delay by a stop signal indicating that the response should not be performed. This task permits estimation of the SSRT, a measure of the time required to suppress a response. The greater this measure, the greater the difficulty in inhibiting a behavioral response. Many functional imaging studies show activation of the VLPFC in Go/No-Go and SSRT tasks, and lesion studies have shown that the extent of damage in the right VLPFC correlates with the SSRT, providing direct evidence for a causal role of the VLPFC in inhibiting the behavioral response during the SSRT task. Damage in other areas of the prefrontal cortex does not correlate with the SSRT, suggesting that response inhibition may depend primarily on VLPFC and not on other areas of prefrontal cortex. The prefrontal cortex and basal ganglia, moreover, seem to subserve distinct aspects of response selection and inhibition, with the striatum subserving the lower-order translation of stimuli to behavioral responses and the VLPFC and DLPFC subserving adaptation to changing task rules. Finally, backward-masking procedures used in conjunction with electrophysiological recordings have shown that inhibitory cues can be processed similarly with or without conscious awareness, and therefore the 'higher' cognitive process of behavioral inhibition can be influenced by stimuli that are outside of awareness.

Response inhibition seems to mature to a greater degree (i.e., it changes over a larger range of values) than does selective attention from childhood to adulthood. Performance differences on a Go/No-Go task are greater than performance differences on tasks of attentional control when measures of performance in young children are compared with performance measures on the same tasks in adults. Moreover, the difference in frontostriatal blood-oxygenation-level-dependent (BOLD) activation between young children and adults is greater for tasks requiring response inhibition than for tasks requiring selective

attention. The development of response inhibition may, therefore, be even more important than that of selective attention for behavioral control and the successful transition from childhood and adolescence into adulthood.

Impaired Control and Psychopathology

Impairments in attention or inhibitory control have been implicated in a wide variety of disorders, including attention-deficit/hyperactivity disorder, anorexia nervosa, bulimia nervosa, obsessive-compulsive disorder, and schizophrenia. In this article, we focus on the evidence for impaired cognitive control in BD as an example of the relevance of control to the understanding of psychopathological processes. A similar approach has been used for several other disorders.

BD is a chronic, but treatable, disorder of affect, thought, and behavior that produces long-term interpersonal and functional disability. *The Diagnostic and Statistical Manual*, Version IV (DSM-IV) defines BD by the history of at least one manic episode, defined as elevated mood and energy that lasts for at least a 2-week period. In addition, patients with BD often have periods of depression, with low mood, low energy, and loss of interest in people and activities that were previously enjoyable. Sufferers of BD have difficulty controlling their behaviors, thoughts, and emotions. They engage in impulsive behavior (e.g., spending sprees); they often have racing thoughts when in a manic state and difficulty controlling ruminations about negative experiences when in a depressed state; and they are emotionally labile, unable to control their emotions, which can change quickly over a large range, from profound sadness to excited elation. These symptoms suggest an impaired ability to exercise cognitive control of behaviors and thoughts as traditionally defined, as well as difficulty with the cognitive control of emotion, which sometimes is termed 'emotional regulation.'

Consistent with a putative deficit in cognitive control, patients with BD exhibit anatomical and functional abnormalities in brain regions and circuits that subserve cognitive control, including the ACC, DLPFC, and VLPFC. Persons with BD, for example, have reduced ACC and DLPFC activity compared with healthy controls while performing the Stroop task. Activity of the VLPFC is also lower in patients with BD who are in the euthymic state as they make erroneous, impulsive responses on the Go/No-Go task, suggesting that a trait deficit in top-down prefrontal control may underlie a behavioral tendency toward impulsivity in these people.

In addition to these deficits in cognitive control as traditionally defined, persons with BD are also reported to have anatomical and functional abnormalities in brain regions such as the orbitofrontal cortex and the ventral

portion of the medial wall, that have been implicated in emotional regulation. In addition, prefrontal control of affective state seems to be impaired in persons with BD, reflected in hypoactivation of the subgenual prefrontal cortex (Brodmann's Area 25), during depressive episodes. The abnormalities in prefrontal BOLD activation seen during depressed and manic episodes are generally hemisphere- and state-specific, with left prefrontal reductions reported during depressive states and right prefrontal reductions reported during mania.

Conclusion

The constructs of self-regulation and cognitive control that we have reviewed are useful in understanding both normal function and psychopathological processes. We have outlined self-regulation at several levels. First, we illustrated the differences between behaviors that are automatic and those that require effortful control. Second, we defined the central concept of conflict as it relates to the need for self-regulation and control, and we reviewed how the brain is thought to detect conflict and resolve it by appropriately deploying cognitive control. Third, we reviewed the role of response inhibition in the control of behavior. Finally, we have exemplified the usefulness of these concepts to understanding psychopathological processes through discussion of what are believed to be core deficits in self-regulatory control in persons with BD.

Conscious and the Unconscious

Glossary

Continuous flash suppression – A method discovered by Tsuchiya and Koch for making visual stimuli subliminal. When a static stimulus is presented to one eye and a stream of rapidly changing images to the other eye, the static stimulus is consciously suppressed but still processed. Unlike pattern masking, continuous flash suppression allows conscious and unconscious stimuli to be presented for the same period of time (e.g., >1 s).

Event-related cortical potential (ERP) – An electric potential recorded from the scalp by an electroencephalogram in which the trace has been time-locked to the occurrence of a stimulus and noise-reduced by averaging over many trials. Characteristic negative-going and positive-going changes in voltage occur over the several hundred milliseconds following a stimulus onset that can, in principle, indicate the nature of the processing at different times. For example, it has been shown that a positive change in voltage at around 300 ms (the P300), associated with attention and memory processing, can be elicited by stimuli the person is not conscious of.

Implicit learning – Ability to acquire knowledge that is unconscious. For example, we can use the rules of grammar to comprehend and produce grammatical utterances within a fraction of a second, yet we cannot describe more than a few rules of grammar. We can also learn to appreciate certain styles of music, to obey cultural rules, or to gain perceptual motor mastery of a domain without consciously knowing the underlying regularities.

Implicit memory – The influence of a past event, on current behavior and judgments without being able to recollect the prior event. For example, people with anterograde amnesia, due to damage to the hippocampus and temporal lobes, are unable to form new biographical memories yet can be influenced by new events. If shown a list of words, they may not recall seeing the words, yet when given the starting letters of the words they will be more likely to complete the letter stems as the words because of having seen the list of words. Implicit memory is different from implicit learning in that implicit memory need not involve acquiring any unconscious knowledge: completing letter stems as a word involves only knowledge of which the person is conscious (*viz.*, the spelling of the word). In this case,

there are no unconscious contents, but implicit memory is often called unconscious memory because it is a form of memory – broadly construed – that the person is not conscious of as memory.

Pattern masking – One of the most common laboratory techniques for producing subliminal perception. The mask consists of jumbled parts of the target stimulus. If the mask occurs just before (forward masking) or just after (backward masking) the target, with the difference in stimulus onsets being on the order of 10–100 ms, an otherwise consciously reportable briefly flashed target is rendered subliminal. The mask is just as effective if presented to a different eye from the target, indicating the mask interrupts processing at a central level.

Signal detection theory (SDT) – It allows the experimenter to distinguish ‘discriminability’ and ‘bias’: discriminability is the ability of a subject to discriminate the presence versus the absence of a stimulus, and bias is the tendency of the subject to say ‘present’ rather than ‘absent.’ Imagine a light is shown very briefly on half of trials and the subject has to say ‘yes’ or ‘no’ in each trial. Subjects may be biased to say ‘no’ a large or small proportion of the time without their underlying perceptual ability to discriminate changing. In SDT, discriminability depends on the distance apart from the distribution of neural activation for when the stimulus is present and for when it is absent; the bias to say ‘yes’ depends on whether the criterion amount of neural activation above which ‘yes’ is said is low or high. With a strict criterion, a person may say ‘no’ almost all the time when a stimulus is presented and still have a high ability to discriminate.

Subliminal perception – The influences on thoughts, feelings, or actions of stimuli that affect neural activity but are not consciously reported. Unlike implicit learning, subliminal perception need not involve changes in the pattern of synaptic connections.

One of the most fundamental problems facing psychology and neuroscience is the nature of consciousness. In this article, we sketch a variety of broad theoretical positions, describe a range of behavioral and neurophysiological measures of consciousness in the context of these theories, and review key findings concerning the existence and nature of unconscious perception and

learning. Finally, we consider possible functions of consciousness.

Theories of Consciousness

Worldly Discrimination Theory

According to worldly discrimination theory (WDT), the content directly expressed in any behavior (e.g., pointing to where a dog is) is the content of a conscious mental state (e.g., consciously knowing “There is the dog”). Thus, a person shows that s/he is consciously aware of a feature in the world when s/he can discriminate it with choice behavior. This theory often makes use of signal detection theory (SDT), a statistical framework for quantifying the discriminability of a stimulus. SDT itself is mute on the subject of consciousness, and can thus be combined with different theories. The combination of SDT with WDT asserts that continuous information available for discriminations is necessarily the content of conscious mental states. That is, if over many trials a person can reliably indicate that a certain stimulus was present or not (to any degree above chance), then the information allowing that discrimination must be conscious, on WDT. This theory captures one property of conscious knowledge, namely that it allows choice behavior. However, rightly or wrongly, it does not respect other properties associated with consciousness. Consider blindsight patients, who have damage to the primary visual area in the cortex, V1. In the ‘blind’ part of their visual field they can make some discriminations very accurately; for example, whether an object is moving up or down. According to WDT, blindsight patients see movement consciously because forced-choice discrimination is the result by which we infer they see at all. However, two properties of blindsight suggest intuitively that the seeing is not conscious, and indeed are the reason why their ‘sight’ is called ‘blind.’ First, blindsight patients do not spontaneously attempt to use the information practically or inferentially. If they are thirsty, a glass of water in their blind field is not drunk. Second, blindsight patients themselves think they do not see. Indeed, they may insist that the attempt to discriminate shapes, motions, or sizes of objects in their blind field is nonsensical and they can offer only pure guesses. Other theories have tried to locate a divide between conscious and unconscious processes that respect one or both of these intuitions.

Integration Theories

According to integration theories, conscious contents are widely available to many cognitive and/or neural processes. This core idea has been variously expressed as, for example, fame in the brain, broadcast within a

global workspace (an idea made popular by Bernard Baars), activity within a ‘dynamic core,’ or integrated information (as elaborated respectively by Gerald Edelman and Giulio Tononi). The intuition offered by Edelman and Tononi is that, on the one hand, consciousness cannot arise in a system only making a simple discrimination similar to a thermostat: our conscious experience seems to always involve making many discriminations at once. On the other hand, consciousness cannot arise in a system merely making a set of independent discriminations similar to a photographic plate: our conscious experience seems interconnected, integrated, and unified. According to dynamic core and integrated information theories, a mental state is conscious if it provides a sufficiently informative discrimination among a large repertoire of possible states, where successful discrimination requires both differentiation and integration.

Higher-Order Thought Theories

According to higher-order thought (HOT) theories, a mental state is conscious when we are aware of being in that state, a view pursued by David Rosenthal and Peter Carruthers among others. Accordingly, it would be odd to say that a mental state is conscious yet, the person is not aware of being in that state. HOT theories differ from WDT in that it is the ability to tell the mental state one is in, rather than what state the world is in, that determines whether a mental state is conscious. In the context of SDT, HOT theory is associated either with the criterion of standard SDT, or with the second level of discrimination: discriminating not the world (as in WDT), but the accuracy of one’s responses (i.e., whether responses reflect knowledge or guessing).

The above theories, excepting some neural integration theories, describe conditions for asserting whether or not a particular mental state is conscious. They do not generally pertain to whether an organism is conscious or unconscious. These are scientifically different problems as, for example, a person who is unconscious (e.g., in a coma or dreaming) can have conscious mental states (as suggested by functional magnetic resonance imaging (fMRI) scans of some coma patients asked to imagine different activities: relevantly different parts of the brain become active). As we will see, measures of consciousness can and do address the conscious status of both mental states and individuals.

There is no consensus about which of the above theories best captures intuitions concerning consciousness, which is best supported by evidence, or which should be exclusively adopted in scientific research. Consequently, for current purposes we will treat the measures motivated by each theory as picking out a separate aspect of consciousness or mental life, of interest in its own right. Thus,

the behavioral ability to discriminate a feature in the world can be taken to indicate that a person is, in a very weak sense, conscious of that feature. Saying this much makes a less strong assumption than WDT; one can assume that a person can be (in a very weak sense) conscious of a feature without assuming that they are conscious of it with a conscious mental state. For example, a person with blindsight sees – and is therefore in that sense conscious of – an object moving up, even though the seeing is not conscious. For HOT theory, it is only if the person is aware of seeing that the seeing is a conscious mental state. Some philosophers disagree with this assumption; they prefer to say higher-order thoughts allow introspective or reflective consciousness but are not needed for mental states to be simply conscious. There is no need to quibble over words; clearly, the distinction between those perceptual or learning processes that allow awareness of knowledge and those that do not is interesting, whatever terms one uses (conscious vs. reflectively conscious, etc.). A conscious mental state also may or may not be inseparable from the global availability of the content of the state. However, the availability of information – for example, to figure in intentional control of one's actions – and the fine balance between differentiation and integration, are surely key features of our conscious mental life, regardless of whether one thinks they constitute conscious awareness. The degree of informational differentiation and integration may well be related to the level of consciousness of an individual. In fact, it will help consider a tripartite distinction (adapted from David Rosenthal) of being conscious of the world, being conscious of a mental state, and simply being conscious to some degree.

Behavioral Measures and Findings

Objective Measures

Objective measures refer to the ability to choose accurately under forced choice conditions. If one presupposes WDT, then such ability indicates a conscious mental state; with less strong assumptions, such ability simply indicates that one is conscious of the state of affairs discriminated. Conversely, knowledge is unconscious if a distinction in the world expresses itself only in nonintentional characteristics of behavior (such as its speed), or in physiological characteristics not expressed in behavior at all (e.g., galvanic skin response – how sweaty the person is; or brain activity as revealed by fMRI), or indirectly in other behaviors with related but different contents.

When objective measures indicate that people are not conscious of a masked visual stimulus, such as a word or a number, the impact of that stimulus on behavior and brain is greatly diminished compared to the effects of clearly visible stimuli. Nonetheless, some influences of the

masked stimulus persist. Greenwald and his colleagues have shown that when people are not conscious of masked flashed numbers (presented for 33 ms), the size of the number influences the speed of a subsequent judgment of a consciously presented number: semantic characteristics of the subliminal number are partially accessed, even if semantic access is generally diminished when a person is not conscious of a stimulus. Dehaene and colleagues have shown that when people are not conscious of masked words, nonetheless local field potentials, as revealed by implanted electrodes in the amygdala (part of the brain responsible for emotional perception), distinguish threatening from nonthreatening words. Similarly, when people are not conscious of an image of a naked body, nonetheless spatial attention is drawn to the image location. Skeptics worry that these and similar results may be due to the subject being conscious of the stimuli to a small degree: the inevitable noisy estimate of discriminability never allows knowing when discriminability is exactly zero. In any case, one can conclude that stimuli that one is at most minimally conscious of, can influence reaction times, brain activation, and other physiological measures.

Strategic Control

Strategic control determines the conscious status of knowledge by the person's ability to deliberately use or not use the knowledge according to instructions. In Larry Jacoby's process dissociation procedure, a person tries to avoid using the information (exclusion task) or make sure they do use it (inclusion task); any difference in influence of the stimulus between these conditions is taken to indicate conscious knowledge, and any use of it despite intentions in the exclusion condition is taken to indicate unconscious knowledge. This measure can be motivated by integration theories: the ready availability of information to inference and intentions shows its conscious nature on such theories. On higher-order theories, by contrast, there is no incompatibility between control and the relevant mental states being unconscious (e.g., as in hypnosis, where people can engage in strategic behavior without awareness of their strategies).

People flashed words can be asked to complete word stems either (1) with the flashed word (inclusion instructions) or (2) making sure it is not the flashed word (exclusion instructions). If the word is flashed quickly enough (about 50 ms), then people will complete the stem with the word at above baseline levels even when told not to (i.e., while under exclusion instructions). Although people use the word under inclusion instructions (so they are conscious of the word in a weak sense), they cannot use the information that the word was present in their intentions, as revealed by their inability to exclude the word (thus, there is poor integration of the information with mental activities generally). Similarly,

when words are presented to people under general anesthesia, in the next few days people have a tendency to reproduce the words to word stems even when told to avoid any words they think they heard under anesthesia.

People can gradually acquire knowledge of the structure of an environment (by implicit learning) in such a way that the knowledge does not allow strategic control. For example, in the serial reaction time (SRT) task, used by Axel Cleeremans and others, people have to press one of four buttons depending on whether an 'X' appears in one of four corresponding locations. Unbeknownst to people, there is a predictable sequence of locations. Consequently, people become faster and faster at pressing the buttons. People are subsequently told about the existence of the sequence, and asked to produce a sequence that was not the one they had just been exposed to (exclusion instructions). If the training sequence is not highly predictable and is presented quickly, people cannot help but tend to produce the training sequence in exclusion, that is, even when trying to avoid it.

Subjective Measures

Subjective measures test whether people are aware of the mental states they are in. When a person successfully makes a series of discriminations about the world, to test for awareness of knowing, confidence ratings can be given on each trial. If, on all the trials, when the person says 'guess' nonetheless the discrimination performance is above baseline, then there is evidence that the person has knowledge about the world that they do, not know have: unconscious knowledge according to higher order theories (the guessing criterion). Further, if a person is aware of when they know and when they are just guessing, there should be a relation between confidence and accuracy. Thus, no relation between confidence and accuracy is another indication of unconscious knowledge according to higher-order theories (the zero-correlation criterion). Sometimes methodologically weaker forms of subjective measures are used, for example, only after a block of trials or a whole experiment are people asked to report if they saw anything or knew about a relation.

Right from the very beginning of research into subliminal perception in the nineteenth century, subjective measures were used. The fact that people can be substantially above chance in perceptual judgments (e.g., about what words were displayed) when believing they are just guessing is a robust phenomenon. Such stimuli can produce widespread brain activations and strong effects on choice behavior. Further, flashing unusual shapes that people are not aware of seeing can make people like those shapes more in the future, a phenomenon called 'the mere exposure effect.' Flashing brand names of a thirst-quenching drink can dispose people to choose that brand if they are thirsty. When people are not aware of

seeing stimuli, the stimuli can have further intriguing effects. For example, flashing images of very intelligent people can reduce self-esteem; flashing images of clowns or unattractive people can increase self-esteem. Complicated masking procedures are not necessary to interfere with awareness of seeing; unattended words can influence people who think they did not see any words (so-called inattentional blindness). In contrast to these positive effects, there is no evidence that commercially available subliminal self-help tapes have any effect beyond placebo on study effectiveness, memory ability, or self-esteem.

Various types of brain damage interfere with awareness of seeing. People with blindsight can discriminate shape, size, orientation, and even the emotional expression of faces without being aware of seeing, though processing the meaning of words is limited. People with visual neglect (typically with damage to the right inferior parietal lobe) are often not aware of seeing stimuli in the left side of space. Nonetheless, even the meaning of such stimuli can facilitate processing stimuli on the right-hand side of space for these people.

People can gradually acquire knowledge of the structure of a domain (implicit learning) without being aware of their knowledge. Arthur Reber asked people to memorize strings of letters made by an artificial grammar. When people were subsequently informed about the existence of a grammar, they could classify new strings as obeying the grammar or not without being able to say what the rules were. Indeed, people can classify above chance when they believe that they are literally guessing or using nothing but intuition.

A possible weakness of subjective measures arises when the terms on the scale used are not well defined to people. The term 'guessing' can mean simply "I am not very sure" in everyday life: having knowledge without being absolutely certain does not entail the person is unaware of the knowledge. Nonetheless, in the case of artificial grammar learning at least, people can classify above baseline even when they would bet on a random event such as a coin toss rather than on their own classification decision. In sum, people can have knowledge even when they sincerely believe they do not.

Thus far, the measures have dealt with whether or not a person is conscious of either an event or a mental state (conscious contents). Next we consider some measures that can also bear on the conscious level of an individual.

Brain Measures

EEG Measures

In 1929, Hans Berger discovered that waking consciousness is associated with low-amplitude, irregular electroencephalographic (EEG) activity in the 20–70 Hz range and it

is now known that unconscious conditions such as non-dreaming deep sleep, coma, general anesthesia, and epileptic absence seizures show predominantly low-frequency, regular, and high-amplitude oscillations. Event-related cortical potentials (ERPs) have been used to assess whether a stimulus is consciously perceived or not, though there is dispute about whether early components are most indicative of conscious awareness (i.e., amplitude changes ~ 100 ms vs. ~ 300 ms after stimulus onset). Such ERPs are also associated with other functions beyond consciousness *per se*, for example, in novelty detection, so are unlikely to serve as pure consciousness indices. The proprietary ‘bispectral index’ combines various aspects of the EEG signal to estimate anesthetic depth (conscious level) and hence, probability of accidental waking during surgery. EEG measures of consciousness float free of theory, only gaining purchase through attempted reliable correlations with one or more of the behavioral measures above.

Neural Correlates

A useful way of addressing experimentally the distinction between conscious and unconscious processing is via the influential notion of a ‘neural correlate,’ which refers to patterns of activity in brain regions or groups of neurons that have privileged status in the generation of conscious experience. For example, Stanislas Dehaene and colleagues have shown using fMRI that consciously perceived words evoke widespread cortical activity as compared to equivalent masked stimuli the subject is not conscious of, which evoke only local activity. This evidence is congruent with integration theories such as global workspace theory, though other evidence suggests that being conscious versus unconscious of a mental state may involve a difference in activation only in a small area: the mid-dorsolateral prefrontal cortex. Another ongoing controversy is whether synchronized neural activity, for example, in the so-called ‘gamma’ band (~ 20 – 50 Hz) and especially around 40 Hz, constitutes a dynamical correlate of consciousness; the intuition here is that neural synchrony may account for the ‘binding’ of contents within integrated conscious scenes.

In addition to investigating the neural correlates of conscious contents (of the world or of mental states), it is also possible to examine the neural correlates underlying the conscious level of an individual. Here, ample evidence indicates that normal consciousness is specifically associated with thalamus and cortex. Regions such as the hippocampal system and cerebellum can be damaged without a loss of consciousness *per se*; indeed, in cases such as Rasmussen encephalitis, an entire cortical hemisphere can be surgically removed without loss of consciousness (though not without other effects). Whereas highly localized cortical damage can delete specific conscious contents such as color, shape, and motion, damage to

certain thalamic nuclei or to brainstem regions such as the reticular formation can abolish consciousness permanently. Finally, brain imaging evidence (pioneered by Steven Laureys) has shown that even in apparently unconscious conditions such as the ‘persistent vegetative state,’ stimuli can evoke significant though not widespread cortical responses, as compared to healthy controls. Such imaging studies provide a much needed fine-grained means of diagnosing disturbances of conscious level and establishing recovery potential of brain trauma patients.

Neural Complexity

Several recent measures build on the observation that conscious scenes are distinguished by being simultaneously integrated (each conscious scene is experienced ‘all of a piece’) and differentiated (each conscious scene is composed of many distinguishable components and is therefore different from every other conscious scene). The ‘dynamic core hypothesis’ (DCH) of Gerald Edelman and Giulio Tononi proposes that consciousness arises from neural dynamics in the thalamocortical system with just these features, as measured by the quantity ‘neural complexity’ (C_N). C_N is an information-theoretic measure that is high if each subset of a neural system can take on many different states and if these states make a difference to the rest of the system. The ‘information integration theory of consciousness’ (IITC; proposed by Tononi a few years after the DCH) shares with the DCH the idea that conscious experiences provide informative discriminations among a vast repertoire of possible experiences. In the IITC, the quantity Φ is defined as the ‘information integrated’ across the informational ‘weakest link’ of a system. Importantly, Φ is a measure of the capacity of a neural system to integrate information, whereas C_N is a measure of the actual dynamics of the system. A third measure, ‘causal density,’ measures the fraction of causal interactions among elements of a system that are causally significant; it is low both for highly integrated systems and for collections of independent elements. While complexity measures such as these cannot yet be applied to interactions between all sets of neurons in a whole brain, they can be applied to the summaries of neural activity at multiple sites as provided by, for example, EEG or fMRI. Work employing and developing these measures has only just begun.

The Function of Consciousness

The different theories of consciousness imply different functions. According to WDT, consciousness allows behavioral discrimination in the world; yet, WDT begs the question of why consciousness is required: intuitively

most people accept that automata without consciousness can make discriminations. Integration theory offers clear functions, depending on the theory, to do with flexibility or dealing with novelty. Higher-order theories need to locate the function of consciousness not in the powers of any mental state about the world, but in what can be gained by being aware of such mental states.

Functions for consciousness are easy to suggest though hard to establish. It has been suggested that consciousness allows flexibility, intentional action, or ability to deal with novelty. Yet hypnotizable people can engage in novel intentional actions without being aware of their intentions. For example, they can 'forget' the number 4, counting '1, 2, 3, 5, ...', flexibly overcoming habit, without being aware of any intention or mental state containing the content 'four.' It has been suggested that consciousness allows rationality, yet at least sometimes its reasoning function is only *post hoc*, as revealed by 'choice blindness': people are asked to select the most attractive of two faces and then to describe why they made each selection. On some trials the pictures were switched by sleight of hand immediately after a choice was made; subjects often failed to detect the switch but nevertheless offered a plausible account why they chose a particular face. Indeed, it has been shown that sometimes deliberating on a complex choice leads to worse decisions than being distracted by another task. It has been suggested that consciousness of our own mental states allows us to be conscious of others' mental states, allowing more sophisticated social interactions. Yet we can be affected by the emotion of a face without being conscious of it. Finally, it has been suggested that our rich consciousness of our mental lives arose from sexual selection: it arose

precisely because, similar to the peacock's tail, it is costly yet pointless.

Disorders of Face Processing

E J Barbeau, Université de Toulouse, Toulouse, France

S Joubert, Université de Montréal, Montréal, QC, Canada

Glossary

Capgras syndrome – A disorder in which the patient has the feeling that an impostor has stolen the face and the appearance of a close acquaintance, usually the spouse. This syndrome can sometimes also apply to other objects than faces.

Configural processing – Different types of configural processing are distinguished in the literature on faces. The ability to detect two eyes above a nose and a mouth is called ‘first-order configural processing.’ Holistic configural processing is related to the ability to build a gestalt out of the face elements, with the idea that the whole is more than the parts. Second-order processing is related to the processing of the distance between these elements.

Metamorphopsia – A disorder in which faces or other objects appear distorted.

Person agnosia – A disorder in which patients have a loss of semantic knowledge about people. Consequently, people cannot be recognized through any modality (such as face, voice, or name).

Prosopagnosia – A visual disorder in which familiar faces are not recognized anymore. In the pure form of this disorder, other objects such as tools and animals are recognized normally.

Prosopamnesia – An impaired learning of new faces encountered after brain lesion. In contrast, processing of faces learned premorbidly is normal.

Faces are visual stimuli that are both socially important and complex to process. They are important because a wealth of information is extracted simultaneously from them – not only identity, but also gender, age, expression, intention, gaze, lip reading, trustworthiness, attractiveness, etc. All this information must be extracted quickly and reliably to ensure proper social interactions. Faces, compared to other object categories (e.g., the tool category), are also complex because they are all very similar to each other. Furthermore, faces are usually processed at the exemplar level, that is, each face must be individualized. Information about a face is also extracted from a variety of elements, some of which are subtle, such as eyes–nose–mouth configuration or

zygomatic contracture. Overall, face processing is a challenge to the visual system. Probably due to its social importance and visual complexity, a variety of disorders can affect faces to a greater extent compared to other classes of objects.

In this article, we first describe prosopagnosia, the most well-known disorder of face processing. Following this description, we present several of the key issues that have been debated since prosopagnosia was identified as a specific clinical syndrome. These issues are: varieties of prosopagnosia; overt versus covert recognition; site of the lesions; face versus object recognition; prosopagnosia and facial expression; and finally, mechanisms that are impaired in prosopagnosia. A review of the pathogenesis, epidemiology, and criteria/diagnostic work-up tests follows. In a second section, misidentification delusional syndromes (Capgras, Fregoli, and intermetamorphopsia) and the mirror sign are reported.

Definition and History of Prosopagnosia

The most well-known disorder of face processing is prosopagnosia, a disorder of face identification. Prosopagnosia is an inability to recognize familiar persons from their faces. Prosopagnosic individuals also have difficulties learning new faces. Although this is not systematically the case, visual processing of other objects can be normal, highlighting the specificity of this syndrome. The impairment cannot be explained by a general cognitive dysfunction. Face detection, that is, knowing that a face is a face, is normal. One of the characteristics of prosopagnosics is that they have good skills at using extra-facial visual cues, such as a specific haircut or distinctive trait, gait or posture, further highlighting that it is facial features that they cannot process. Recognition using other modalities such as voice or name is preserved. Prosopagnosia should, therefore, be distinguished from person agnosia (also called cross-modal agnosia for persons), which is characterized by impaired biographical or semantic knowledge about people. In person agnosia, familiar people cannot be identified through any modality (e.g., face, voice, name, verbal description).

Similarly to most neuropsychological syndromes, prosopagnosia does not occur in an all-or-none fashion. In some severe cases, however, the inability to recognize faces can even extend to the patient's close relatives and his/her own face. Patients with prosopagnosia usually tend to hide their deficit, as it is very embarrassing and disabling in daily life. Since familiar persons cannot be recognized from their faces, prosopagnosic patients develop good skills at identifying persons using other cues. They may also develop explicit coping strategies, for example, asking a standard question in order to hear the voice of the person they want to identify.

Prosopagnosia is the most well-known face-processing disorder because of the implications it has in so many social interactions. The cognitive system that subserves face identification may be viewed as a hub providing access (once the face has been properly identified) not only to the name of the person, but also to the affective valence related to that person, to information regarding social hierarchy, to the personal life episodes related to that person, to the plans made with this person, etc. All of this information is crucial for adequate interactions.

Although there have been various reports, from as far back as the nineteenth century, of patients with difficulties in recognizing persons from their face, the name 'prosopagnosia' was coined in 1947 by a German psychiatrist, Joachim Bodamer. He was among the first to argue that some patients may show isolated impairment of face processing, rather than a general impairment in visual object processing. Although there have been some group reports of prosopagnosic patients, neuropsychological single-case studies are more common in the literature on prosopagnosia due to the rarity of this syndrome and also because single-case studies allow an in-depth and extensive investigation of the domains and processes that are impaired or preserved on an individual basis. More recently, brain imaging of prosopagnosic patients has opened new research perspectives such as characterizing the network of brain areas involved in face identification or studying how various categories of faces are processed (such as famous faces vs. parents' faces).

Varieties of Prosopagnosia

Based on the distinction made between apperceptive and associative visual agnosia (a disorder limited to objects other than faces), a similar dissociation between apperceptive and associative prosopagnosia is sometimes proposed in cognitive neuropsychological models. Apperceptive prosopagnosia refers to a difficulty in building a proper percept of a face (i.e., abnormal face perception). Consequently, this (improper) percept cannot be matched to stored

representations of faces in memory and cannot be recognized as familiar or not. On the other hand, face perception is often considered to be normal in associative prosopagnosia, even though intact perceptual representations cannot access corresponding memory representations. Although this taxonomy has some clinical utility in distinguishing patients and in understanding some aspects of face processing, such as covert recognition, it is unclear if this distinction is valid. As mentioned earlier, the apperceptive/associative distinction largely stems from cognitive neuropsychological (box and arrows) models, and, given the current knowledge, it is uncertain how a percept can be processed independently of any memory trace activation or top-down activation. It is also possible that the visuoperceptual abilities of reported cases of associative prosopagnosia have not been exhaustively investigated.

Overt versus Covert Recognition

Prosopagnosic patients show impaired overt (explicit) recognition. There are, however, considerable reports indicating that some of these patients show preserved covert (implicit or unconscious) recognition. A variety of methods have been used to study covert recognition such as skin conductance responses, behavioral methods (reaction times, faster relearning, etc.), or electrophysiological recordings. However, it is not yet clear how findings from these different methods can be reconciled. There are broadly three models accounting for covert recognition. One proposes that recognition is carried out correctly but that the outcome of this computation does not access awareness, awareness being viewed in this case as depending on a separate module. Other lines of evidence have been proposed to support the view that there may be dual processing routes in the brain, one accessible to awareness, the other not. A third approach, supported by both empirical evidence and neurocomputational modeling suggests that covert recognition is in reality only the residual activity of the impaired recognition system used in overt recognition.

Site of the Lesions

Lesions leading to prosopagnosia involve the visual ventral pathway and most notably the ventral occipitotemporal region (lingual, fusiform, and parahippocampal gyri). Prosopagnosia is often related to bilateral lesions. Whether lesions limited to the right hemisphere are sufficient to elicit prosopagnosia has sparked intense debates before brain imaging could be available. It is an important question because if face processing depends largely upon a single (right hemisphere) region, this would be a strong argument that the brain has evolved a specialized system processing faces independently from

other objects. Although there may have been some doubts before brain imaging could be available, recent case studies appear to support the idea that right-hemispheric lesions are sufficient to elicit prosopagnosia. Conversely, lesions limited to the left hemisphere, except perhaps in one patient, never lead to prosopagnosia. These results highlight the importance, and the dominance, of the right hemisphere in face processing. Two locations in the occipitotemporal region appear to be crucial to process faces: the occipital face area (OFA), located in the inferior occipital cortex, and the fusiform face area (FFA), located anteriorly to the OFA along the middle fusiform gyrus. These regions have been identified using functional imaging, as they are regularly activated when faces are presented. The investigation of the role of these regions in prosopagnosic patients with preserved or impaired OFA and FFA has only begun recently.

Face versus Object Processing

Are faces processed by a different system or different mechanisms from other objects? Some authors have indeed argued that prosopagnosia may be an artifactual syndrome related to uncontrolled factors. A host of such uncontrolled factors have been proposed:

1. Faces are usually processed at the exemplar level, that is, a level at which one can say whether a face is familiar or not. This is not the case with other objects, which are usually processed, at least in the lexical domain at the basic (entry) level, that is, an apple is named an apple, not as a single exemplar of its category (Snow White's apple).
2. Pure prosopagnosia, that is, a disorder of face processing with normal object processing, is rare and it is always possible to argue that processing of other object categories has not been properly investigated. In particular, many early reports have relied mainly on accuracy measures without reporting speed of processing.
3. Low-level visual factors, such as intracategory homogeneity, luminance, contrast, spectral density, etc., between faces and other categories of objects have not always been satisfactorily controlled.
4. Face perception requires processing the configuration of the parts (eyes–nose–mouth). Consequently, face perception may be impaired not because of any specific process related to faces (domain-specific process) but because it over-relied on a general configural perception mechanism.
5. Likewise, humans may be viewed as experts at processing faces. A possibility is that it is this expertise (for faces and any other objects with a similar level of expertise), rather than specific face processes, that is impaired in prosopagnosia.

6. In addition, there are only a few case reports of patients presenting with the opposite dissociation, that is, impaired object processing and normal face processing.

Overall, however, various authors working with both acquired and developmental prosopagnosic patients have spent a good deal of effort to convincingly refute these possibilities, particularly in most recent reports.

Prosopagnosia and Facial Expression

Can prosopagnosic patients process facial expression? This important question highlights the notion that different systems may process different aspects of the visual information that can be extracted from a face, an idea that would further support the notion of specificity of the processes carried out to identify faces. There is some agreement that identity and facial expression may be processed by two independent visual pathways, and most models of face processing posit two different pathways that diverge early after a face has been detected, one for identity, and the other for expression processing. Furthermore, some studies indicate that the spared facial expression processing route may help prosopagnosic patients identify a face, suggesting an independent and parallel route. However, this dual-route hypothesis has recently been discussed on the ground that the evidence was not so strong. Alternative models have been proposed, whose merits now have to be assessed.

Mechanisms Impaired in Prosopagnosia

The exact nature of prosopagnosia is still largely controversial. A dominant view suggests that faces are special because some sort of configural processing is essential. Support for this hypothesis comes from the inverted-face effect. Although inverted faces have almost the same physical characteristics as the same faces upright, control subjects are faster and more reliable at processing upright than inverted faces (see also the Thatcher effect, which shows that subjects are much faster at processing facial elements when faces are presented upright than when the same elements are processed on an inverted face). This effect is less important for inverted compared to upright objects. Inverted faces somehow lose their faceness and are then processed as regular objects. Some prosopagnosic patients do not show the inverted-face effect (i.e., they show the same level of effect for both faces and objects). However, an old alternative hypothesis that has recently gained some support is that prosopagnosia may be related to a specific difficulty in processing the eye region (the so-called ocula region). There have also been suggestions that faces may be special because individualization requires precise curvature processing. Overall, it is probable that there are several possible causes of prosopagnosia, the independence of each being largely unknown.

Pathogenesis

Acquired prosopagnosia is mostly caused by infarcts of the posterior cerebral artery, which affect the ventral occipitotemporal region (sometimes only the right). Other common causes are traumatic brain injuries, encephalitis, and dementias, although in these cases prosopagnosia is usually not the only cognitive disorder. Associated symptoms are left hemifield (~25% of prosopagnosic patients), left upper quadrant (~20%), upper field (~10%), or tubular (~10%) defects. Associated achromatopsia is frequent (~60%), as well as visual (object) agnosia (~25%) or visual agnosia and alexia (~35%) and topographical agnosia (a difficulty in recognizing landmarks such as buildings).

Prosopagnosia may also have a developmental origin. In this case, the skills needed to process faces never developed normally, either because of a genetic origin or neonatal injuries. It has been shown that developmental prosopagnosia shares many characteristic features with acquired prosopagnosia. The genes involved in developmental prosopagnosia are not known yet. However, the recent publications of large familial series suggest that some forms are autosomal dominant. Developmental prosopagnosia may have heterogeneous causes. A possibility is that developmental prosopagnosia is related to a defective innate subcortical mechanism that directs attention to faces during childhood. However, other possibilities, such as cortical abnormal development, also have to be considered. Developmental prosopagnosia shares some similarities with dyslexia, dysorthographia, and dyscalculia, as all are related to the abnormal development of very specialized cognitive systems.

Epidemiology

Several studies have compiled data on about a hundred cases each. Although many patients are not documented for various reasons, these data suggest that prosopagnosic patients as a whole are not that uncommon, particularly in association with other visual disorders such as visual agnosia. Acquired pure prosopagnosia, on the other hand (not associated with visual object agnosia or other symptoms), is rare.

Developmental prosopagnosics may not be aware of their difficulties, because they do not know that faces may be individualized and recognized. They usually become aware of their difficulties during the teens. Consequently, the prevalence of developmental prosopagnosia is unknown, and some researchers have proposed that there may be more developmental prosopagnosic patients than acquired prosopagnosic patients.

Criteria and Diagnostic Work-Up/Tests

Diagnosis of prosopagnosia is carried out using neuropsychological tests following a logical order.

Assessment of the Face Recognition Impairment

This step is simply carried out presenting photographs of known faces and asking for identification. Close-ups of famous faces are most often used. If the patient fails to provide the name, the examiner assesses whether the face is familiar or not and asks if any information about the person can be provided. Criteria for prosopagnosia requires that a significant number of faces that should be familiar are found to be unfamiliar compared to matched control subjects.

Verification that the Failure to Recognize Faces Cannot Be Explained by Visual or General Intellectual Impairment

If prosopagnosia is suspected, visual perception must be assessed by an ophthalmologist who will carry out assessment of acuity, visual field, color perception, etc. Some of these tests can, however, be performed clinically, for example, by asking the patient to read from some distance, classify color pens, etc. Some standard neuropsychological tests of visual perception also include low-level visual discrimination subtests (e.g., identify noisy letters on a background of random dots). Similarly, the patient must be able to perform the tasks correctly. Particularly after a brain lesion, it is important to assess general intellectual abilities using, for example, intelligence as well as short- and long-term memory scales.

Assessment of the Specificity of the Findings

Although the patient may not have any low-level visual impairment, it is necessary to verify if he or she is also impaired at processing other objects, that is, if he or she also shows visual agnosia or alexia. This is carried out by using reading and confrontation naming tests as well as standard visuoperceptive and visuospatial batteries. These batteries, specifically designed for this purpose, comprise a variety of subtests enabling the assessment of the perception of shapes, sizes, silhouettes, visual or conceptual matching, three-dimensional rotations, spatial relations, etc.

Another important aspect is to determine whether semantic knowledge about familiar persons is preserved. Simultaneously, recognition using other modalities will also be assessed, for example, asking the patient what he knows about some famous people whose names are

provided either orally or better, visually. Access to this knowledge from the name, voice, or verbal description must be preserved for a diagnosis of prosopagnosia.

It should be possible following this step to determine if the patient presents with pure prosopagnosia or prosopagnosia with other associated syndromes.

Characterization of the Prosopagnosia

When a diagnosis of prosopagnosia has been made, it may be useful, at least clinically, to know whether it is more apperceptive or associative in nature. A standard test consists in presenting the face of a person and asking the patient to recognize the face of that person while it is presented from a different view among distractors. In this condition, the patient must build a unique representation of the face and be able to recognize it independently of the perspective, which implies being able to use (possibly) domain-specific processes such as configuration. This test does not require using memory as both the exemplar and target are presented simultaneously. If the patient fails, this suggests he or she shows apperceptive prosopagnosia; conversely, if the patient succeeds, this suggests he or she is able to build a correct percept out of the face and that the patient shows associative prosopagnosia. Such tests, although popular, have been criticized because patients may perform this test based on feature processing (e.g., shape of the eyebrows or haircut) and also because although they may succeed, they usually take much more time than control subjects. Other means to characterize the prosopagnosia further is to determine how facial and other objects configurations are processed, if the patient shows the inverted-face effect, to assess covert recognition, to assess memory for new faces, to assess visual imagery of premorbid familiar faces, etc.

Management

Severity usually decreases during the few months following brain injury in acquired prosopagnosia. However, it is difficult, if not impossible, to rehabilitate face processing if there is any defect left. Management thus consists in helping the patient to cope with his problem, assisting in identifying the specific features that may help in recognizing other persons.

Other Disorders of Face Processing

There are other disorders of face processing than prosopagnosia and their variety suggests that faces may hold a special status in cognition.

Metamorphopsia

Metamorphopsia is a syndrome in which the shape of objects appears distorted. It can be permanent, affect parts of the visual field, and may have a retinal, cortical, or even subcortical origin. In some instances, however, metamorphopsia may be restricted to faces, either permanently or transiently when associated with epilepsy. Faces or parts of the face are then seen as larger (macropsia) or smaller (micropsia), facial elements may be misaligned or turned sideways by several degrees, etc. Metamorphopsia does not necessarily prevent identification. It is usually considered a visuosensory deficit. As for prosopagnosia, whether face metamorphopsia is related to face-specific mechanisms or not is matter of debate.

Prosopamnesia

Prosopagnosia refers to a difficulty in learning new faces in the absence of the problem with face perception and recognition of previously familiar faces. Only a few patients presenting with prosopamnesia have been reported. The existence of prosopamnesia suggests that learning mechanisms of new faces are distinct from pre-morbid stored representations of faces.

Misidentification Delusional Syndromes

Misidentification delusional syndromes include Capgras, Fregoli, and intermetamorphosis syndromes. In the Capgras syndrome, the face, and identity, of a highly familiar person, usually the spouse, is thought to have been stolen by an impostor (or a double, a duplicate that takes the form of a thief, an alien, etc.). It is sometimes referred to as a 'hypofamiliarity syndrome.' This syndrome appears to predominate in the visual modality and there have been some reports of a dissociation between the face, which is thought to have been duplicated, and the voice, which is not subject to delusion. This situation is very distressing for both the patient and family, sometimes leading to complicated situations. It is observed in dementias (e.g., Lewy body disease and Alzheimer's dementia) and in psychotic patients. In dementia disorders, this condition usually fluctuates during the day, being enhanced at dusk. It has been shown that Capgras patients did not show normal skin conductance response when presented with photographs of the subject of their delusion. This finding has led to the suggestion that Capgras patients showed normal overt recognition but abnormal affective recognition, leading to a double dissociation with prosopagnosic patients showing abnormal overt recognition but normal skin conductance response and covert recognition. Capgras syndrome is most often associated to humans but may also be related to highly affective objects (e.g., a dog).

In contrast to the Capgras syndrome, the Fregoli syndrome (in reference to the famous Italian quick-change artist) refers to a 'hyperfamiliarity syndrome.' It is the delusional belief that a significant person (e.g., family member) is incarnated in other persons. These persons may be unfamiliar and any one of them may be the subject of the delusion. Intermetamorphosis refers to the situation when a significant relative is replaced by another significant relative (e.g., the husband is replaced by the father). This double delusion distinguishes intermetamorphosis from the Fregoli syndrome, although they are not always easy to disambiguate and are sometimes confused in the literature. Both may be accompanied by reduplicative paramnesia (the feeling that a place such as the hospital or home has been reduplicated).

The status of face perception versus person knowledge in misidentification delusional syndromes is not always clear and merits further exploration.

Mirror Sign

The mirror sign is the phenomenon of not recognizing one's own image when looking at oneself in a mirror. It is sometimes called 'negative heautoscopy,' in contrast to 'positive heautoscopy,' a reduplicative hallucination of seeing one's own body at some distance ('out-of-body experience'). The person seen in the mirror is mistaken for a relative or a stranger. Semantic knowledge of what a mirror is and of its properties is usually preserved. Other persons' reflections may be correctly identified. Associated behavior may be to grope at or behind the mirror or to attempt to engage in a dialog with the (unrecognized) reflection. The mirror sign is usually observed in dementing illnesses, particularly Alzheimer's dementia as well as in psychotic patients.

Glossary

Case studies – The single patient methodology consists in providing an exhaustive analysis of a single patient performance. The overall performance on a set of tasks that jointly relate to various processing mechanisms is used to constrain the interpretation of the pattern of impairments. Caramazza (1986) argued that the use of impaired performance to constrain cognitive theory can only be meaningful in the setting of single patient methodology.

Categorical perception – Auditory perception is said to be categorical because discrimination is better for stimuli belonging to different phonemes (e.g., /p/-/b/) than for stimuli belonging to acoustic variants of the same phoneme, even though physical differences are the same in both the cases. Developmental dyslexics show poorer categorical perception than normal readers.

Dyslexia subtypes – Distinct subtypes of developmental dyslexia have been described which correspond to specific patterns of reading (and spelling) performance. A strong version of subtypes would require each behaviorally defined subtype to further demonstrate distinct cognitive disorder and distinct neural dysfunction.

Group studies – The average performance of a group of patient is interpreted. Group research is motivated by the assumption that members of the group show an important set of common characteristics. However, it has been argued that grouping patients with similar symptoms does not insure that the patients in the group are homogeneous in terms of the components of processing that are impaired in these patients.

Irregular word – The phonological form of the written word cannot be obtained by application of grapheme-phoneme mapping rules. Reading depends on some degree of partly arbitrary associative learning between orthography and phonology. Specific impairment of irregular word reading is a defining feature of developmental surface dyslexia.

Magnocellular system – The magnocellular system corresponds to the cortical dorsal stream of the visual pathways. Visual magnocells have large receptive fields, respond in a fast transient fashion, have broadband wavelength sensitivity, prefer low spatial frequencies, and are sensitive to low-contrast stimuli. Anatomical, neuro-imaging, and behavioral studies have been

provided in support of a magnocellular stream deficit in dyslexic individuals, leading to the magnocellular theory of developmental dyslexia.

Phonological awareness – Sensitivity to the sound structure of spoken words. Phonological awareness is assessed through tasks requiring the identification and manipulation of phonological units such as syllables, rhymes, or phonemes. Phoneme awareness, the sensitivity to phonemes, more strongly relates to reading performance and is typically impaired in individuals with phonological dyslexia.

Pseudo-word – A letter sequence that corresponds to none of the lexical forms in a given language but is pronounceable. Reading pseudo-words depends on a process that allows generalization from mappings between orthography and phonology. Specific pseudo-word reading impairment is a defining feature of developmental phonological dyslexia.

Visual attention span – The visual attention (VA) span corresponds to the number of distinct visual elements which can be processed simultaneously in a multi-element display. With respect to reading, the VA span corresponds to the number of orthographic units simultaneously processed in a letter string. A visual attention span disorder typically dissociates from phonological disorders and might play a critical role in the acquisition of specific orthographic knowledge.

Definition

Developmental dyslexia (or specific reading disability) is a specific learning disability characterized by an unexpected difficulty in learning to read in children who have at least average intelligence, who do not have general learning difficulties, and whose reading problems are not due to extraneous factors that might interfere with learning to read (such as sensory acuity deficits, severe emotional problems, acquired brain damage, or inadequate educational opportunity).

Semiology

Reading problems in developmental dyslexia are manifested in extreme difficulties in acquiring single word identification and decoding skills. Reading comprehension

skill may be affected as a consequence of poor word identification but listening comprehension is preserved. Spelling difficulties are frequently associated with specific reading disorders and often remain into adolescence even after some progress in reading has been made. Associated emotional and behavioral disturbances are common. In most English countries, the diagnosis of dyslexia proceeds on the basis of a discrepancy between reading accuracy and aptitude as measured by IQ tests. However, the validity of this discrepancy definition is becoming increasingly debated. Whereas measures of oral reading accuracy are typically used in English, timed tests of word and pseudo-word reading are standard practice in non-English countries.

Prevalence

Dyslexia is a common developmental disorder, with prevalence rates ranging from 3% to 17% of school age children. This variability is partly due to methodological differences between the studies. Using a one standard deviation cutoff, 16% of school-age children are diagnosed as dyslexic readers; they are no more than 2.5% when using a two standard deviation cutoff. The frequency of developmental dyslexia also differs according to the characteristics of the language in which children are taught to read. Most current knowledge about developmental dyslexia derives from studies conducted on English speakers and diagnosis is more difficult in more transparent languages such as Italian or German.

Persistence

Developmental dyslexia is a persistent condition. Although the reading performance of dyslexic readers improves with time, the gap between dyslexic and non-dyslexic readers remains all across the life span. The clinical features of dyslexia however vary with age. In deep languages in which dyslexic children exhibit low accuracy scores in reading, adolescents and young adults may be able to read words accurately but reading remains effortful and slow. Spelling problems may be useful clinically in differentiating dyslexic from average readers in older individuals.

Cognitive Feature

Assuming that phonological awareness is a core deficit in developmental dyslexia, some definitions of developmental dyslexia have been proposed that include the phonological deficit as a defining feature. However, there is evidence indicating that phoneme awareness is script dependent, so that phonological deficits are harder to detect in children who have learned to read in transparent languages. In nonalphabetic languages such as

Chinese or Japanese, a rapid naming deficit, not the phonological deficit, is the most dominant type of cognitive deficit in dyslexic children. Finally even in deep languages, cases of developmental dyslexia have been reported who exhibit no associated phonological disorders, and the existence of nonphonological core deficits in developmental dyslexia is still hotly debated. Based on current knowledge, general definitions which do not include cognitive-based criteria seem more parsimonious.

Heterogeneity

A distinction has been drawn between different subtypes of developmental dyslexia whose reading profiles parallel those previously described in acquired dyslexia. Some rare cases of deep dyslexia (poor word and pseudo-word reading, concreteness effect, and semantic errors), visual dyslexia (all reading errors are visual), and neglect dyslexia (neglect the left or right side of horizontally presented words) have been described in children. However, the two varieties of developmental phonological dyslexia and surface dyslexia are more frequent and better documented.

Case studies

Developmental phonological dyslexia

Prototypical cases of developmental phonological dyslexia show selective difficulties in pseudo-word reading but relatively preserved irregular word reading. Lexicalization errors (e.g., chait → chart; a phonologically similar word is produced instead of the target pseudo-word) are relatively common responses. A similar pattern is observed in writing with selective poor pseudo-word spelling but preserved word spelling abilities. A phonological processing disorder has been found in all reported cases of developmental phonological dyslexia. All exhibited poor phoneme awareness and poor verbal short term memory. Cases of phonological dyslexia have been described in children in a number of different languages, but diagnosis of phonological dyslexia may be more difficult in transparent languages in which phoneme awareness is acquired more easily.

Developmental surface dyslexia

In developmental surface dyslexia, reading of irregularly spelled words is impaired but reading accuracy is adequate for regular words and pseudo-words. Regularization errors resulting from the application of a rule-based system are typically observed (e.g., bear → beer) as well as visual paralexias (e.g., orchestra → orchard). Individuals with developmental surface dyslexia also display confusions between words with the same pronunciation but different spellings. Irregular word spelling is severely impaired but

the phonological aspects of words are preserved leading to phonologically plausible errors (e.g., whistle → wisle). All reported cases of developmental surface dyslexia showed preserved phonological abilities. Their phoneme awareness and verbal short-term memory skills were within the normal range of age-matched controls. In transparent languages, the diagnosis of surface dyslexia lies on difficulties in homophone heterograph comprehension and stress assignment.

Group Studies

In group studies, subtypes of reading disability have been identified based on the relative imbalances on the tasks of irregular word and pseudo-word reading. Regression techniques have been used to identify dyslexics with larger-than-expected discrepancies between irregular word and pseudo-word reading, based on the linear relationship between irregular words and pseudo-words in the control group. Individuals with unusually impaired irregular word reading relative to pseudo-words were labeled surface dyslexics. The opposite pattern defined the phonological dyslexia subtype. Using this procedure, two groups of phonological and surface dyslexic children have been identified as compared to age-matched controls. However, only a third of the children exhibited discrepancies between irregular word and pseudo-word reading and most were impaired on both types of items, thus showing a pattern of mixed dyslexia. Furthermore, the surface dyslexics' performance was very similar to that of younger normal readers, so that the surface dyslexic group virtually disappeared when a reading-age control group was employed. In contrast, substantial numbers of phonological dyslexics were identified in the comparison with reading-age-matched but younger controls. Such results were interpreted as showing that children with surface dyslexia in the chronological age comparison actually exhibited a developmental lag and that only those with phonological dyslexia reflected true developmental deviance.

Cognitive Bases

In most research, despite the heterogeneity of the dyslexic population, the tendency was to treat developmental dyslexia as a unitary syndrome with a single underlying cognitive disorder. However, a few attempts rather consider that the cognitive origin of developmental dyslexia is multifactorial. In this line, different cognitive disorders would independently contribute to the poor reading outcome of dyslexic children.

Phonological Deficit

Behavioral evidence

Phonological awareness – the sensitivity to the sound structure of spoken words – has been consistently reported as impaired in children with developmental dyslexia. This ability can be evaluated at the syllable level by testing rhyming abilities or at the phoneme level through tasks such as phoneme deletion (say cat without the /k/) or spoonerisms (basket-lemon → lasket-bemon). Other evidence for a phonological processing disorder comes from studies showing that dyslexics are poor at verbal learning and pseudo-word repetition. They have poor verbal short-term memory and have difficulties in object naming. Difficulties in acquiring phonological awareness and skill in alphabetic coding have been viewed as the consequence of poorly specified phonological representations. Some results however suggest that phonological representations may be intact and that the phonological deficit primarily surfaces in tasks requiring verbal short-term memory.

Causal relationship

The phonological theory postulates that a phonological disorder is the cognitive basis of developmental dyslexia. The most compelling evidence for a causal relationship between poor phonological skills and developmental dyslexia is provided by training and intervention studies. Indeed, direct instruction designed to facilitate phonological awareness and letter-sound mapping improves learning to read. Studies on normal reading acquisition further support a causal relationship in showing that phonological awareness strongly relates to reading progress and that children's knowledge of the phonological structure of language prior to literacy instruction is a good predictor of later reading ability. Early assessment of phonological abilities (phonological awareness, verbal short-term memory, and letter sound knowledge) thus allows identifying children at risk to develop reading problems.

Consequence on reading

By impairing the development of grapheme–phoneme skills, the phonological disorder is expected to primarily impact pseudo-word reading. Accordingly, dyslexic readers as a group typically show poor pseudo-word reading. The self-teaching hypothesis further claims that phonological recoding is critical to the acquisition of word-specific orthographic knowledge. Poor phonological abilities might therefore more drastically impact development of the reading system. This is compatible with the observation that most dyslexic readers are impaired in both pseudo-word and word reading.

Allophonic Perception

Studies using speech perception tasks typically evaluated categorical perception. They showed evidence that dyslexic readers perceive phonetic boundaries less sharply than normal readers do, mainly because they are better at discriminating acoustic differences between stimuli belonging to the same phoneme category. Interestingly, some studies used sine wave analogs of speech that can be either perceived as electronic sounds resembling whistles (acoustic perception mode) or recognized as syllables, after debriefing (speech perception mode). They revealed that the deficit was speech specific. Ill-specified phoneme representations in developmental dyslexia might explain the deficit in phoneme awareness and could interfere with the establishment of unambiguous connections between graphemes and phonemes.

Naming Speed Disorder

Behavioral evidence

A growing number of data point to naming speed deficits in developmental dyslexia. Naming speed is investigated through tasks of rapid automatized naming (RAN) that require children to name arrays of familiar items – letters, digits, colors, or objects – as quickly as possible. Performance on the colors and objects versions of the task predicts later reading performance in preliterate children, but the relationship between RAN and reading tends to be stronger for letter/digit tasks in older children. Along with phonological awareness, performance in RAN is one of the most powerful predictors of reading in the English language. It is the strongest predictor of reading performance in transparent orthographies and nonalphabetic languages.

Relationship with phonology

For some scholars, performance in RAN depends on the speed with which phonological information corresponding to letter names can be accessed from memory. According to this view, RAN performance is just another measure of phonological abilities. In contrast, other scholars consider that RAN performance is independent from phonology and that the cognitive deficits that lead to poor RAN performance are an independent source of reading disability. This assumption is supported by evidence showing that RAN performance accounts for unique variance in reading beyond that explained by phonological skills. Furthermore, phoneme awareness and rapid naming are differentially related to reading subskills: the former more strongly correlates with reading accuracy and performance in pseudo-word reading, the latter with reading speed and measures of orthographic knowledge. However, the cognitive processes which underlie RAN are not yet well understood. RAN is a complex task

that involves several different processes – from the uptake of visual information to the articulation of the spoken response – many of which are also necessary for reading. Current knowledge does not provide strong evidence that performance on the RAN task just reflects phonological processing skills and is not influenced by other cognitive dimensions.

Motor Problems

Dyslexics have been described as having balance and motor-coordination disorders. Their writing is appalling and they show soft signs of a cerebellar disorder, such as reach and gaze overshoot and muscle hypotonia. Given the role of the cerebellum in motor control and automation, a cerebellar dysfunction would affect speech articulation. This would lead to poor phonological representations and poor phonological skills which would be directly responsible for reading acquisition disorders. The cerebellar deficit hypothesis was presented as a biological explanation of the co-occurrence of phonological deficits and low level motor impairments in developmental dyslexia. However, motor impairments are only found in a subset of dyslexic individuals.

Visual Deficits

Congenital word blindness

At the end of the nineteenth century, severe reading acquisition disorders were described as congenital word blindness. It was thus agreed that reading difficulties were the result of a visual processing disorder. This hypothesis was largely contested in the mid-twentieth century, and the phonological hypothesis now dominates the scene. Nevertheless, there is evidence that at least some aspects of visual processing are impaired in many dyslexic individuals.

Low-level visual disorders

Low-level visual processing deficits have been reported in developmental dyslexia. These low-level visual deficits have been linked to functional anomalies in the magnocellular visual subsystem. They manifest themselves by poor motion perception, atypical eye movements, and reduced contrast sensitivity at low spatial and high temporal frequencies. However, poor performance in low-level visual tasks relates to pseudo-word reading and is typically associated with phonological disorders. The amodal version of the magnocellular theory of developmental dyslexia was proposed to account for the co-occurrence of phonological and low-level visual deficits in dyslexic children. This theory postulates that magnocellular temporal processing deficits result in basic visual and auditory processing impairments. The impairment in low-level auditory transient processing

would entail problems with phonological analysis which remain the most plausible proximal source of the reading problem. Accordingly, magnocellular deficits have been reported in the context of phonological dyslexia but not in the surface dyslexia subtype.

Visual attention span deficit

Deficits in processing strings of visual elements presented simultaneously have been reported in developmental dyslexia. It has been hypothesized that impaired multi-element processing might reflect deficits in allocating attention across letter or symbol strings, thus limiting the number of elements that can be processed in parallel during reading. This disorder was interpreted as reflecting a visual attention (VA) span disorder, namely a reduction in the number of distinct visual elements that can be processed in parallel in a visual display. Different subgroups of dyslexic children have been identified characterized by either a single phonological disorder or a single VA span deficit, or the two disorders, or none of them. The VA span deficit was found to account for the reading performance of dyslexic children, independently of their phonological skills. Moreover, data suggest that a majority of dyslexic children exhibit a single disorder, thus providing additional support for the hypothesis that the phonological and VA span deficits might contribute independently to developmental dyslexia. Further evidence were reported that the visual attention span disorder is specific to parallel processing and affects the number of letters processed at each fixation during text reading. The visual attention span was found to be impaired in case studies of developmental surface dyslexia but preserved in developmental phonological dyslexia.

Visual attention span abilities correlate with the reading outcome of dyslexic children. Strong relationships have been found with both irregular word and pseudo-word reading accuracy and speed. In limiting the amount of orthographic information extracted during reading, a visual attention span reduction would interfere with normal development of orthographic knowledge, thus leading to poor irregular word reading and spelling, i. e., a pattern of developmental surface dyslexia. Regular word and pseudo-word would remain unaffected as far as the visual attention span is large enough to process groups of letters that correspond to relevant orthographic units. However, a severe reduction impacting the processing of relevant sublexical orthographic units would end up affecting regular words and pseudo-words as well.

Impaired Temporal Processing

Defects in phonological processing have been speculated to derive from a basic deficit in temporal resolution of rapidly changing auditory stimuli. Although auditory

stimuli are well detected by dyslexic individuals when presented in isolation, performance is impaired when they are displayed in rapid succession. Actually, similar findings have been reported in the visual (and tactile) modality suggesting that the disorder might follow from a more general difficulty to rapidly allocate perceptual attention to sequences of stimuli in any sensory modality. The sluggish attentional shifting theory of developmental dyslexia assumes that the rapid stimulus sequence processing deficit is secondary to weakened parietal-lobe-supported attentional capture. The attention of dyslexic individuals once engaged cannot easily disengage. The sluggish attentional capture and prolonged attentional dwell time would impair speech perception and reading skills via distorted phonological representations. Accordingly, the temporal processing disorder was typically reported in dyslexic participants with a phonological deficit.

Neural Mechanisms

Developmental dyslexia is a neurobiological disorder. Postmortem studies, anatomical magnetic resonance imaging (aMRI) and diffusion tensor imaging (DTI) methods have been used to examine anatomical differences between dyslexic and nondyslexic brains. Methods based on positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) have led to identify those of the cortical areas involved in reading which manifest atypical functioning in developmental dyslexia. Electroencephalography (EEG) and magnetoencephalography (MEG) techniques revealed hemodynamic deviances in developmental dyslexia.

Brain Structure

Postmortem microscopic evaluations of brains of people with lifelong reading disability revealed small, focal malformations such as ectopias (nests of cells in unusual locations) and dysplasias (focally distorted cortical lamination) located mainly in the left perisylvian regions. However, such malformations which reflect cortical neural migration anomalies do not necessarily characterize the whole dyslexic population inasmuch as only a few brains were investigated, some of which belonged to individuals who probably met the diagnostic criteria for specific language impairment. Nevertheless, a number of other structural particularities have been found in developmental dyslexia. The Heschl gyrus and planum temporale atypical symmetry suggest a language laterality disorder. The planum parietale which is the core of the supramarginal gyrus seems to have a different morphology and less supramarginal gray matter was reported in dyslexic individuals. The frontal lobe also shows atypical

asymmetry and decreased gray matter density, in particular in Broca's area. Differences have also been found in the cerebellum, and voxel-based morphometry further revealed abnormal gray matter density in the left fusiform gyrus, a key region for reading. Microscopic examinations of the thalamus further revealed that the magnocellular layers of the lateral geniculate nucleus are disordered and the magnocells over 27% smaller in dyslexic brains. The disorder is selective inasmuch as no particularities were reported in the parvocellular system. Auditory magnocells in the medial geniculate nucleus also differ in dyslexic brains, in accordance with an amodal magnocellular dysfunction.

In summary, a great number of cortical regions are, at least, more variable in morphology in dyslexic individuals. Such structural differences have sometimes been associated with specific behavioral impairments, suggesting that the relationship might be causal. However, no single neuroanatomical marker distinguishes dyslexic from control individuals. Multiple anatomical differences have to be taken into account suggesting that there may be different neurobiological subtypes of dyslexia.

Brain Function

Brain imaging investigations have demonstrated differences in activation patterns between typical and dyslexic readers at all ages. Dyslexic individuals demonstrate atypical activations in the three left-hemisphere neural systems of reading, namely the inferior frontal, temporo-parietal, and temporo-occipital regions. Although our knowledge of the neurobiological bases of developmental dyslexia greatly improved in the last decades, it is noteworthy that inconsistencies between the studies are frequently observed which might result from the heterogeneity of the dyslexic population and/or differences in investigation methods.

The frontoparietal network

Atypical activations have been reported in the region of the left inferior frontal gyrus (including Broca's area) which is believed to serve articulation, verbal short-term rehearsal, and phonological analysis during reading. This region seems to be less active in dyslexic readers in some studies but others reported higher than normal activation. Because it is more likely in older, mostly compensated individuals, enhanced activity in the left inferior frontal gyrus might represent a compensatory response to overcome failure of phonological processing in more posterior areas.

More generally, defect of activation in the left inferior frontal and supramarginal gyri is viewed as reflecting the dysfunction of a left-sided functional network related to phonological processing and verbal working memory. PET examination of the neural activity of these two left perisylvian regions during a discrimination task using sine

wave analogs of speech further revealed that they were less active during the speech perception mode than the acoustic mode in a group of dyslexic individuals with poor phoneme awareness. Because the two modes involved physically identical auditory stimuli, poor activation restricted to the speech mode suggests specific difficulties to engage phonological processes. It has further been hypothesized that absence of activation in the insula linking the anterior and posterior language areas might relate to a disconnection within the left perisylvian network. The role of these regions in reading and phonological processing is comforted by results from intervention studies. After intense phonological intervention, a significant increase in the activation of the left hemisphere neural circuits of reading was observed in the dyslexics. This increase in brain activity was associated with an improvement of reading performance.

The temporo-parietal areas

Deficient activation in the left angular gyrus during pseudo-word reading tasks was further reported in developmental dyslexia. This area and nearby temporal and parietal areas further show less activity during rhyme judgment and short-term memory tasks, suggesting that the angular gyrus is poorly connected with other areas involved in the mediation of reading in dyslexic readers. A failure of activation in the angular gyrus/temporo-parietal junction bilaterally during motion detection tasks was interpreted as evidence for a dysfunction of the visual magnocellular system. Activity in this region correlates with reading performance but reduced left temporo-parietal activation remains when the dyslexic children are compared to reading-age-matched controls, suggesting that reduced activity in this region is not just the consequence of their poor reading level. The temporo-parietal junction appears as one of the principal loci of cerebral dysfunction in dyslexia. This could be due to the role of the left temporo-parietal areas in reading-related attentional processing, that is, those attentional processes involved in graphemic parsing during pseudo-word reading and in the integration of visual features in a coherent whole as required for word recognition by sight.

The occipito-temporal region

Finally, a failure of a left occipito-temporal region named the visual word form area (VWFA) to function properly during reading is viewed as the neural signature of developmental dyslexia. A deficit in activation of this region was reported in well-compensated adult dyslexics irrespective of language (French, English, or Italian). This area which is involved in the rapid, effortless recognition of familiar words is a visual unimodal area that encodes the abstract identity of strings of visual letters and develops progressively during learning to read. Poor development of the VWFA in developmental dyslexia

might thus be the consequence rather than the cause of the reading disorder.

Genetic Component

Dyslexia is an etiologically complex disorder with a strong genetic basis. Linkage studies have provided chromosomal sites that might harbor factors involved in dyslexia predisposition. Four genes have been identified (DYX1C1 on 15q21, KIAA0319 or DCDC2 on 6p22, ROBO1 on 3p12) which are not specific to reading-related neuronal circuits but are involved in brain development (neuronal migration or connectivity). Because a family history of dyslexia confers an increased risk of developing reading problems, it is possible to investigate dyslexia prospectively. The identification of at-risk children thus allows the prediction and prevention of reading disabilities.

Remediation

The use of phonology-based training methods, acoustically modified speech training and nonverbal audio-visual training, showed increased activation in the brain regions involved in reading. Change in brain activity correlated with improved phonological or reading performance. However and whereas improvement in phonological abilities was observed after intensive phonological training, generalization to reading was inconsistent and some children did not respond to remediation. Furthermore even when intensive training emphasizing phonological processing improved reading performance, the remediation effect was restricted to reading accuracy and hardly extended to reading rate.

Glossary

Attentional blink – A research paradigm in which participants are instructed to respond to two targets embedded in a stream of stimuli that occur in rapid succession. If the second target occurs close in time to the first target, its occurrence is not reported and attention is said to have ‘blinked’.

Avoidance learning – A form of motivated learning in which organisms generate correct responses in order to avoid receiving negative reinforcers.

Dimensional theories – Theories of emotion which postulate that individual emotions are organized along two fundamental dimensions of valence and arousal.

Emotional perseveration – The persistence of an affective state or emotional reaction despite a change in context indicating that the emotion is no longer appropriate.

Reversal learning – A form of associative learning in which cue-outcome contingencies are reversed in their reward value.

Social referencing – The use of nonverbal social communicative cues, such as arm gestures, eye gaze shifts, or facial expressions, to instruct someone where to direct their attention and how to react to stimuli in the environment.

Information processing capabilities of neurocognitive systems evolved to solve socio-ecological problems to ensure reproductive fitness and survival of the species. Such problems necessarily entailed emotional considerations inherent in courtship and mating, territorial defense, maternal behaviors, predator-prey interactions, and bodily sustenance. Emotions serve to prioritize behavior in accordance with such biologically relevant goals, and brain systems that mediate emotional functions are intimately connected with others dedicated to domain-specific cognitive processes and executive control. Although Western philosophical traditions sometimes cast the relationship between cognition and emotion as antagonistic, the nascent field of affective neuroscience illustrates how emotion acts iteratively and integratively with various cognitive domains to produce complex human behaviors.

Emotion–Cognition Convergence Zones within the Limbic and Paralimbic Forebrain

Emotions arise from somatic signals in response to sensory triggers that signify the presence of a salient event in the environment. The limbic and paralimbic regions of the forebrain are anatomically poised to integrate information from both the internal milieu and the external world, and these structures combine information from parallel cortical and subcortical processing pathways ([Figure 1](#)). Subcortical afferent pathways that carry information about visceral activity and sensory features of the world can swiftly initiate emotional behaviors. At the same time, cortical pathways elaborate the meaning of afferent input and compare it to stored knowledge accumulated from prior experience. Afferent sensory pathways converge on particular limbic and paralimbic forebrain structures – including the amygdala, insula, anterior cingulate cortex, and orbitofrontal cortex – that integrate the information and guide executive control regions to select appropriate responses ([Figure 1](#)). These structures communicate to each other and send efferent projections back to sensory and association cortices involved in relevant cognitive functions, such as attention and memory, to modify ongoing actions, fill in perceptual details, and update representations of the significance of features of the environment. The interplay between cognitive and emotional processes is therefore fluid and iterative during the management of complex behaviors.

Role of the Amygdala

The amygdala is an almond-shaped collection of approximately a dozen subcortical nuclei that reside in the anterior portion of medial temporal lobe. These nuclei have been implicated in a variety of affective, social, motivational, visceral, olfactory, and cognitive functions. The amygdala is the most densely connected structure in the primate forebrain and exerts powerful influences over processing in other brain areas. For instance, the amygdala has feedback projections to almost all stages of the ventral visual cortical stream, including the primary visual cortex (V1). The amygdala receives direct sensory input from the thalamus that bypasses the primary sensory cortices, which provides a rapid route to detect emotionally salient stimuli in the environment and to

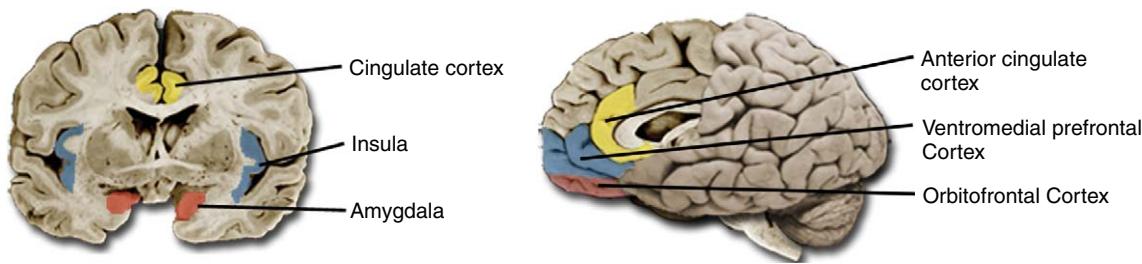

Figure 1 Limbic and paralimbic brain regions important for emotion–cognition interactions. The anterior cingulate cortex is the cortical component of the Papez circuit for emotion, which is based on control of the hypothalamus, and has dense interconnections with the amygdala, insula, and orbitofrontal and ventromedial cortices.

initiate emotional reactions. Because this subcortical route provides only crude sensory information, the amygdala combines this information with that arising from more refined cortical processing pathways. The amygdala orchestrates emotional output via connections to the hypothalamus, which controls the autonomic nervous system and release of stress hormones, as well as brain stem motor nuclei involved in emotional expression and defensive reflexes. Output projections to the basal ganglia and prefrontal cortex initiate coping responses to emotion-eliciting situations.

Role of the Insula

The insula is an evolutionarily older portion of the cortex that is covered by the frontoparietal and temporal opercula on the lateral surface of the brain. The insula contains multiple functional components, including a portion of primary gustatory cortex, secondary somatosensory cortex, sensory association areas, and visceromotor cortex. The insula serves as a convergent point of interoceptive processing from somatic afferents, which are integrated in a more anterior segment in the right hemisphere. From there, viscerosensory information is relayed to the orbitofrontal cortex, anterior cingulate cortex, and amygdala. The insula is important for the transmission of pain and has been implicated in awareness of somatic states. The anterior insula and anterior cingulate cortex contain neurons with a unique spindle morphology (von Economo neurons) that are found in hominoid primates, elephants, and whales, but whose function is unknown.

Role of the Anterior Cingulate Cortex

The cingulate cortex lies at the base of the medial wall of the forebrain and surrounds the corpus callosum. The anterior division has a more primitive cytoarchitecture, is divided into subgenual and rostral divisions, and is anatomically connected to limbic and autonomic motor structures. The subgenual division is implicated in mood disorders and visceromotor activation, whereas the rostral

division is associated with multiple functions, including the affective component of pain, motivational aspects of attention, expressing and evaluating emotional states, emotional learning, and integration of affect during demanding cognitive processing. Bidirectional connections with the posterior cingulate and its dorsal frontoparietal and hippocampal connections provide links to visuospatial, mnemonic, and attentional processing.

Role of the Orbitofrontal and Ventromedial Prefrontal Cortices

The orbitofrontal cortex lines the ventral surface of the frontal lobe. It contains a portion of secondary gustatory and olfactory cortices and its posterior sector is densely connected with diencephalic, striatal, and limbic/paralimbic structures. Dorsocaudally, the orbitofrontal cortex blends with paracingulate and dorsolateral heteromodal prefrontal cortex, and the confluence of these areas constitutes the ventromedial prefrontal cortex. One of the key functions of the orbitofrontal cortex is the representation of motivational value that is used during decision-making and contingency learning to guide goal-directed behavior. The medial orbital sector also signals pleasurable aspects of sensation while the ventromedial prefrontal cortex is engaged during internalized thoughts and feelings. In humans, damage to the orbitofrontal and ventromedial prefrontal cortices often cooccurs and leads to disorders of personality, affect, motivation, impulsive behavior, and social cognition and comportment.

Emotional Influences on Perception and Attention

Emotional Biases in Perception

Prioritizing stimuli with potential emotional significance has adaptive value to the organism, particularly for engaging defensive reflexes. Several perceptual and attentional mechanisms contribute to the rapid detection of emotional stimuli, including reflexive orienting, top-down attentional biases, and engagement of subcortical

processing pathways that are selectively tuned to emotional sensory features. Stimuli with high threat potential, such as snakes or angry facial expressions, elicit autonomic responses and activation of limbic forebrain structures even when presented subliminally (without conscious awareness). Under these circumstances, the amygdala interacts with other subcortical areas to a greater degree than when emotional stimuli are presented supraliminally. Emotional stimuli also are detected more rapidly than neutral stimuli on an attentional blink paradigm, in which participants report two target words separated by a short lag within a stream of other words. This performance benefit is reduced in amygdala-lesioned patients, which suggests that the amygdala can override capacity-limited perceptual encoding processes to allow emotional triggers to reach awareness. In neglect syndrome patients, emotional stimuli are detected in the contralesional visual field more often than neutral stimuli, presumably by recruiting these subcortical circuits.

The amygdala also modulates processing along cortical visual pathways as a function of emotional significance. For instance, emotional facial expressions elicit greater activation in occipitotemporal cortices, including the fusiform gyrus and superior temporal sulcus, relative to neutral expressions. However, amygdala-lesioned patients exhibit reduced emotional modulation of fusiform face activity, implicating a role for amygdalocortical feedback projections in facial affect perception. In anxiety disorders, prepotent threat signals are readily detected, and, accordingly, sensory-limbic pathways are hyperactivated in response to emotional elicitors. Even relatively innocuous social stimuli (e.g., the face of an unknown individual with neutral expression) can yield potentiated amygdala responses in social phobia. Such observations suggest that appraisal mechanisms combined with plasticity in corticolimbic circuits contribute to the manifestation of perceptual biases in affective disorders.

Emotional Interactions with Attentional Systems

Once detected, emotional stimuli recruit additional attentional processes to elaborate the meaning of the stimulus and its spatiotemporal context. Changes in the autonomic nervous system alert the organism to the presence of a potential emotional trigger which, in turn, redirects processing resources to react appropriately. When presented in complex environments, emotional stimuli bias attentional orienting and sustained attention to help localize the relevant stimulus and determine any change in its meaning. For instance, eye and head movements will be directed toward a lurking predator to initially locate it, and subsequent eye fixations will be spatially distributed to make inferences about its direction of movement and to identify possible escape routes. Positive emotional states tend to expand attentional focus and make individuals

more open to novel sensory stimulation and social interactions, whereas negative emotional states tend to focus attention on specific spatial locations and induce vigilance and social withdrawal. During social interactions, facial expressions, gestures, eye gaze, and vocalizations are used to communicate to others the emotional status of the environment (social referencing), and these cues must be attended and interpreted appropriately.

In response to emotional cues, amygdala efferents to the nucleus basalis of Meynert in the basal forebrain facilitate acetylcholine release that broadly targets neocortical receptor sites, including those in the frontoparietal attentional control system. Under these cholinergic influences, synaptic plasticity is enhanced and cortical neurons reduce their threshold for firing, implicating a readiness for information processing associated with high attentional states. Amygdala damage in rodents leads to failures in the cholinergic regulation of attentional responses to conditioned cues that predict rewarding outcomes. Other connections between the amygdala and dorsal frontoparietal cortices occur through feedback projections to sensory cortices or through frontal interfaces (e.g., anterior cingulate, orbitofrontal cortex, inferior frontal gyrus, or insula) (**Figure 2**). The amygdala and ventral visual processing areas are also the targets of modulation by attentional control circuits in response to emotional stimuli. For instance, hemodynamic responses in the amygdala and fusiform gyrus are sensitive to the amount of visual exploration allocated to facial expressions of emotion, and directing amygdala-lesioned patients to attend local facial features (such as the eye region for fear expressions) can improve their recognition abilities under some circumstances, presumably via attentional modulation of processing in face-sensitive occipitotemporal cortices.

The rostral anterior cingulate and adjacent medial prefrontal cortex have been particularly noted for their role in linking emotional evaluation with attentional control circuits. On an emotional oddball task in which individuals are presented with task-irrelevant emotionally arousing distractors while responding to interleaved neutral attentional targets, the rostral anterior cingulate responds equally to both stimulus categories. However, if the task instructions are switched and the arousing stimuli become the attentional targets, activity in the rostral anterior cingulate doubles in magnitude, which suggests a convergence of attentional–emotional processing. Moreover, when individuals attend to their emotional experience in response to negatively arousing pictures, activity in the medial prefrontal cortex increases relative to when they attend to the surface features of the pictures. In neurobiological models of depression, these regions are hypothesized to maintain a balance between dorsal attentional systems and ventral emotional systems to regulate mood states.

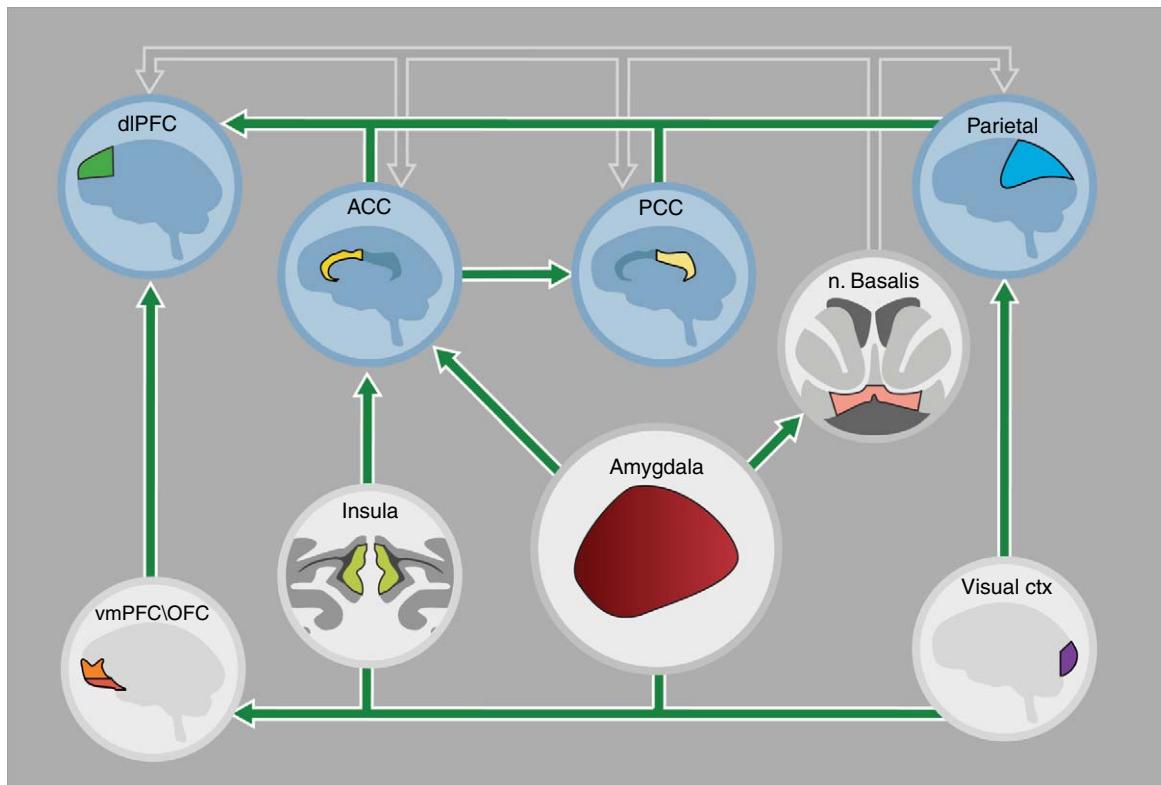

Figure 2 A neural circuit model of emotional interactions with visuospatial attentional control circuits. Visual input activates parallel pathways leading to the amygdala for emotion recognition and the parietal lobes for action preparation. Engagement of the cholinergic system in the nucleus basalis (n. Basalis) increases cortical arousal broadly. Targeted projections via cortical interfaces, including the ventromedial prefrontal cortex (vmPFC), orbitofrontal cortex (OFC), anterior cingulate cortex (ACC), and insula, bias processing in the dorsal fronto-cingulo-parietal attentional control system (shaded in blue). Feedback projections are equally important for the cognitive control of emotion (not indicated). Striato-thalamic projections are eliminated for simplicity. ctx = cortex, dlPFC = dorsolateral prefrontal cortex, PCC = posterior cingulate cortex.

When attention is socially directed by a combination of emotional expressions and eye gaze, these facial features are processed independently until approximately 300 ms after stimulus onset, at which time the two cues interact to guide spatially-directed attentional orienting. Facial expression activity in the amygdala is altered by gaze direction, and one hypothesis suggests that its activity is enhanced when the meaning of the gaze-expression combination is ambiguous. For instance, greater amygdala activity is seen to angry facial expressions with averted gaze (and no peripheral target present) relative to gaze directed at the viewer. In the former case, the source of the anger is unknown and additional information is needed to evaluate the meaning of the attention-directing cue. Furthermore, the superior temporal sulcus codes for violations of expectancies when viewing eye gaze shifts in others. When individuals watch someone fail to spatially track a peripheral target through misappropriated gaze shifts, activity in the superior temporal sulcus is enhanced relative to when the target is correctly foveated. These findings provide a foundation upon which to delineate how attention modulates activity in cortico-limbic

structures to interpret the intended meaning of others' nonverbal actions during social exchanges.

Emotional Influences on Learning and Memory

Conditioned Fear Learning

One of the most fundamental ways in which organisms learn about the emotional significance of events in the environment is through the process of classical (Pavlovian) conditioning. When appetitive or aversive reinforcers are present in the environment, it is important to determine which sensory cues and contexts reliably predict their occurrence. During fear conditioning, a relatively innocuous conditioned stimulus such as a tone is presented just prior to an innately (unconditioned) aversive reinforcer, such as an electric shock. Following several tone-shock pairings, the tone acquires negative value through its predictive association with the impending shock and begins to elicit characteristic defensive responses indicative of a state of fear, including startle

reflex potentiation, behavioral immobility, and increased sweating. These conditioned fear responses also transfer to features of the global environment in which the shock occurs even in the absence of the cue itself (contextual conditioning). In humans, fear conditioning can be acquired even when individuals are not consciously aware of the cue-outcome contingency, particularly when the cues themselves are fear-relevant (e.g., angry faces). Thus, simple forms of conditioned fear learning are implicit in nature, although more complex fear associations depend on explicit knowledge of the predictive relationships among the cue, reinforcer, and their spatio-temporal context. The strength of learning generally depends on the intensity of the reinforcer, which shows that emotional arousal is critical to the acquisition of such conditioned behaviors.

A wealth of research in humans and nonhuman animals has elucidated the neurobiological mechanisms of this form of emotional learning (Figure 3). Across species, the amygdala has been implicated as a key structure that performs computations that underlie associative learning during fear conditioning. Rodents or humans with amygdala damage are impaired in conditioned fear learning, despite having normal fear responses to the reinforcer itself. In humans, amygdala damage impairs physiological expression of conditioned fear learning even when the patients have intact explicit knowledge regarding the cue-reinforcer contingency. Neuroimaging studies have consistently shown that activity in the thalamus, amygdala, anterior cingulate gyrus, and sensory cortex increase during the acquisition of conditioned fear. Of these structures, the amygdala is most tightly linked to individual differences in the physiological expression of fear learning, and

its activity tends to be greatest during the early portion of training when the emotional associations are initially formed. In posttraumatic stress disorder, the amygdala is hyperactive during conditioned fear learning, which suggests that chronic stress potentiates sensory associations to threatening stimuli. Maladaptive expression of conditioned behaviors also contributes to pathophysiological changes underlying other psychiatric conditions, such as specific phobias, in which there is aberrant regulation or generalization of the fear potential of cues that signal danger.

Amnesic patients with selective hippocampal damage show the opposite pattern as amygdala-lesioned patients – they exhibit normal physiological acquisition of conditioned fear on simple cue-reinforcer paradigms but fail to explicitly remember the contingency pattern. However, physiological impairments arise in amnesia when the training paradigm is more complex, such as trace conditioning, wherein a retention interval separates the end of the cue and the onset of the reinforcer. Moreover, amnesic patients have difficulty forming contextual associations to the reinforcers and thus fail to exhibit a return of fear when they re-encounter a conditioned stimulus in a place that was previously associated with shock. Neuroimaging studies have confirmed the role of the human hippocampus in healthy adults who undergo contextual and trace fear-conditioning regimens.

Emotional Modulation of Explicit Memory

Although the amygdala and hippocampus exhibit partially independent functions during conditioned learning, they cooperate during the formation and retrieval of explicit (declarative or conscious) emotional memories. Emotionally arousing stimuli coded by the

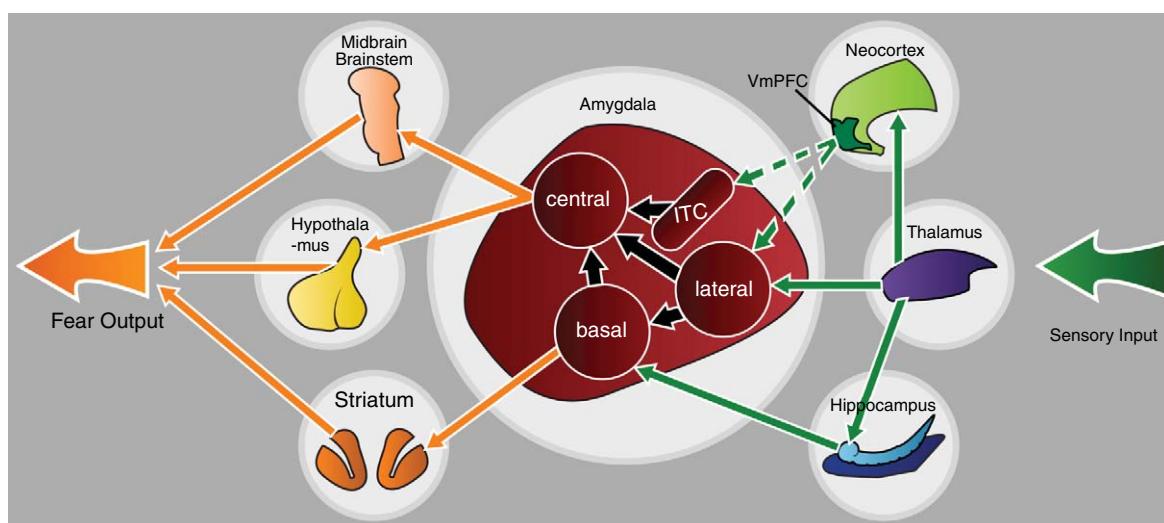

Figure 3 A neural circuit model of fear conditioning. Fearful stimuli activate the amygdala via both direct thalamic and indirect thalamo-cortical routes. Fearful behavior is initiated through brainstem, hypothalamic, and fronto-striatal outputs from the amygdala. Extinction of fear is mediated by inhibitory influences from the ventromedial prefrontal cortex (vmPFC). Contextual modulation of fear is mediated by the hippocampus. Feedback projections are not shown. ITC = intercalated cell group.

amygdala interact with hippocampal-dependent encoding and consolidation processes through two routes. First, bidirectional neural pathways link the amygdala and hippocampus directly and indirectly via adjacent rhinal cortex interfaces, which provide rapid communication channels for coupling their activity, including high-frequency oscillatory firing, to boost memory for emotional events. Second, the amygdala controls the peripheral release of stress hormones, including noradrenaline and cortisol, in response to emotionally arousing events by engaging the hypothalamic–pituitary–adrenal axis. These hormones feed back onto receptor sites located throughout the cerebrum, including the hippocampus and the amygdala itself, although such effects take time to unfold relative to the direct neural interactions. Studies in nonhuman animals have shown that stress hormone-dependent processing in the amygdala and hippocampus is important for enhancing memory consolidation for emotionally arousing tasks, such as avoidance learning.

In humans, enhanced functional coupling among the amygdala, hippocampus, and rhinal cortex has been observed in neuroimaging paradigms that examine subsequent memory for emotionally arousing material. Encoding-related activity in and functional interactions among these regions increase for arousing stimuli that are later remembered relative to those that are later forgotten, and this successful encoding activity is greater for arousing than for neutral material. Epileptic patients with partial amygdala lesions exhibit reduced encoding-related activity for emotional stimuli in the hippocampus and vice versa, which indicates a functional reciprocity between these regions to support emotional memory encoding. These patients also fail to show less forgetting over time of emotionally arousing material relative to neutral material, which is a behavioral hallmark of arousal-mediated memory consolidation in healthy individuals. Hence, when the amygdala is engaged concurrently with memory-related structures in the medial temporal lobe, there is a selective long-term retention boost for emotionally arousing information. Other regions make contributions to emotional memory formation, including lateral prefrontal and sensory cortices, which implicates a distributed network to support encoding processes that are enhanced in the presence of an emotionally evocative stimulus.

Human evidence also implicates a role of stress hormones in enhancing memory for arousing events. When individuals are presented a short story with emotional and neutral segments, their memory for the emotional segment is enhanced relative to the neutral portions of the story. However, patients with bilateral amygdala damage and healthy adults under the influence of propranolol, a beta-adrenergic blocker, do not exhibit a boost in retention for the emotional portion of the story. Direct influences of propranolol on amygdala activity have also been reported, but it is unclear whether these effects

selectively affect hippocampal interactions that support emotional memory formation. The effects of cortisol on human emotional memory have not been as well-established in terms of neural mechanisms, although moderate stress-induced increases in cortisol levels generally produce beneficial effects during encoding but impairing effects during retrieval.

While studies in nonhuman animals have emphasized the role of the amygdala and adjacent medial temporal lobe structures during the encoding and consolidation stages of memory, human research has shown that these regions also play important roles during retrieval. Functional coupling among the amygdala, rhinal cortex, and hippocampus is enhanced during the successful retrieval of emotionally arousing stimuli relative to neutral stimuli. Moreover, the amygdala and hippocampal activity during retrieval is selectively associated with a particular retrieval operation – recollection – that is accompanied by a vivid sense of traveling back in time to re-experience the event and retrieve contextual details associated with it. These structures are also engaged and functionally coupled with activity in right ventral prefrontal cortex during the recall of autobiographical memories, and the degree of amygdala activity during retrieval predicts the level of emotional intensity associated with the recovered memory. Relative to trauma-exposed individuals, patients with posttraumatic stress disorder exhibit exaggerated responses in limbic forebrain regions, including the anterior cingulate and amygdala, in response to reminders of their traumatic experience, although chronic stress yields structural damage to the hippocampus, which may result in less contextual specification of traumatic memories. Thus, medial temporal lobe structures, in consort with prefrontal and sensory cortices and stress hormones, interact during both encoding and retrieval to yield explicit retention advantages for emotionally arousing events to ensure their selective retention in long-term memory. The amygdala and its hormonal targets influence other brain regions to support implicit forms of memory, such as the cerebellum for motor learning and the striatum for procedural learning (**Figure 4**).

Whereas amygdala–hippocampal coupling engenders memory advantages based on the arousal aspects of emotional stimuli and experiences, additional mnemonic boosts are provided by affective valence. Affective valence (pleasantness) and arousal (intensity) are construed as orthogonal dimensions of emotion which may exert independent effects on cognition. Stimuli that are low in arousal but nonetheless affective in meaning tend to be more semantically or thematically related than randomly selected neutral stimuli. Amygdala-lesioned patients typically show normal retention advantages for these affectively valent, low-arousing stimuli, and neuroimaging studies have shown that successful encoding of

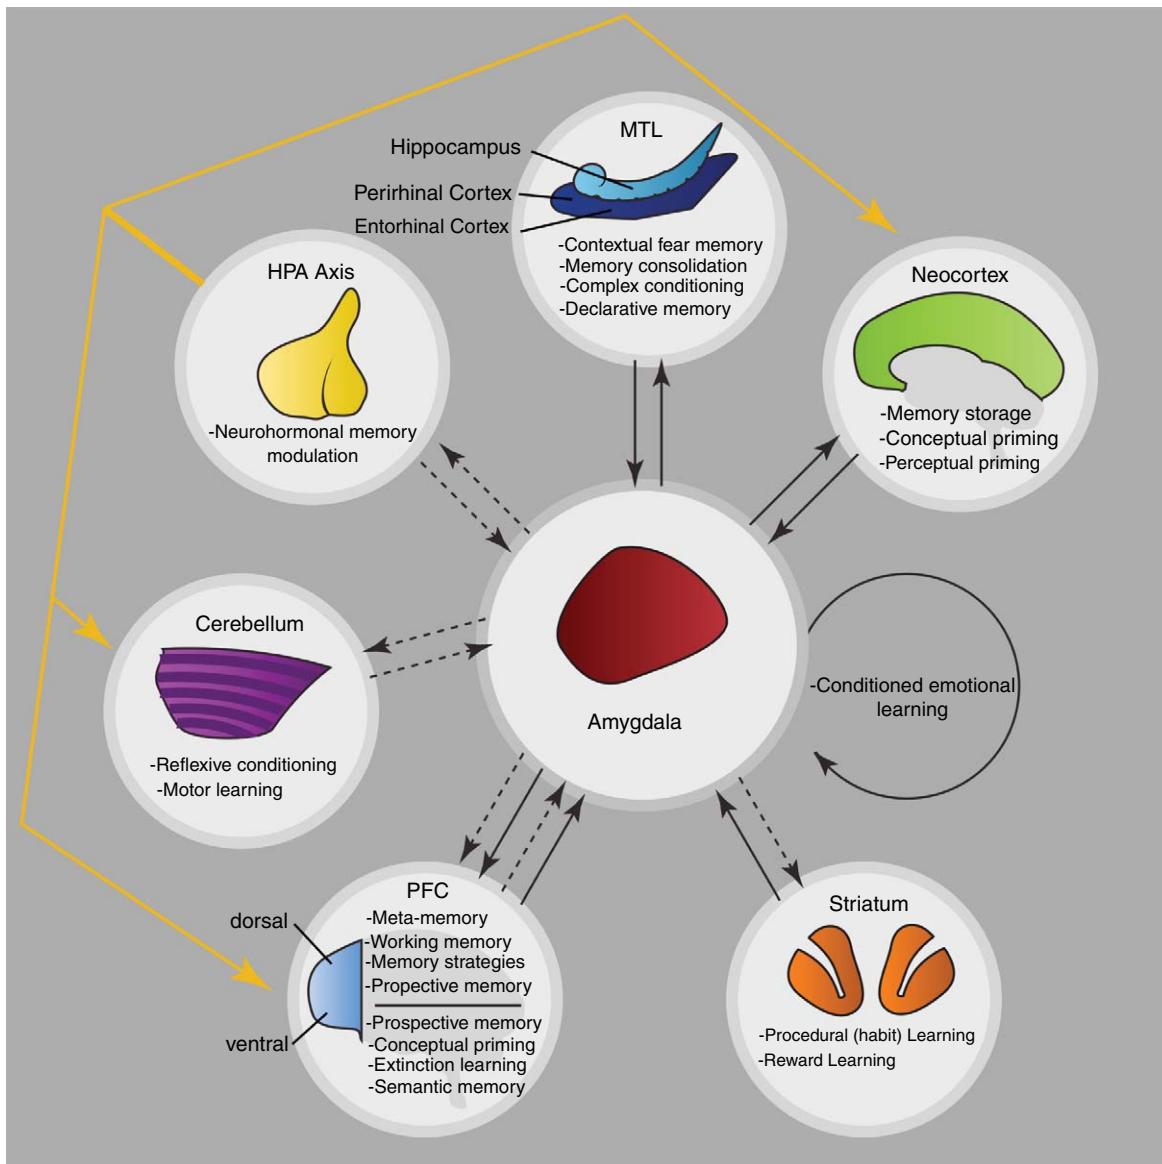

Figure 4 A neural circuit model of arousal-mediated memory effects. Distributed brain systems that support specific forms of memory interact with the amygdala either directly (solid lines) or indirectly (dashed lines). When an emotionally arousing stimulus is detected by the amygdala, various memory processes are engaged, depending on the behavioral goal, to facilitate remembering the circumstances of the event and reacting appropriately. Engagement of stress hormones via the hypothalamic–pituitary–adrenal (HPA) axis further enhances memory consolidation via feedback projections to cortical sites (yellow lines). Memory effects of emotion in the absence of high arousal are not amygdala dependent but instead engage semantic memory networks in frontotemporal cortical areas (not shown). MTL = medial temporal lobe, PFC = prefrontal cortex.

these stimuli yields greater activity in the left hippocampus and a region of left ventrolateral prefrontal cortex associated with deep semantic processing. Theories of memory biases in mood disorders emphasize a contribution of spreading activation in semantic networks along emotion nodes or attractors, which helps organize information in memory. Semantic and organizational encoding benefits do not involve the amygdala but instead engage left fronto-temporal cortices to process and relate information more deeply when a common valence is shared among items.

Cognitive Control of Emotion

Extinction and Reversal Contingency Learning

The emotional significance of a sensory stimulus is often malleable and contextualized so that its meaning varies across time or place. One way in which changes in emotional significance can be learned is through alterations in stimulus–outcome associations. For instance, if a conditioned fear stimulus no longer predicts an impending aversive event, then fear responses should subside and a new safety memory formed (extinction learning).

Alternatively, a conditioned fear stimulus may instead begin to predict a pleasurable outcome, yielding a switch in its affective valence (reversal learning). Such outcome-dependent changes in affective value critically involve the ventromedial prefrontal cortex and its inhibitory influences over the amygdala (Figure 2). Stimulating the ventromedial prefrontal cortex in rodents elicits reductions in amygdala responses to conditioned fear stimuli and a concomitant suppression of fear behavior. Human neuroimaging studies have confirmed that during fear extinction training, activity in the amygdala decreases, and activity in the ventromedial prefrontal cortex reflects the behavioral expression of extinction learning. Posttraumatic stress disorder patients fail to engage these prefrontal control circuits during fear extinction, which may partly explain why they continue to respond to traumatic reminders even in safe environments. Neurologic patients with orbital and ventromedial prefrontal cortex damage are impaired in reversal learning – they persist in responding to conditioned cues in a stereotyped way, despite knowing that emotional outcomes are no longer likely to occur (emotional perseveration). The lack of emotional flexibility in these patients adversely affects their interpersonal relationships and livelihood as they do not appropriately update their expectations and actions according to changes in the value of behavioral outcomes. A fundamental tenet of exposure and counterconditioning therapies is that outcome-based control mechanisms implemented in the ventromedial prefrontal cortex can be trained to help patients with affective disorders overcome maladaptive conditioned behaviors.

Cognitive Reappraisal

An alternative method to teach individuals to modify their affective responses is to use cognitive resources to lessen the negative impact of an emotional event (cognitive behavioral therapy). Several techniques can be effective in this regard. For instance, individuals can be instructed to reframe the meaning of a stressful situation by mentally imagining a more positive outcome while reflecting on it. Other techniques ask individuals to imagine being less personally involved in the event or to reallocate attentional resources away from emotional aspects of the situation. In all of these examples, cognitive resources, such as working memory, attentional set shifting, and mental imagery, are used in an effort to change one's emotional experience. During cognitive reappraisal of negative emotion, activity in dorsal frontoparietal and dorsal anterior cingulate regions increases, whereas activity in the insula, amygdala,

and other limbic areas decreases in accordance with self-reported reductions in negative affect. Such studies of emotion regulation show that the relationship between emotional and attentional control systems is reciprocal, depending on the behavioral goal (Figure 2). Although the specific areas recruited depend on the cognitive operations used, in general these investigations illustrate how executive control regions restore a balance across cognitive and affective systems to regulate behavior in response to the vagaries of life experiences.

Glossary

Diffusion tensor imaging (DTI) – A magnetic resonance imaging (MRI) technique that measures water diffusion through biological tissues. This noninvasive method can be used to visualize white matter tracts in the brain.

MRI morphometry – An analytic approach to structural MRI data analysis that enables the comparison of the size and shape of specific brain structures, for example, at different ages or across different species.

Ontogeny – The development of an organism from the fertilized egg to its mature form.

Phylogeny – The evolutionary development of a species.

Theory of mind – The ability to attribute mental states – beliefs, intents, desires, pretending, knowledge, and so on – to oneself and others, and to understand that others have beliefs, desires, and intentions that are different from one's own.

Saying that evolution involves changes in the genome really does not tell us much by itself. To make meaningful contact with the organism and its life history, it is important to consider genetic changes in the context of development. For example, building a bigger brain could entail adding more neurons or, alternatively, increasing connectivity and synapse number while maintaining neuron number. We know that all neocortical neurons are generated early in development. Thus, increasing brain size by adding more neurons would require changing gene activity early in development. Tinkering with the genome at this early stage could have a variety of secondary effects, both positive and negative, such as extending the life span. In contrast, enlarging the brain by increasing synapse number could be effected by changing the actions of genes expressed later in development, even as late as adulthood. There may be a bias toward modifications late in development, given that modifications early in development could have deleterious effects that extend across the rest of the life span.

Second, both developmental and evolutionary researchers explore the relationship between variations in brain structure and variations in brain function. Stemming directly from Darwin's doctrine of continuity, there is a strong tradition in the neurosciences and psychology that the brain and mind of humans differ only quantitatively from those of our relatives. As Darwin put it, the differences are matters of degree and not of kind. Darwin's doctrine of continuity does not fit well with our modern understanding of evolutionary change, but it remains popular – in part because it serves as a rationale for viewing model animals as simplified versions of human beings. Yet, humans are not simply macaque monkeys with additional components or layers of complexity – macaques and humans are both specialized endpoints of evolutionary history, each having changed in particular ways since their divergence about 25 million years ago. Increasingly, experimental psychologists are embracing significant species differences in psychological organization, although there is still a lack of consensus about the nature of human cognitive specializations, as discussed below.

Similarly, in development, children are often – but overly simplistically – viewed as simplified versions of adults. Infants exhibit certain behaviors that are adaptive

Most cognitive neuroscience research to date has focused on the relationships between the brain and behavior in the human adult. We can gain additional insights into these relationships by considering how this finely tuned organ came to be, both from an evolutionary and a developmental perspective.

The tradition of linking evolution and development together dates back to 1866 to the well-known 'biogenetic law' of Ernst Haeckel: "Ontogeny recapitulates phylogeny." For Haeckel, ontogeny and phylogeny were two aspects of the same process. The biogenetic law was discredited long ago as a general principle of biology. It assumes that evolution acts only at the endpoints – that is, adult stages – of development, whereas evolution can, and does, modify organisms at every stage of development. The process of development is not merely a series of architectural changes that are required to yield the mature organism: the intervening organizations have to be functionally viable in the social and ecological contexts in which immature animals find themselves.

There are, however, other reasons to consider development and evolution together. One reason is that evolutionary changes are modifications of developmental programs – a concept explored in evolutionary developmental biology, a field commonly known as 'evo-devo.'

at their stage of life, but that are no longer needed later in life, such as grasping and suckling reflexes. Infants also exhibit cognitive capacities that adults do not; they can discriminate subtle phonetic differences, even between sounds that are not used to distinguish between words in their native language – a capacity that allows them to learn language readily. Adolescents, too, are not merely adults with diminished capacity. They exhibit, strongly, reward-driven behavior and high levels of novelty seeking – behaviors that maximize the potential for learning. Such behaviors are associated with tangible risks, however, and after a period of exploration and learning during the teen years, it might make sense to curb these exploratory tendencies to a certain extent.

In summary, comparative studies show that while there are many similarities between humans and other animals, in particular other primates – which is expected because we do share common ancestors – there are also important differences. These differences are manifested not only in the highest-order cognitive and behavioral functions, but also at a variety of levels of organization and a variety of points in development. On the flipside, developmental studies do provide evidence of emerging levels of complexity from infancy to adulthood, but at each stage of development we are adapted to our particular circumstances.

Below, we provide a brief overview of current topics in evolution and development that relate to higher-order cognitive functions and the brain regions that support them, given that these are the functions for which the cross-species and developmental differences are most salient. We first consider ideas about the evolution and development of behavior, then brain anatomy, and finally brain function.

Comparative and Developmental Psychology

There have been several efforts to characterize the nature of the differences between humans and the great apes – chimpanzees, bonobos, gorillas, and orangutans – the animals most closely related to us. Tomasello and colleagues, for example, see the differences mainly in terms of the elaboration of social cognition in humans, as compared to cognition related to the physical world. Povinelli and colleagues, on the other hand, see a deeper distinction involving capacities for abstract representation that cuts across the social/physical distinction. For the latter view, what is uniquely human is the emergence, during childhood, of symbolic systems, including language as well as the ability to represent unseen causes and abstract categories.

The idea that language is a human specialization is no longer highly controversial. Additionally, humans, but not

nonhuman primates, understand physical interactions of objects in terms of abstract or unobservable causes or relations – a way of understanding the world known as ‘folk physics.’ Similarly, humans understand the knowledge states of other individuals – so-called ‘theory of mind’ – which is another example of how we understand the world in terms of abstract causes or relations. Povinelli and colleagues have argued that chimpanzees (1) do not understand that other individuals – or they themselves – possess minds and (2) do not understand how minds work. Thus, for example, chimpanzees do not understand that one has to have certain kinds of perceptual experiences to possess certain kinds of knowledge. In contrast, starting around 4 years of age, children performing the Sally-Anne test begin to demonstrate understanding of what knowledge others have access to.

Humans have the ability to extract abstract relationships between multiple mental representations. This ability, referred to as ‘relational reasoning,’ allows us to represent higher-order relationships between sets of mental representations. Analogical reasoning is a form of relational reasoning that involves abstracting a relationship between familiar items and applying it to novel representations. Forming analogies allows us to determine general principles from specific examples, and to establish connections between previously unrelated pieces of information. Analogical thought is an important means by which cognition develops. For example, children use analogies to learn new words and concepts by association with previously learned information. Penn, Holyoak, and Povinelli have argued that nonhuman primates lack the ability to integrate multiple mental relations, an ability that is considered a key component of human cognition.

Comparative and Developmental Neuroscience

Comparative Neuroanatomy

Human brain evolution is remarkably poorly understood, although it is beginning to yield its secrets to modern comparative studies. It is clear that evolution affected the human brain at many levels of organization, from the molecular biology of neurons to patterns of long-range cortico-cortical connectivity. Moreover, human evolutionary specializations are not limited to brain regions that are usually associated with higher-order cognitive functions. There are, for example, differences in the morphology and biochemistry of neurons in anterior cingulate area 24, a limbic region implicated in the affective regulation of behavior. Additionally, there are cellular and modular organizations of primary visual cortex that may be reflected in changes in the response properties of higher-order visual cortex. Thus, human specializations

are observed at the cellular level even in terms of basic visual processing.

Brain Size and Proportions of Lobes and Regions

The most conspicuous and well-known specialization of the human brain, however, is its remarkable size. Our closest relatives are chimpanzees, and average adult-human-body size is only slightly larger than that of a chimpanzee; yet, our brains are about 3 times larger: chimpanzee brains average a little less than 400 cc, while human brains average approximately 1400 cc. Most of the difference reflects an expansion of the neocortex and its associated white matter in human evolution. Although the human and chimpanzee lineages diverged some 6–7 million years ago, paleontological evidence indicates that most of this increase in brain size occurred over the last 2 million years, a point at which hominins may have begun to incorporate large amounts of animal flesh in their diet.

Traditionally, this large increase in size was thought to reflect the addition of tissue to the classical higher-order association regions, not only including the prefrontal cortex, but also the temporal and parietal association regions. The conclusion that prefrontal and other higher-order cortical regions disproportionately expanded in humans has more recently been challenged by Semendeferi and colleagues. Using MRI morphometry, they reported that the relative proportions of the cerebral mantle occupied by the frontal, parietal, and temporal lobes are about the same in humans and great apes, despite the much larger absolute size of the human brain. It must be remembered, however, that prefrontal cortex is not the same as frontal cortex: the frontal lobe contains motor and premotor cortex, in addition to prefrontal cortex. Similarly, the parietal and temporal lobes contain primary somatosensory and auditory areas, respectively, as well as association cortex. As it happens, the sizes of the primary, sensory, and motor areas in humans are, in absolute terms, very similar to those of great apes, while the association cortical regions are vastly larger in humans. Comparisons of sensory versus association nuclei of the thalamus yield similar results. Thus, the available evidence supports the classical conclusion that humans underwent an enormous evolutionary expansion of association cortex, although it is important to note that the evidence comes mainly from a handful of very old studies.

The evolutionary enlargement of the human brain could have had a number of effects on the internal organization of the brain. Many researchers have followed Brodmann in concluding that the human brain has cortical divisions (areas) that are not present in smaller-brained primates. Therefore, for example, his human map contains areas 44 and 45 – which collectively

constitute a large part of Broca's area – in the human frontal lobe, areas that are missing in his monkey maps. This is intuitively appealing, since one might expect that humans evolved new cortical areas to support novel human functions. The truth of the matter would seem to be more complicated, however: there is reasonable (if not definitive) evidence that homologs of Broca's and Wernicke's language areas exist in nonhuman primates, their lack of language notwithstanding. One might argue, more generally, that the expansion of cortex in human evolution should be accompanied by the addition of new cortical areas, since larger-brained mammals typically have more cortical subdivisions than smaller-brain mammals, but we currently lack the detailed and reliable cortical maps for humans and great apes that would allow us to definitively identify homologous areas across species and determine whether humans possess areas that nonhuman primates lack. The example of language cortex should, however, prompt us to take seriously the idea that human brain evolution was not simply an add-on process, but that it also involved modifying preexisting structures to support novel functions.

There is, in fact, evidence that the evolution of language involved physical changes in the brain other than the addition of new areas. Buxhoeveden and colleagues have described differences in the size and spacing of cortical microcolumns between the left and right Wernicke's areas of humans, differences not observed in chimpanzees or macaques. Recently, Rilling and colleagues used diffusion tensor imaging (DTI) to compare the organization of white matter pathways that interconnect Wernicke's and Broca's areas in humans, chimpanzees, and macaques. In humans, it has long been supposed that Wernicke's and Broca's areas are linked by a specific fiber bundle, the arcuate fasciculus. Using DTI, Rilling and colleagues found that the arcuate fasciculus of humans, but not chimpanzees, carries fibers from a broad region of middle and inferior temporal cortex, ventral to Wernicke's area, which are known to represent word meaning.

The advent of DTI, which enables the noninvasive tracking of fiber pathways, is a landmark in comparative neuroscience. For the first time in the history of neuroscience, it is possible to directly compare the connectivity of the human brain to that of chimpanzees and other nonhuman primates, and to explore how evolution reorganized the system of white matter fascicles that bind cortical areas into higher-order neurocognitive systems. It seems likely that the arcuate fasciculus findings will be the first of many demonstrations of evolutionary specializations of human brain connectivity.

Of course, fiber organization and long-range cortical connectivity, as important as they are, represent just one level of brain organization. As noted above, evolutionary specializations of the human brain have now been

documented at finer levels of organization, such as micro-architectural organization of neuronal groups and the biochemical and morphological characteristics of different cell types. Evidence from recent comparative genomic studies points to the possibility of rather profound differences in the organization of the molecular machinery that regulates cerebral energy metabolism and the formation and stabilization of synapses.

There remain major unanswered questions in our understanding of human brain evolution. For example, while it seems likely that the genetic program regulating the generation of neurons in embryonic life was modified in human evolution, we do not know which genes were involved. Moreover, it has been argued that human postnatal development is not simply a stretched-out version of ape development, but also includes uniquely human pre-adult developmental stages. We know very little about the genetic and neurodevelopmental correlates of such changes. There is, as noted above, evidence from gene-expression studies suggesting that energy metabolism and synaptic biology of adult human cortex were modified in human evolution; what are the psychological counterparts of these changes? Finally, we still know very little about the nature of changes in the large-scale regional organization and connectivity of human cerebral cortex that support distinctively human higher-order cognitive functions.

Fortunately, we now have methods, such as DTI and various molecular techniques, that – in the context of comparative studies – will enable us to progress on these fundamental questions about human nature. Unfortunately, comparative studies have historically not enjoyed very strong support from funding agencies, and the US government recently decided to end support for its chimpanzee facilities. Without the ability to compare humans to chimpanzees, our closest relatives, our ability to understand what it is about our minds and brains that make us human will be severely compromised.

Human Brain Development

Just as a comparison of brain structure between humans and other species can provide clues regarding possible differences in mental capacity, so can it be helpful to examine how the brain changes over development. A healthy human child is born with a brain that looks remarkably like the brain of an adult, albeit 3.5 times smaller. Our brains undergo substantial structural changes during infancy and childhood. The number of synapses in the brain reaches a maximum density of about 150% that of the adult level in the first year of life, with pruning of excess synapses taking place over the rest of childhood and adolescence. Long-range projections between brain regions are established, and the axons that functionally connect these distant regions become myelinated, leading

to faster neuronal transmission. By around age 9, a child's brain is approximately the same volume as that of an adult. However, upon closer examination, structural differences between these brains can still be observed.

During the second decade of life, changes in brain structure are less dramatic but still important. Cortical gray matter volume, which reflects neuronal density and the number of connections between neurons, peaks at around age 10–12, and then begins to decline. Gray matter loss occurs at different rates in different subregions of the brain. By the metric of rate of gray matter reduction, both prefrontal and parietal cortices exhibit protracted developmental time courses. During this second decade, steady increases are observed in white matter volume – which reflects myelination and increased axon thickness. Greater coherence of white matter tracts over development is associated with better performance on tasks that require interaction between regions connected by these tracts. In summary, both cortical pruning within brain regions and increased neuronal connectivity within and between regions underlie changes in brain function over development.

The finding that gray matter peaks at a different age for different brain regions shows that the brain matures in a piecemeal manner. The fact that brain development unfolds quite similarly across individuals invites the speculation that this piecemeal maturation is finely orchestrated. Indeed, as noted previously, evolutionary pressures come into play at all stages of development, such that brain function at each stage should be age appropriate.

Although brain maturation may, in broad strokes, unfold in a fairly stereotyped way, there are significant individual differences between children in brain structure and in the trajectory of brain maturation. These differences can provide insight into structure–function relationships. Interestingly, recent longitudinal work indicates that the dynamics of gray matter increases and decreases over childhood are associated with differences in intellectual ability, particularly in anterior PFC.

Developmental Functional Brain Imaging Research

The pattern of developmental changes in brain activation over childhood and adolescence has been generally characterized as a shift from diffuse to focal activation and from posterior to anterior activation. Differences are usually quantitative, with one age group engaging a region more strongly or extensively than another, but sometimes qualitative, with a shift in reliance on one set of brain regions to another.

Importantly, the precise pattern of change observed depends not only on the ages being examined and the brain region in question, but also on the task being performed during functional brain imaging. We have found

that a region may exhibit adult-like patterns of activation during middle childhood in one cognitive task, but not another. Thus, a region's cellular architecture and pattern of connections may be sufficiently developed to contribute effectively to a neural circuit underlying one task or cognitive function, but not to another. An important current and future direction for developmental neuroimaging studies, and also for comparative neuroimaging studies, is to examine developmental changes in the pathways and functional interactions between brain regions.

Conclusion

Both evolutionary and developmental approaches to cognitive neuroscience explore the differences in brain structure and function between organisms. Developmental cognitive neuroscience has focused on age-related differences in the function of a brain region or the organization of a brain network. In contrast, evolutionary neuroscience has, until quite recently, emphasized the similarities rather than differences between species, in particular between humans and nonhuman primates. Developmental and individual differences research shows us that, even within a species, there can be salient differences in structural and functional organization; it stands to reason, therefore, that differences should be observable across species.

We remain profoundly ignorant about how the human brain changed in evolution, but going by current evidence, it is clear that the human brain is not simply an enlarged monkey or ape brain: it is a different brain. Similarly, we still know relatively little about how the human brain develops and changes over the life span, but it is important to keep in mind that the adult brain is not merely the child brain with additional functions and circuits. Each stage of development must be functionally viable, and it is of interest to consider not only the adult brain as an endpoint, but also the specializations of the infant, child, or adolescent brain.

Glossary

Androgens – A natural or synthetic steroid hormone that stimulates or controls the development and maintenance of masculine characteristics in vertebrates. Endogenous or natural forms are produced chiefly in the testes. The primary endogenous mammalian androgen is testosterone.

Aromatase – Aromatase is an enzyme that is responsible for a key step in the biosynthesis of estrogens (estradiol or estrone) from androgens (testosterone and androstenedione, respectively).

C19 steroids – C19 steroids are a subset of androgens synthesized in the adrenal gland (adrenal androgens), that have 19 carbons and include dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulfate (DHEA-S), and androstenedione.

Estrogens – A natural or synthetic steroid that stimulates or controls the development and maintenance of female secondary sex characteristics. Endogenous or natural forms are produced chiefly in the ovaries. The primary endogenous mammalian estrogen is estradiol.

Neurosteroids – Neurosteroids are neuroactive steroids which are synthesized in the central and peripheral nervous system that can rapidly alter neuronal excitability through neurotransmitter-gated ion channels and alter gene expression through intracellular steroid hormone receptors.

Progesterone – Progestins are synthetic progestogens (e.g., medroxyprogesterone acetate (MPA)), are often combined with estrogens in contraceptive regimens or postmenopausal hormonal therapies, and may differ from progesterone in their behavioral effects.

Progestogens – Progestogens are steroid hormones that maintain the uterine lining and are thus important in maintaining pregnancy. Progesterone is the most important and the only naturally occurring human progestogen. ‘Allopregnanolone’ is derived from progesterone and affects mood and cognition.

‘progestogens’ (**Table 1**). Aromatase is the enzyme that converts testosterone and other C19 steroids (androgens with 19 carbon atoms) to estradiol. Because of this, it may be unclear, in some studies, whether testosterone has direct effects on the central nervous system (CNS) or whether it has been converted to estradiol which then affects CNS function. Aromatase is expressed in the brain, and is classically thought to regulate neuroendocrine processes and behaviors important to reproduction. However, recent studies suggest that aromatase also affects mood and cognition and thus will be considered here. Progesterone is the most important and the only naturally occurring human progestogen. Allopregnanolone is derived from progesterone and affects mood and cognition. Synthetic progestogens, herein termed progestins, are often combined with estrogens in hormone therapies and may differ from progesterone in their behavioral effects. In general, androgens are considered male sex hormones as the greatest single source of androgens are the testes and they typically have masculinizing effects. Estrogens and progestogens are considered female sex hormones as their greatest single source is the ovary. However, all of these hormones are present in each gender, albeit at different levels. Sex steroids are usually thought of as being produced in the gonads. However, some – notably estradiol, progesterone, and allopregnanolone – are produced in the CNS and these are termed neuroactive steroids or ‘neurosteroids’.

Two Major Roles of Sex Hormones

The two major ways in which sex hormones affect the CNS, mood, and cognition are through organizational and activational mechanisms. Organizational effects are achieved by developmental influences of sex hormones during critical periods that result in generally permanent sexually dimorphic differentiation of brain morphology that gives rise to sexually dimorphic physiology and behavior in adulthood. Activational effects are acute effects of gonadal hormones on the fully developed nervous system and, in general, serve to maintain sexually dimorphic physiology and behavior in adulthood.

Major Classes of Sex Hormones that Effect Mood and Cognition

The three main classes of sex steroids are ‘androgens’ and ‘estrogens’ – of which the most important human derivatives are ‘testosterone’ and ‘estradiol’, respectively – and

Table 1 Sex hormones known to affect mood and cognition

Androgens	Estrogens	Progesterogens
Testosterone	Estradiol	Progesterone
Androstanedione	Estrone	Allopregnanolone
Dihydrotestosterone		Progrestins
Dehydroepiandrosterone		
Anabolic steroids		Aromatase

Organizational Effects aka Developmental Programming by Sex Hormones

Androgens

Testosterone exposure early in life accounts for most of the known sex differences in brain structure, physiology, and behavior in rodents and nonhuman primates. Discrete periods of endogenous testosterone surges occurring pre- and postnatally suggest that these may be critical periods of organizational effects. Removal of testosterone in males by the administration of antiandrogens or castration increases female-typical behavior, whereas early administration of testosterone to females increases male-typical behavior. Behaviors that may be affected include juvenile play, grooming, aggression, sexual behavior, and maze performance (spatial ability). Sexually dimorphic behavior in the human is apparent in juvenile play (playmate and toy preferences), perhaps spatial ability, aggression, sexual orientation, gender identity, and the prevalence of behavioral pathologies such as autism, schizophrenia, and depression and anxiety disorders. Thus, sex-hormone exposure early in life may have lifelong influences on behaviors relevant to cognitive function and mood.

Estrogens

Since testosterone and other C19 steroids are converted to estradiol in the brain via aromatase, estradiol may have organizational effects in the CNS and on behavior. However, there is little specific data available about organizational effects of estrogens on mood or cognitive function.

Progesterogens

There is little evidence of organizational effects of progestogens on mood or cognitive function.

Activational Effects

Mood

Androgens

Testosterone administration in male and female rats reduces fear- and anxiety-related behavior. Mood changes, including dysthymia, depression, anxiety, and

irritability, may be found in men with low testosterone levels or hypogonadism. Classic hypogonadism may be observed in young and middle-aged men, and exogenous testosterone treatment may improve mood. Men with refractory depression may improve with exogenous testosterone therapy. Age-related hypogonadism is a part of normal aging in the later life of men. Scores on tests of depression may increase with decreasing testosterone levels. Thus, an association between testosterone and mood in men is supported by the observations that depression may be associated with reduced testosterone concentrations, mood in hypogonadal men may be improved by exogenous testosterone administration, and testosterone itself may have antidepressant properties.

The ovaries contribute about 50% of circulating testosterone either by direct secretion or by precursor production. Thus, the decline in ovarian function at menopause is accompanied by reductions in testosterone as well as estrogen. Testosterone supplementation improves the overall sense of well-being, as well as mood, suggesting that testosterone affects mood in women as well as men.

Aromatase

Understanding of the effects of androgens and estrogens on mood and cognition is complicated by aromatase – the enzyme that converts testosterone and other C19 steroids to estradiol. Animal studies suggest that hormone-related depression may involve the effects of estradiol on the neural serotonergic system which is perturbed in depression. In female rats, estradiol induces gene expression of the 5-hydroxytryptamine (serotonin (5-HT)) a receptor and the serotonin transporter (SERT) in the dorsal raphe nucleus, both of which are targeted by antidepressant pharmacotherapy with selective serotonin reuptake inhibitors (SSRIs). This results in increased densities of 5-HT_a receptors and SERTs in forebrain regions which in the human are involved in the control of mood, cognition, and emotion. In male rats, castration decreases, while testosterone or estradiol increases, 5-HT_{2a} receptor and SERT gene expression. 5 α -dihydrotestosterone has similar actions as testosterone; however, it cannot be converted to estradiol by aromatase. 5 α -dihydrotestosterone does not affect the 5-HT_{1a} receptor or SERT gene expression, suggesting that the effects of testosterone are due to its conversion to estradiol by aromatase.

Because of this conversion, it is unclear in many studies whether testosterone has direct effects on the CNS or whether it has been converted to estradiol which affects CNS function. Aromatase is expressed in the brain, and recent studies suggest that aromatase affects mood and cognition.

Aromatase knockout female, but not male, mice show increased depressive-like behaviors. Polymorphisms in the cyp19 gene, which encodes the aromatase enzyme,

are associated with depressive symptoms in women. Modifications in brain aromatase activity may affect how steroids such as estrogens modulate aggressive behavior. In animal studies, previous social experience regulates aromatase activity in the brain, and may modulate the effects of aromatization on the likelihood of aggression or components thereof such as hostility or irritability. Thus, aromatase activity may modulate certain aspects of mood.

Ovarian sex hormones

The endogenous cyclicity of ovarian sex hormone production affects emotional behavior and involves both estradiol and progesterone. Anxiety disorders such as generalized anxiety disorder, posttraumatic stress disorder (PTSD), and panic disorder are about twice as common in women than men. Anxiety represents a dysregulation of the fear circuitry. In female rats, fear- and anxiety-related behaviors vary with the estrous cycle – with lower levels than those of males during the afternoon of proestrous when estrogens and progestins are at their peak.

Depressive disorders, including dysthymia, depression, atypical depression, and seasonal depression, are about twice as common in women than in men. The risk of depression in women increases shortly after puberty and remains elevated through menopause. Women are prone to depression during times of reproductive hormone change such as puberty, the postpartum period, the premenstrual phase of the menstrual cycle, and the perimenopause, as well as during oral contraceptive use. Thus, the female reproductive system function modulates mood; however, the mechanisms are not well understood.

Not all women experience changes in mood with changing reproductive hormone milieu, suggesting a subset of vulnerable individuals. Premenstrual dysphoric disorder (PMD) is a cluster of both negative mood symptoms and physical symptoms that occur during the luteal phase of the menstrual cycle and disappear after the onset of menstruation. Women with and without PMD do not differ in gonadotropin or gonadal steroid production. Pharmacological suppression of ovarian function eliminates PMD; adding back estradiol or progesterone results in the return of PMD symptoms within 2 weeks that remit by the fourth week. The same pharmacological manipulations in women without PMD result in no effects on mood. Thus, PMD appears to be an abnormal response to normal hormonal changes and levels.

Likewise, for some women, pregnancy is a time of elevated risk for depressive and anxiety disorders. Women at greater risk of depression during pregnancy are younger, from lower socioeconomic strata, not married, and are less educated. A clinical conundrum concerns whether to treat depression during pregnancy – as antidepressants may be teratogenic – while untreated maternal depression increases the risk of poor obstetric

and neonatal outcomes. Abrupt changes in the hormonal milieu appear to be instrumental in the heightened risk for depression during the postpartum period.

During the perimenopause, the best predictor of a depressive episode is a prior history of depression. However, there is also increased risk of a first episode of depression during the perimenopause. A history of PMD or poor sleep patterns are risk factors for perimenopausal depression. The prevalence of vasomotor symptoms (hot flushes) is also associated with increased risk for depression during the perimenopause. Hot flushes may disrupt sleep-exacerbating mood disturbances, or they may reflect a particular underlying physiology that enhances risk.

Taken together, there appears to be a subset of women at risk for deleterious effects on mood of a changing reproductive hormone milieu. Factors that contribute to individual vulnerability are not understood; however, genetic factors are implicated. Monozygotic twins are highly concordant for PMD, whereas dizygotic twins are not. Women whose mothers had PMD are much more likely to have PMD themselves.

Estrogens

In general, estrogens are associated with positive effects on mood. Estrogen receptors are ubiquitous in brain areas important in mood. Estradiol regulates neurotransmitter systems implicated in depression including serotonin, norepinephrine, dopamine, acetylcholine, γ -aminobutyric acid (GABA), and glutamate, signal transduction systems important to cell survival, and has immediate effects on neuronal excitability. As mentioned above, estradiol induces gene expression of the 5-HT_{2a} receptor and the SERT in the dorsal raphe nucleus both of which are targeted by antidepressant pharmacotherapy with SSRIs. This results in increased densities of 5-HT_{2a} receptors and SERTs in forebrain regions, which, in the human, are involved in the control of mood. Estradiol also increases dendritic branching and synapse formation in the hypothalamus and hippocampus during the rat estrous cycle, and dendritic pruning follows when estrogen levels fall. As the estrous cycle is only 3–4 days in length, these represent rapid changes in neuroarchitecture and implicate synaptic remodeling in the modulation of mood by estrogens. Thus, a plethora of neural mechanisms are available through which estrogens may modulate mood.

Anxiety represents a dysregulation of the fear circuitry. Estradiol has been found to both facilitate and disrupt fear learning. These apparently contradictory findings may be due to the antagonistic roles of different estradiol receptors. There is considerable evidence that estrogens regulate aggressive behavior in many species, including the human. However, this relationship is influenced by several other important variables such as aromatase activity, estrogen receptor expression and related cofactors, and social experience. Estrogen replacement therapy in

surgically or naturally postmenopausal women has positive influences on mood and well-being. However, these positive effects on mood and well-being are attenuated by the addition of a progestogen. In animal studies, estradiol has synergistic effects with SSRIs on behavior and serotonin neurochemistry, and in surgically or naturally postmenopausal women estrogen replacement therapy can facilitate the antidepressant actions of SSRIs.

Progestogens

Progesterone may affect mood directly, primarily through interaction with progesterone receptors, or via the progesterone derivative allopregnanolone which is produced peripherally and centrally. In the brain, allopregnanolone is thought to have no effect on progesterone receptors but instead acts as a positive modulator of the GABA-A receptor. Corticotropin-releasing factor (CRF) has numerous functions in the brain including coordination of stress responses by the hypothalamic–pituitary–adrenal (HPA) axis and many other aspects of emotional arousal. In female rats, progesterone administration reduces responsiveness to CRF, and systemic administration of progesterone or allopregnanolone has anxiolytic effects.

Allopregnanolone accumulates in the brain and plasma during the luteal phase of the menstrual cycle. The increase in progesterone levels during the luteal phase of the menstrual cycle is considered to be partly responsible for the negative mood changes in PMD. Although ovarian steroids are required for the onset of premenstrual symptoms, women with PMD may also have altered GABA-A receptor sensitivity. Likewise, postmenopausal women have significantly greater negative mood symptoms during progesterone treatment than during treatment with estradiol or placebo if their circulating allopregnanolone levels are similar to those observed in the midluteal phase of the menstrual cycle, but not if they are either higher or lower. These observations suggest that optimal levels of allopregnanolone are critical for mood.

Postmenopausal hormonal therapies include a progestogen when prescribed to women with a uterus to reduce endometrial proliferation and the associated cancer risk. One of the more common progestogens in postmenopausal hormonal therapies is the progestin medroxyprogesterone acetate (MPA). In postmenopausal women, hormonal therapy using micronized progesterone has more beneficial effects on vasomotor symptoms, somatic complaints, anxiety, and depressive symptoms than MPA-containing hormonal therapies.

Cognition

Androgens

Cognitive ability including memory, attention, language, and visuospatial ability declines with age. In men, the average free testosterone index (the ratio of serum total

testosterone to sex hormone-binding globulin (SHBG)) may decline by as much as 50% between 30 and 80 years of age. Older men with higher levels of the free testosterone index have better scores in tests of visual memory, verbal memory, visuospatial function, and visuomotor scanning; whereas men who are hypogonadal have lower scores on tests of memory and visuospatial function, and a faster decline in visual memory. There is some evidence that age-related decrements in testosterone and at least some aspects of cognition may be causally related. Exogenous testosterone therapy in older men has been observed to improve certain aspects of cognitive function, notably spatial ability. Several studies also have found that men with mild cognitive impairment and men with Alzheimer's disease have lower circulating total or bioavailable testosterone. Furthermore, low testosterone levels are a risk factor for the development of Alzheimer's disease as much as 10 years in advance. Testosterone-replacement therapy in men with mild cognitive impairment or Alzheimer's disease has been the focus of a few small studies. The results have been mixed, but deserve further study.

Aromatase

Some experimental and clinical studies also suggest that aromatase activity impacts cognitive function. In songbirds, local aromatization of testosterone to estradiol enhances hippocampal-dependent processes, including spatial memory. In male rats, inhibition of brain aromatase ameliorates the spatial learning impairment induced by exogenous testosterone administered into the hippocampus, and systemic administration of an aromatase inhibitor facilitates working memory. Aromatase inhibition has been observed in some clinical studies, but not others, to prevent the improvements in memory produced by testosterone administration. Aromatase inhibitors used in cancer treatment have been observed in some studies to impair verbal and visual learning in women. Thus, aromatase activity may improve or impair specific cognitive processes, most likely by regulating estradiol levels.

Estrogens

Of all the sex hormones, the evidence for estrogen effects on cognitive function is most abundant. Estrogen acts across a broad range of neurotransmitter systems including acetylcholine, catecholamine, and GABA in animals and human beings. Estrogen receptors are present in many limbic regions involved in learning and memory, including the hippocampal formation and amygdala, and the cerebral cortex. Estradiol enhances synaptic plasticity, neurite growth, hippocampal neurogenesis, and long-term potentiation. The broad range of these effects suggests that estrogen may act as a conductor, orchestrating the functions of multiple systems important to cognitive function.

Cognitive function varies with menstrual cycle phase. In general, estrogen has been shown to enhance performance in working memory tasks, and delayed match-to-sample tasks. However, decreased performance on a delayed match-to-sample working memory task has been observed in association with the high estradiol levels of the follicular phase of the menstrual cycle when specific emotional facial expressions are used as stimuli. Thus, the effects of estradiol on memory for certain emotional information may be different. In general, male mammals appear to have better spatial ability than females. Performance on spatial-delayed-recognition span tests is poorer in primates when estradiol levels are high at mid-cycle than in the follicular and luteal phases, suggesting that estradiol influences spatial ability.

Decrements in cognitive function are associated with menopause. Estrogen therapy initiated in the early postmenopausal period improves cognitive function, particularly memory, and may decrease risk of Alzheimer's disease. Estrogen therapy initiated late in the menopause has no beneficial effects on cognitive function, and may increase the risk of Alzheimer's disease, suggesting a critical window for beneficial effects of postmenopausal hormonal therapy on cognitive function.

Progestogens

The majority of research on sex hormone effects on cognition has focused on estrogens. However, progestogens have powerful effects on a broad range of neural systems, and these effects may be progestogen specific. While progesterone has important neuroprotective properties that may protect against cognitive decline with age, other progestogens may not share these characteristics. In rats, acute treatment with allopregnanolone has GABA_A-agonist effects that impair learning and memory. In women with PMD, difficulty in concentration and impairment in working memory accompanies mood changes during the luteal phase when progesterone and allopregnanolone concentrations are high. Cognitive disturbances are common during pregnancy and tend to become apparent in the second trimester when progesterone and allopregnanolone levels are high in the brain. In normal, healthy, cycling women, exogenous progesterone administration impairs facial recognition accuracy. Progestogens, most commonly progestins, are combined with estrogens in hormonal therapy for postmenopausal women with a uterus. The inclusion of a progestin may antagonize the beneficial effects of estrogens on cognition.

Combined hormonal therapy initiated late in the menopause increases Alzheimer's disease risk over that reported for estrogen therapy alone. Further investigation is needed to clarify the effects of progestogen on cognitive function.

Glossary

Convergent evolution (homoplasy) – The acquisition of similar traits in unrelated lineages; that is, two lineages share a trait, but not because of common descent with shared ancestry.

Gaze-following – Looking in the direction that others are looking based on various cues including eye, head, and body position.

Mutualism – A type of cooperative interaction in which two or more individuals obtain a benefit from working together that they would not have obtained alone

Perspective-taking – The ability to reason about what others perceive, given that others may perceive aspects of the world differently than oneself. For example, an individual standing in one location may not be able to see everything that is visible to an observer in a different location.

Phylogeny – The pattern of relatedness between species and taxonomic groups, representing the evolutionary branching pattern of speciation leading to extant (living) species.

Social cognition – Processing social information. Social-cognitive skills can depend on the information provided the overt behavioral cues of others (in what direction are they looking or moving?) or depend on more mentalistic processes (what do others see or want?).

Social tolerance – A measure of how individuals in a species interact. Species with high tolerance tend to have more relaxed dominance hierarchies, and can sit in close proximity and even co-feed without much aggression. Species exhibiting less tolerance may have more ‘despotic’ hierarchies and show more aggression when interacting.

Theory of mind – The ability to attribute various mental states – such as beliefs, desires, and knowledge – to other individuals. Perspective-taking is one component of theory of mind.

as a driving force in primate cognitive evolution. This basic thesis – that the sophisticated cognitive abilities of primates have evolved for a social function – has spurred experimental and theoretical investigations for over 40 years. Although, most early proposals of the social intelligence hypothesis were inspired by observations of seemingly complex social behaviors across the primates, however, the psychological mechanisms underlying these behaviors were not well understood. It was not until relatively recently that research began to address the cognitive abilities primates actually use when interacting with others, such as whether other primates share capacities like theory of mind with humans.

In this article, we highlight a selection of complex behaviors that primates exhibit when interacting with others, with special attention to the cognitive mechanisms supporting those behaviors. Fundamental to the study of comparative cognition is the idea that many species may exhibit behaviors that appear similar, even though the psychology underlying those behaviors may differ across taxa. While this distinction may be methodologically frustrating – behavioral observations are a rich source of knowledge about animal psychology, and experimental tests of cognition may not always be viable – in fact, it is a testament to the ingenuity of evolution: the hard social problems that primates face get solved, even if the solution is not always the same! This distinction highlights the importance of thinking about primate social interactions not only in the context of behavioral evolution – the special things that primates (and humans) do – but also in terms of cognitive evolution – the special ways that primates think. We use this framework to analyze primate social behavior, and the differing psychologies underlying this behavior, in three areas: gaze-following, food competition, and mutualistic cooperation. The ultimate challenge of such analyses will be to understand why such different cognitive mechanisms have evolved across species.

Gaze-Following: Reflective Orienting or Understanding of Attention?

Imagine a small group of chimpanzees foraging in close proximity in a forest. One chimpanzee hears something in the trees, and looks up. The other chimpanzees follow suit. What cues lead the other chimpanzees to look up: the change the first chimpanzee’s head position, or more

Introduction

The social world has long been thought to be a major force shaping primate cognition: the social lives of primates are thought to be sufficiently complex to have acted

specifically a change in that chimpanzee's eye position? Did they follow gaze because they thought that the first chimpanzee had seen something, or was the process more reflexive, relying on an egocentric mechanism? Now imagine the same occurrence in a group of capuchins. Did these very different primates use the same cues as the chimpanzees? Do they understand the situation in the same way?

Gaze-following or co-orienting behaviors like this allow individuals to apprehend important objects and events that others have detected in the environment, including food sources, predators, and conspecifics. Thus, gaze-following allows individuals to exploit the information that others have acquired about the world. At the most basic level, diverse species of primates spontaneously follow the gaze (face direction) of human experimenters or conspecifics. Species including chimpanzees and the other great apes; Old World monkeys such as various macaques, mangabeys, and baboons; New World monkeys including capuchins, cotton-top tamarins, and common marmosets, and even some lemur species, all follow gaze, at least to a certain degree in some contexts.

Although gaze-following behaviors are widely shared across the primate order, the psychological basis of these co-orienting behaviors seem to vary widely, especially in how flexibly this behavior is deployed. First, different species may vary in what cues they use to follow gaze. For some species, there is evidence that individuals can successfully follow eye position alone (e.g., apes). Other species, in contrast, appear highly dependent on shifts in the position of the face, head, or even entire body (such as capuchins, tamarins, and lemurs). Interesting, this variation may be due to variation in the amount of information that the eye carries due to differences in eye morphology across different taxa.

Secondly, gaze-following appears to reflect understanding of attention in some species, but may be more of a reflexive response in others. For example, gaze-following in chimpanzees and other great apes suggests that individuals of these species follow gaze because they understand something about the nature of seeing. Apes not only direct their own gaze in the direction of others, but also follow gaze around barriers and past distracting objects that are not the target of another's gaze, sometimes by physically reorienting their own bodies. They may also check back with the actor in attempt to verify the direction of the other's gaze or quickly stop following the gaze cues when they cannot locate the target of the other's gaze. These flexible shifts in behavior across contexts suggest that apes follow the gaze of others because they expect there to be something interesting to see.

The evidence for such behaviors in more distantly related primate species is less complete, mostly because few studies have been conducted. Macaques, like apes,

habituate to repeated gaze cues when they repeatedly cannot locate the target of another's gaze. However, studies of New World monkeys and lemurs suggest that the co-orienting behaviors in some of these species are more reflexive and used in more limited circumstances. For example, cotton-top tamarins will co-orient with conspecifics at high rates during natural interactions (although the cause of this co-orienting is unclear), but fail to follow the explicit gaze cues provided in controlled experimental settings. Similarly, some lemur species co-orient with conspecifics during their natural behaviors, but seem less able to follow gaze in experimental contexts. Thus, although behavioral co-orienting may be common to all primates, not all primates necessarily follow gaze because they understand that others see things. Thus, observations of different species of primates altering the direction of their gaze in response to another individual doing the same does not mean that this behavior is modulated by the same cognitive mechanism.

Competition for Food: Behavioral Predictions or Visual Perspective-Taking?

Imagine the same group of chimpanzees foraging in the forest. As most of the group is distracted, busy following the gaze of that first chimpanzee, a young male realizes that the group has come upon a fig tree with many ripe fruits. He knows that if he has to compete with more dominant individuals for this food, he will likely lose out. Luckily, he spots a large fig that is hidden behind a fallen log and thus out of sight of the others, and quickly runs to take it. What cues led him to target that piece of food, and not another in full view of the other group members? What did he think when he did so? What would it mean if a capuchin was spotted doing the same thing?

Food competition like this is an important consequence of the fact that primates are social living animals: although being gregarious has benefits, it also has costs. Dealing with competition with conspecifics is, therefore, a major problem that primates have to solve. However, there are different ways to deal with such competition that might be quite successful. One possibility is to become a skilled behaviorist, or an expert in using the actions of others in order to decide what to do. In this case, the young chimpanzee might be especially sensitive to the orientation his competitors head and body, as well as any indication that the competitor was going to approach another piece of fruit. A soon as the competitor headed one way, the male headed the other – in this case, to the fruit behind a log. An alternative strategy is to become a mentalist. Rather than depend on the actions of others when making social decisions, a mentalist might form representations of what others perceive – or even

know – and act based on this model of what is going on in the other individual's head. In this case, the male might have realized that, even though he could see the fallen fruit, the competitor could not do so from his different spatial position, and thus it was safe to take the fruit.

These two potential mechanisms might look the same in a naturalistic context, leaving even the most skilled observer of wild chimpanzees and capuchins in a tough predicament: how to determine if chimpanzees and capuchins are approaching this problem in the same way? Luckily, these different underlying psychologies predict very different outcomes in experimental manipulations. For example, a behavior-reading strategy might function perfectly well in most natural situations in which the behavior of others is readily apparent. However, this kind of cognition should break down when such behavioral cues are not available for the formation of predictions. A mentalist strategy, in contrast, should be functional in this context whenever there are cues to what another agent perceives, because a mentalistic can infer how seeing is linked to future behavior – even if the competitor has not yet undertaken any actions to observe and react to. This type of cognition, consequently, would potentially allow animals to integrate different types of behavior and contextual cues into a representation of an unobservable phenomenon – another's psychological state – without limiting behavioral predictions to only specific types of input from the environment (the current behavior of that individual, such as the direction in which they are facing at the moment).

These different hypothetical mechanisms for predicting other's behavior has been tested in chimpanzees in a situation where two chimpanzees must compete for access to food. As in the example above, the two chimpanzees had differing knowledge about the food that was available: the subordinate could see both pieces, but only one was visible to the dominant. When both individuals were released into this room, the subordinate targeted the piece that only she could see – a result that is consistent with either cognitive mechanism. Support for a mentalistic view, however, is provided by a condition where the subordinate was released before the dominant. Even though monitoring the other chimpanzee's actions would not be successful in this context, the subordinate still preferred the hidden piece. This suggests they predicted what the competitor would do, instead of simply reacting to what she was doing. A second set of studies further supported the hypothesis that chimpanzees used a mentalistic strategy. Here, both the subordinate and a dominant watched the food items being baited, but sometimes the dominant was switched with another dominant before the competition began; that is, although a dominant always saw the baiting, and a dominant always was competing for the food, sometimes the current competitor had not witnessed the baiting and thus did not know

where the food was located. The subordinates made more attempts to obtain the food when the current dominant had not been present during baiting than when no switch occurred. Thus, the chimpanzees behaved as though they understood that seeing the baiting led to knowing where the food was located – even without overt behavioral cues on the part of the dominant.

Following these initial studies, several experiments using competitive paradigms have assessed similar perspective-taking skills both in apes and monkeys. For example, when rhesus macaques can choose to steal food from one of two human experimenters, they show sensitivity to variations in visual access and prefer to approach food in front of an experimenter with limited visual access (e.g., because their eyes are covered) than food in front of an experimenter with unimpeded visual access (e.g., their mouth is covered in a similar fashion, but they still can see). Studies with chimpanzees have similarly shown that they prefer to retrieve a piece of food that a competitive human cannot see, even attempting to disguise their interest in the food as they approach. Critically, in both of these examples the experimenters provide no direct behavioral cues to what they can and cannot see, such as by touching or approaching some of the food. Rather, primates in these studies must infer which food option is 'safe' from the direction of the humans' gaze and whether the gaze is impeded by barriers – suggesting that these primates do not simply react to the behaviors that they observe, but rather predict what others will do by reasoning about their unobservable psychological states in a flexible manner.

Moreover, some evidence suggests that the perspective-taking that chimpanzees and rhesus monkeys engage in extends to the auditory modality – providing further evidence that these species can integrate many disparate cues to reason about psychological states. For example, when rhesus macaques are confronted with a human competitor sitting in front of two boxes containing food, they preferentially steal food from the box that is silent, and do so only when the competitor cannot already see their actions. This suggests that rhesus monkeys recognize how their behavior will alter the psychological state of the human: if the human cannot see them, then the noise will alert him to their presence. If the human can already see them, then noise will have no impact on the human's knowledge about their behavior. Chimpanzees similarly prefer a silent approach over a noisy one when competing with a human over food.

This mentalistic strategy, however, does not appear to be shared by all primates. For example, both capuchins and marmosets have been tested in versions of the conspecific competition paradigm. Subordinate capuchins are quite successful when released concurrently with the dominant: like chimpanzees, they preferentially target the hidden piece of food. However, in the critical test in

which the subordinate is given a head start and must make a decision in the absence of any behavioral cues, capuchins are flummoxed – in fact, it seems they are not sure which piece to approach until they can see the direction the dominant will take first. Similarly, marmosets target the hidden food in the basic food-competition task, but a series of additional tests suggests that they lack any real understanding of visual access, supporting the conclusion that their successful behavior when competing is due to a behavior-reading mechanism. That is, both species appear to depend heavily on the behavior of the competitor, rather than reasoning about what the competitor sees or knows, when competing for contested food.

Thus, although chimpanzees, rhesus macaques, capuchins, and marmosets all show the same complex behavior in the naturalistic context – targeting the hidden piece of food and thus successfully competing with a dominant – they appear to do so in very different ways: chimpanzees and rhesus depend on a mentalistic interpretation of the situation ('she can not see the food, thus it is safe for me to approach and take it'), whereas capuchins and marmosets depend on the behavior of their competitor to make their social decisions ('she is heading toward that piece, thus I will try to take the other').

Mutualistic Cooperation: Working Together or Working Alone In Proximity?

As the same group of chimpanzees is foraging in the forest, it becomes clear that the earlier noise in the trees was not incidental – it is a group of red colobus monkeys that have (unfortunately for them!) strolled too close to their ape predators. The chimpanzees become silent, and then a subset of the group takes off after the monkeys, some in the trees and some on the ground. After a lengthy pursuit, one of the adult males makes a kill, and later shares meat from the carcass with one of his close allies. What did the chimpanzees understand about the pursuit as it was happening, and how did they view their individual behavior in the context of the group's behavior as a whole? Why did the successful male share meat with his friend? If several capuchin monkeys are spotted chasing and catching a squirrel in a similar fashion, would such behavior be under the control of similar cognitive mechanisms as those seen in chimpanzees?

Group-level cooperative activities such as this are increasingly thought to be important for understanding human cognitive evolution: one thing that seems to distinguish us from even our closest phylogenetic relatives may be the ability to pool individual resources to reach a common goal. In many ways, humans are the ultra-social species! Consequently, examples of complex cooperation in other primates are often quite telling, giving researchers hints of what might have changed in the

human lineage. Cooperation is certainly not something that is unique to the human, however – indeed, like food competition, cooperation in primate societies results from the fact that primates are gregarious. Thus, many primates have been studied in experimental paradigms that examine the cognitive abilities underlying cooperative behaviors.

Human-like cooperation seems to involve many interacting components: in cooperative situations, people typically take on different, mutually reinforcing roles (division of labor), account for what others meant to do, as opposed to what they ultimately ended up doing (attend to the intentions of others), and choose their partners based on how they acted previously in cooperative contexts (reputation and image scoring). One possibility is that some primate species might understand their particular cooperative endeavors like humans. Other primates, however, might cooperate quite successfully without possessing all those components – or, indeed, any of these components. For example, did the pursuing chimpanzees view themselves as part of a group effort to obtain meat, or did each individual have his own strategy to obtain a monkey (but happened to act simultaneously with several other individuals with the same idea?). Did the male who made the kill share meat because he understood that his friend played a crucial role in capturing the monkey, or did something else (such as a desire to prevent intrusive begging) drive his generosity?

We distinguish two broad types of strategies from successful cooperation – recognizing, of course, that many other variants undoubtedly exist. One type of cooperation stems from high levels of inter-individual tolerance: because individuals of such species tend to be in proximity to one another, they show high rates of by-product cooperation just by virtue of time spent together in close affiliation. For example, the chimpanzees in the hunting example may like to groom and sit near each other; thus, they tend to be together when a group of colobus appears. Although their actions in the pursuit appear mutually reinforcing toward the goal of capturing the monkey, the goal is not shared from the perspective of individual chimpanzees. Rather each individual tries to catch the monkey on his own without regard for what other individuals are doing. An alternative is cognitive cooperation: species that have some understanding of the cooperative act itself and the role of their partners in that act. For example, the hunting chimpanzees might actually have realized that hunts are more likely to be successful if different individuals pursue the monkey from different directions, even playing different roles in the pursuit (e.g., one chimpanzee chasing the monkey in the clutches of another). As with gaze-following and food competition, experimental tests of cooperation can help to disentangle these two solutions to the problem of cooperation.

Tolerance appears to play a critical role in facilitating cooperative behavior across a number of species, and

variation in tolerance predicts successful outcomes in cooperative tasks both within and between species. For example, in one study, rhesus and Tonkean macaques were confronted with a problem: there was food placed under a large stone, but no single individual monkey was strong enough to move it. Two monkeys working in tandem, however, could displace the rock and access the food. Only the Tonkean macaques succeeded at doing so, however, and the cause for this differential success seems to be different levels of tolerance in these two species. Rhesus have a ‘despotic’ social structure with strict dominance hierarchies, whereas Tonkean macaques have a more relaxed dominance system. Higher levels of tolerance result in a higher likelihood that a pair of Tonkean macaques would sit in close proximity and attempt to move the stone in tandem. Notably, there was no evidence that the Tonkean macaques understood the problem better than did their close phylogenetic relatives; rather, the Tonkean macaques were just more likely to engage in individual attempts to move the rock at the same time that another individual was doing the same thing.

Results from other primate species confirm that cooperative success can depend heavily on the nature of the relationships that exist between individuals, rather than cognitive abilities *per se*. For example, when pairs of capuchins are presented with an apparatus in which two handles must be pulled simultaneously to acquire food, but the handles are too far apart for one individual to pull both alone, the monkeys show a high rate of success. However, an examination of what the capuchins actually did during the operation of this apparatus indicated that the individuals seemed to pull the handle without regard for what their partner was doing: that is, both pulled at a high rate and thus succeeded basically by accident, but the monkeys did not try specifically to pull in concert with their partner. Similarly, when marmosets were presented with an instrumental cooperative task in which one individual had to pull a lever so that another could grasp a bowl of food, success depended on the role that the dominant and subordinate took. Although individuals had previously shown proficiency in the components of the task when tested alone, only those pairs where the subordinate pulled the lever and the dominant took the food showed any success when working together.

Personal relationships appear to play a similar role in ape cooperation. In a series of experiments, pairs of chimpanzees were confronted with a rope attached to an out-of-reach tray of food. If two chimpanzees pulled both rope ends together, they could eat the food; if one individual tried to pull the rope alone, the rope came unthreaded. The level of tolerance between any two individuals – as measured by their ability to share food in the absence of the cooperative component – was the major determinant of whether that pair would successfully cooperate.

Similarly, bonobos – the sister species of chimpanzees with greater levels of inter-individual tolerance – appear to be more successful than chimpanzees on a version of this task. However, unlike some of the studies with monkeys described above, chimpanzees do not seem to cooperate merely as a by-product of this tolerance. While chimpanzee cooperation is constrained by personal relationships between individuals, it also has a complex cognitive component. For example, chimpanzees know that they need a partner for the cooperative task, and are more likely to recruit that partner (by unlocking a door and allowing the other individual access to the room) when the task requires two individuals than when it can be solved alone. Moreover, chimpanzees prefer to recruit partners that are more successful at the task than those that are less skilled, and recruit those that have recruited them in the past over those that have failed to do so. Thus, chimpanzees seem to remember the past cooperative behavior of others and understand how that influences their own possibility of success now. These results suggest that while tolerance does constrain chimpanzee cooperation, chimpanzees are also cognitive cooperators that understand the role their partner plays in the joint endeavor.

Conclusions: How Does Social-Cognition Evolve?

In this article, we have attempted to highlight some major social problems that primates face, as well as the potential diversity of cognitive solutions to these problems. These particular examples, however, are by no means the only social problems where primates show complex behaviors. Indeed, there are many other examples of primates being quite sophisticated in navigating their social world, in social learning, communication, deception, and knowledge of relationships. Similarly, the cognitive ‘solutions’ to these problems that we have highlighted are not the only ones that primates may use: research on the psychology of most primate species is extremely limited, and it is likely that the future will reveal a much wider range of cognitive mechanisms than research thus far has addressed. However, the examples discussed here serve as important reminders that behavioral complexity can be driven by a diverse set of underlying mechanisms.

In the end, two big questions remain: to what extent do humans and other primates solve social problems in a similar fashion, and why do different species (including humans) solve similar behavioral problems with different cognitive solutions? The first question is a fundamentally phylogenetic one, and research on chimpanzees and bonobos – our two closest primate relatives – have begun to pinpoint how the social cognitive abilities of these apes are shared or differ from our own. As the

studies of gaze-following, perspective-taking, and cooperation mentioned here reveal, in many ways they are surprisingly similar, challenging researchers to come up with new hypotheses about what cognitive traits are unique to our species. The second question is an evolutionary one, and may prove to be the more challenging of the two because it requires reconstructing historical events – evolutionary change and the forces that drove it – that cannot be directly observed. For this question, comparative studies of cognition like those described here, in which the performance of closely related species are examined in similar contexts, are a powerful tool. This is especially the case when such studies are conducted with a focus on the ecological or social variables that may have driven cognitive evolution across taxa.

Studies of social cognition in primates thus provide an important lesson for the cognitive sciences as a whole: there is no such thing as ‘primate social cognition’! Although shared phylogenetic history and convergence does result in cognitive traits that are similar across species, comparative research has increasingly revealed the diversity of primate social psychology. Thus, in many ways it is more appropriate to talk about ‘chimpanzee social cognition,’ ‘rhesus macaque social cognition,’ or ‘tufted capuchin social cognition.’ Notably, this is not just true for primates: research has begun to reveal social-cognitive mechanisms in other groups of organisms as well. For example, wild spotted hyenas live in large social group with monkey-like linear dominance hierarchies and engage in cooperative hunting behaviors. Accordingly, these carnivores (but possibly not their close relatives – the relatively less social brown hyena) appear to possess sophisticated social-cognitive skills that deal with their social landscape, such as understanding of third-party relationships. Canids have emerged as an important model for the evolution of communicative gestures comprehension: in contrast to wolves, dogs are skillful at using points and gaze cues to find hidden food, possibly because of selection during domestication. The most sophisticated social-cognitive skills are found in corvids – a group including jays, ravens, and crows. Studies of these birds have revealed startling parallels with the abilities of primates. Specifically, corvids appear to employ many social cognitive skills (such as perspective-taking or encoding the ‘reputation’ of potential

competitors) to protect their food stores when they engage in caching behaviors.

Such an emphasis on the differences between species can challenge approaches that use a few ‘model’ species for understanding cognitive traits. However, these instances of convergence among distantly related species, like primates and birds, provide opportunities for biologists to test evolutionary hypotheses about the function of specific social-cognitive skills. A complete understanding of the evolutionary pressures leading to complex social cognition requires that scientists look beyond primates to determine the causes and origins of complex cognition. Thus, we hope that we have piqued interest as to what the causes and origins of social cognitive mechanisms might be.

Introduction

The growing recognition of the complex, multisystem nature of normal sleep physiology, which reached a peak in the 1970s, was associated with the appreciation that, far from the traditional view of sleep as benign and innocent, dysfunctional possibilities abounded – and many were soon documented. By the early 1990s the sleep disorders medicine movement had taken shape, and now it is a worldwide process which has changed the interface between internal medicine, neurology, and psychiatry forever.

Today, sleep disorders medicine is a large and still growing field that is testimony to the power of one unique principle: physiology is state dependent. Because the brain undergoes such dramatic reorganization over both the circadian and ultradian phases of its operation, the central control of virtually every bodily function is mechanistically altered over time. As a consequence functions like respiration – once considered stable – are changed beyond recognition as the brain changes its state. In the case of respiration, it is thus quite normal for breathing rate, depth, and efficacy to change as waking gives way to non-rapid eye movement (NREM) and then rapid eye movement (REM) sleep. Airway patency is also normally altered in sleep. Furthermore, inspiratory neurons, defined in waking, may no longer be inspiratory neurons in sleep. Sensitivity to blood gases such as oxygen (O_2) and carbon dioxide (CO_2) may change or even reverse in sleep.

Because sleep disorders medicine is already so complex a field, it may be helpful to approach its many manifestations from the vantage point of general principles. The result of such a re-ordering of data may seem oversimplified to the specialist but can be clarifying for the uninitiated. The principled approach is the one taken here. Readers, and especially medical professionals who seek state-of-the-art details should consult a more detailed and definitive text such as Kryger *et al.*

State Dependence and Pathophysiology

To understand sleep disorders, it is important to recognize the consequences of normal changes in brain-state control systems. Some of these are detailed in the main

entry: sleep. Only the consequences of sleep disorders will be emphasized here.

Any system with changing activation levels and patterns is subject to alterations of its functional capacity according to the ‘level-setting function’ of its control system. The sleep disorders that can be expected are the insomnias (when the level set for waking is too high) and the hypersomnias (when the level set for waking is too low). We now know that level setting is, in part, a function of brainstem aminergic systems. This recognition helps us intuitively link the insomnias to anxiety disorders via the common ground of aminergic hyperactivation. This is a key point because many people who consult sleep disorders specialists (or any other caregiver) are often anxious worriers who have trouble falling asleep. If they are at the opposite end of the arousal spectrum (and feel sleepy all the time), they are more likely to be depressed and lethargic rather than anxious and hyperactive.

These same contrasts and extremes distinguish between otherwise normal short sleepers and constitutionally constructed long sleepers. We do not expect everyone to be 5'8" tall even though that is the mean height. We will not be surprised to find 7' plus individuals (on the high end) and 5'8" or even 4'6" on the short end. We do not advocate shrinking the tall or stretching the short, so why do we make such a fuss about normalizing sleep length? The answer is that administrative and social assumptions work against biodiversity. We want the same work and school schedules for everyone but nor everyone is ready to get up – or go to bed – at the same time.

The brainstem control systems for sleep and wake are not only set at different levels but undergo different rates of change in time. Thus, it may take some people 35 min to fall asleep while others accomplish the task in 30 s. Short sleepers tend to be hyperactive and to postpone sleep onset so that when they do go to bed, they are sleepy as a natural consequence of deprivation and sleep-ready in terms of fatigue. Long sleepers do just the opposite, so spending more time in bed awake.

Complementing the changes in level setting are ‘timing errors.’ These errors may arise in the input–output gating systems that make response to external stimuli more or less likely over the sleep–waking cycle. Gating systems also determine the likelihood that internal stimuli will be generated. These systems change level radically in synchrony with the NREM–REM sleep-cycle oscillation.

They too produce differential effects according to the level at which they are set and give rise to a new kind of dynamic problem. For example, it is not a good idea to turn on motor-pattern generators in sleep before quelling muscle tone. An unwanted consequence of such timing error could be motor activity such as is seen in the so-called parasomnias, including sleep walking, sleep talking, or the REM sleep behavior disorder (RBD). Similarly, it is not a good idea to turn on the visual hallucinations of dreaming before sleep begins or keep them going after awakening. This is the cause of hypnagogic and hypnopompic hallucinations, respectively. These hallucinations are very frightening to affected subjects who assume that they may be psychotic.

Life Cycle Changes in Sleep

The dynamics of sleep propensity and coordination are impressively great for any individual at any time of life, but there are also prominent changes in sleep across the life cycle. Young people sleep longer, more deeply, and feel more refreshed than the elderly who may complain bitterly about their shallow, fragmented, and unrefreshing sleep. Throughout life, sleep is thus always getting worse with respect to itself. Old persons do not sleep like babies anymore than tennis champions play for more than 5 years. In midlife, this conversion from long-and-deep to short-and-shallow sleep begins with the normal loss of slow-wave sleep (SWS) at about age 40. There is an associated fall in anabolic hormone release so that fat/protein ratios increase. This unfortunate progression is not insomnia. It is physiologically less deep sleep and should be accepted as such.

Neurobiological Basis of Sleep Disorders

Sleep and waking are controlled by brainstem neuronal oscillators which must interact in a coordinated way to produce orderly sequences of behavior. Chief among the control systems is the circadian oscillator in the hypothalamus, which programs rest and activity in coordination with ambient light levels. Its activity is also synchronized with body temperature and energy regulation via food and metabolic caloric control (see Figure 1).

The circadian clock normally suppresses the pontine NREM-REM sleep oscillator via an orexinergic signal from the hypothalamus to the aminergic neurones of the pons. This signal keeps those cells active in waking. When aminergic activity reciprocally declines, cholinergic activity increases ultimately leading to REM sleep. The hypothalamic and pontine oscillators, both, interact with the respiratory center in the medulla giving rise to the idea of the brainstem as a set of coupled oscillators whose

interaction is crucial to normal and abnormal sleep. The problems associated with the set points and timing of the neuronal components of these systems have already been discussed here.

Too Little Sleep: The Insomnias

Many factors can influence the necessary reduction of aminergic activity that permits sleep to occur. Chief among them are signals that the thalamocortical system is still in the waking mode. In the vernacular, this is what is meant by ‘taking a problem to bed with you.’ As long as obsessive rumination over uncompleted or conflictual wake-state behavior persists, aminergic activity remains high and sleep cannot be initiated.

If the level of aminergic activity remains high, sleep may be interrupted as maintenance of sleep fails. This leads to early-morning awakening. The best antidote to aminergic overactivity is a combination of relaxation training, self-induced sleep deprivation, and exercise – three physiological processes which favor sleep. We recognize three main timing defects as afar as insomnias are concerned: initial, central, and terminal insomnias.

Difficulty falling asleep with a sleep latency of over 30 min (initial insomnia) is usually related to psychological, psychiatric, or situational problems; it may be due to environmental factors and inadequate sleep hygiene. Central insomnia is, instead, due to a tendency to hyperarousal. External insomnia may be linked to medical or psychological problems ranging from primary sleep disorders, chronic pain from arthritis or cancer, and metabolic disorders such as diabetes and hypertension. Early awakening from sleep (terminal insomnia) is strongly associated with mood fluctuation or it may be due to circadian rhythm alterations such as the advanced sleep phase typical of many elderly patients who have little else to do, go to bed earlier and earlier, and hence awaken in the early morning.

There are acute adjustment insomnias and chronic, idiopathic, or psychophysiologic insomnias when patients report evidence of conditioned sleep difficulty and/or heightened arousal in bed due to somatic or mental tension. This kind of insomnia is aggravated by unfamiliar and irregular sleep-timing settings.

Paradoxical insomnia refers to the complaint of severe insomnia unsupported by objective evidence of sleep disturbance and without commensurate daytime impairment.

The overestimation of sleep difficulties contrasting with polysomnographic (PSG) evidence of adequate sleep represents the key feature of this nosological entity. Drugs or substances of abuse (e.g., nicotine, cocaine, alcohol) may also interfere with the normal physiology of sleep. Therapeutically prescribed drugs responsible for iatrogenic insomnia include antidepressants such as the

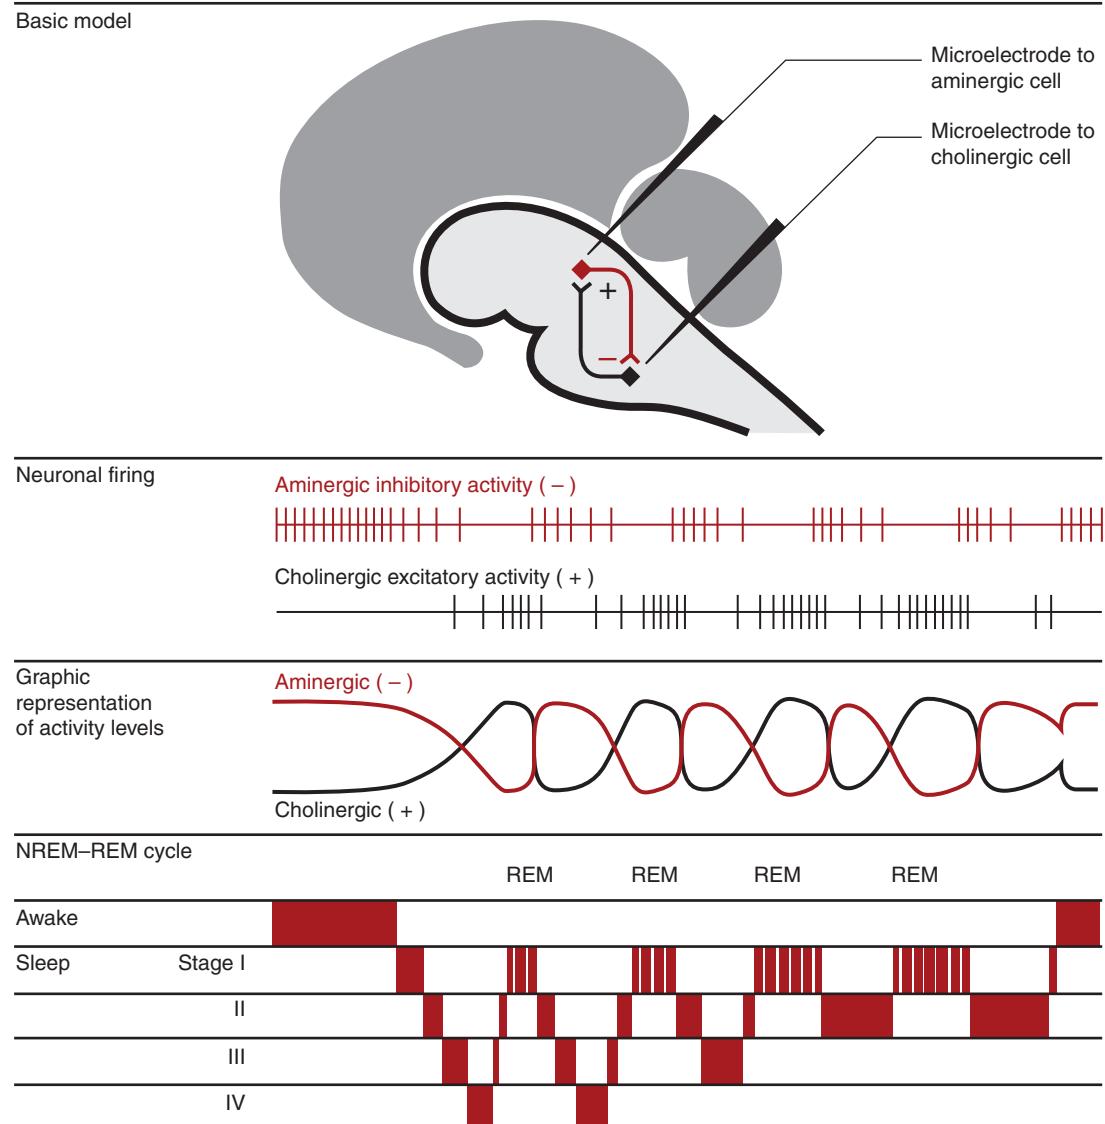

Figure 1 Reciprocal interaction model of state control. This depiction of one night of sleep, based on EEG recordings which differentiate the various stages of sleep, reveals some characteristics of normal sleep. First, sleep is 'deepest' early in the cycle and tends to become shallower. Second, the REM periods tend to be short early in the night and tend to be progressively longer as the night goes on. Animal studies indicate that this rhythm is generated by the alternating activity of specific nuclei of neurons in the brainstem. Some of these nuclei are strongly inhibitory and mediated by serotonin and norepinephrine; their actions are opposed by a group of excitatory cholinergic and glutaminergic neurons. By using microelectrodes, the activity of the various nuclei can be tracked at the level of single neurons, and neuronal firing can be recorded. By plotting the intensity of firing on a vertical axis, the neuronal activity over time reveals a sinusoidal pattern which matches the rhythm of the EEG record.

selective serotoninreuptake inhibitors (SSRIs), clomipramine, antihypertensive medications, the statins, antibiotics, and theophylline.

Unless an organic condition such as sleep apnea or periodic leg movement is suspected, nocturnal polygraphic recording is rarely needed for diagnosis and should be reserved for the insomnias that are refractory to therapeutic trials. Sleep diaries and ambulatory actigraphic devices may help to distinguish the validity of reported symptoms and different patterns of behavior (see

the concluding section titled 'Diagnosis and treatment of sleep disorders').

Pharmacological treatment by hypnotics (benzodiazepines with short or medium half-life such as triazolam and estezolam), and γ -aminobutyric acid (GABA-A) modulator hypnotics (e.g., zolpidem, eszopiclone, or melatonergic agonists such as ramelteon) are sometimes indicated in the acute or subacute conditions for periods <1 month. Sedative antidepressants such as mirtazapine, amitriptyline, trazodone, maprotryptiline, mianserine, doxepine, or

beta-blockers can be helpful in chronic insomnias. The effective use of these drugs must always be supported by attention to sleep hygiene and by cognitive behavioral therapy.

Too Much Sleep: The Hypersomnias

When aminergic activity is low or unsustained by orexin, cholinergic drive increases with consequent feelings of lethargy, fatigue, and even depression. This physiology is associated with sleepiness and a tendency to fall asleep at unwanted times during waking. Among the most common specific causes of hypersomnia are narcolepsy and depression.

Narcolepsy

This rare but instructive sleep disorder is caused by the almost complete loss of hypothalamic neurons containing hypocretin (a.k.a. orexin) – a neuropeptide essential to the maintenance of wakefulness. As a consequence of inadequate facilitation of aminergic neurons in the locus ceruleus and other pontine aminergic nuclei, the REM sleep oscillator is triggered during the daytime. Strong emotion may contribute to this triggering process, which explains why narcolepsy was so long thought to be psychogenic.

Afflicted individuals have compelling attacks of sleep often with sudden loss of muscle tone (cataplexy). These two wake-state symptoms are manifestations of level setting changes in the REM sleep-generator circuits. Narcoleptic patients may also show examples of timing errors in such sleep-related symptoms as sleep-onset REM periods (SOREMPs) with dream-like visions called hypnagogic and with hypnopompic hallucinations and sleep paralysis (the persistence of dream imagery and atonia into the postsleep awakening period; see Figure 2).

Confirming the clinical symptoms, the diagnosis of narcolepsy requires nocturnal polygraphic recording revealing of two or more SOREMPs and a short mean sleep latency, usually less than 2 min. Sleep laboratory testing is followed by daytime assessment of sleepiness by the Multiple Sleep Latency Test (MSLT). Orexin levels in the cerebrospinal fluid (CSF) may be obtained and found to be less than one-third of mean control values. The presence of a human leukocyte antigen (HLA) DQB1 0602 typing is a supportive, but not diagnostic, criteria which may be found in 90% of patients with narcolepsy/cataplexy.

Nowhere in sleep medicine can one find a more complete overlap between the symptoms of a disorder and the underlying pathophysiology. Complementing this intellectual triumph is therapeutic efficacy using drugs known to suppress REM sleep. Anticataplectic drugs include

sodium oxybate (Xyrem) which promotes sleep consolidation and an increase in SWS, during the night, at the expenses of REM sleep. Antidepressants (e.g., venlafaxine, clomipramine, protryptiline, and SSRIs) may also be useful. As for vigilance-promoting agents, the most currently used drug, modafinil, is a proaminergic drug mainly supporting noradrenergic transmission.

Other Hypersomnias

Other central nervous system (CNS) hypersomnias include the idiopathic type (which is not related to REM-sleep alteration but to a tendency to oversleep in NREM) and recurrent types including the Klein–Levin syndrome (KLS) and menstrual-related hypersomnia. KLS is characterized by recurrent episodes of hypersomnia occurring weeks or months apart and associated with overeating, hypersexuality, aggressiveness, and cognitive abnormalities. Alterations in the hypothalamus have been reported. An autoimmune mechanism for this disorder is suggested both clinically and by the HLA association with the DQB1*02 haplotype.

Depression

The pathogenesis of the affective disorders is less well understood than that of narcolepsy, but most models of mood control specify decreased aminergic drive (the ergotropic factor mediating energy availability and release associated with feeling good or even elated mood) and/or increased cholinergic drive (the trophotropic factor favoring energy conservation, rest, sleep, and depressed mood).

Instead of a tendency for the REM-sleep attacks seen in narcolepsy, depressed patients want to go to bed early and stay there for a longer time. Their sleep efficiency is very low because they spend long times awake in bed. They complain accordingly of insomnia. NREM sleep in such patients is typically curtailed and the time of onset of the first REM period is reduced. This change is referred to as a shortened REM-sleep latency.

The first REM period may be both longer and stronger than usual as if the cholinergic REM-sleep drive were acting unopposed. These abnormal sleep features respond promptly to SSRIs (e.g., fluoxetine, sertraline, paroxetine, citalopram) or to mixed reuptake inhibitors (e.g., venlafaxine, duloxetin, mirtazapine, reboxetine) and the widely used tricyclics (e.g., clomipramine, imipramine). A positive response of sleep features to drug initiation is a good predictor of a later benefit in mood regulation. This delay is not well understood but suggests that sleep may have its correlation with mood via a long-term downstream mechanism linking the membrane events to gene expression.

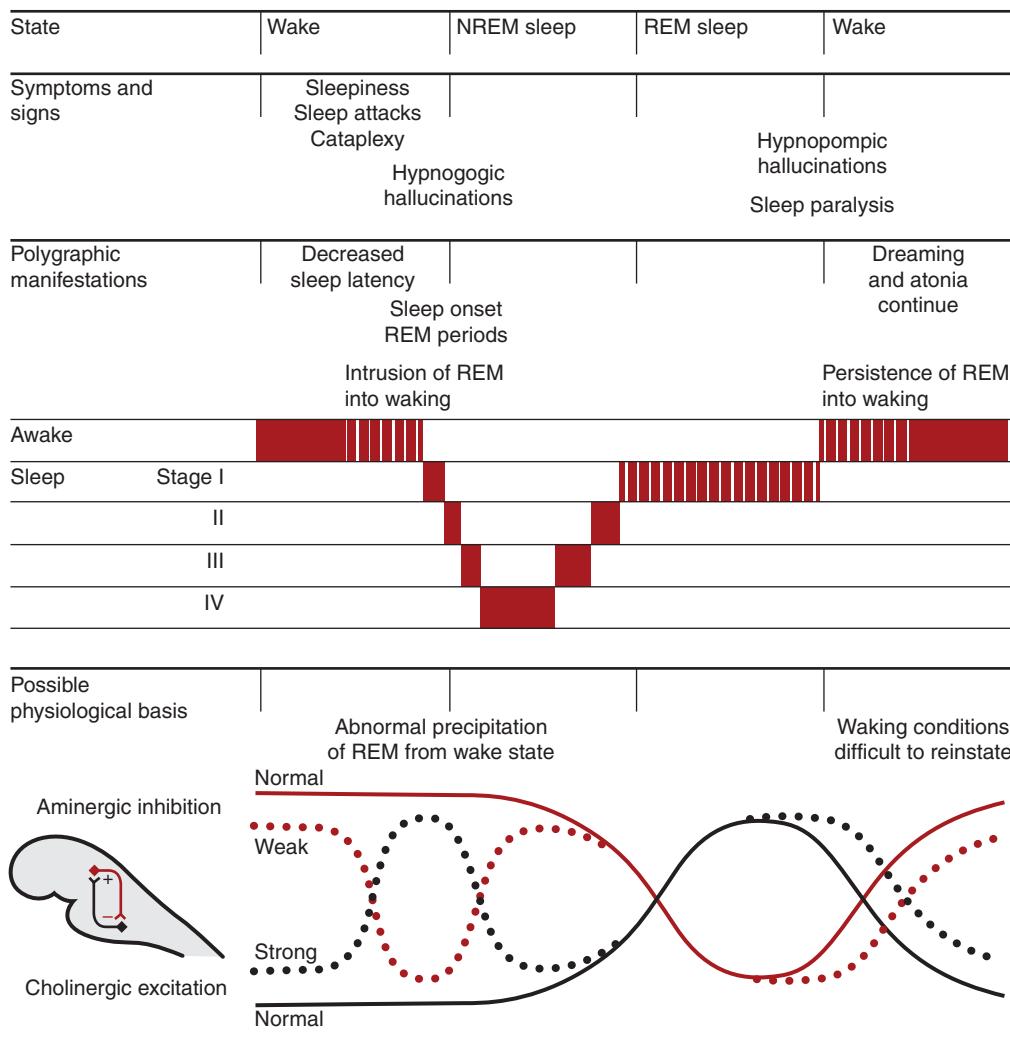

Figure 2 Pathophysiology of narcolepsy. Narcoleptic patients have four abnormalities of sleep–wake-state control that apparently result from changes in the set-point of the REM-state oscillator. They are known as Gelineau's Tetrad honoring the French neurologist who first described them in the nineteenth century. During waking, signs of REM sleep may intrude as sleepiness, sleep attacks, and cataplexy. A sustained REM period or hypnagogic hallucination may occur at the onset of sleep unlike the normal rapid passing through stage I and the first NREM–REM duration may be decreased (measured as shortened REM latency). On arousal, REM physiology and dream psychology may persist as hypnopompic hallucinations and/or motor inhibition (sleep paralysis). Following the first cycle, the system then resets and operates normally except that at the end of REM when there may be a lag in the reinstatement of waking-state conditions and REM phenomena may again escape their normal temporal bounds. The reciprocal interaction model accounts for all these phenomena by hypothesizing either a decreased level of aminergic inhibition (red dotted line) and/or increased level of cholinergic excitation (black dotted line) in the pontine oscillator. The clinical efficacy of aminergic agonists such as amphetamine or amine-reuptake blockers such as imipramine may be due to a resetting of aminergic inhibition back up to level (heavy red line). By reciprocal interaction, this would also reset the level of the cholinergic generator back down to its normal level (heavy gray line).

Sleep Apnea Syndromes

As pointed out in the introduction, it is normal, though still surprising and unexpected, to realize that normal males may omit as many as 50 breathing efforts per night. As a function of the lowered set point of aminergic and related activation systems, the respiratory oscillator of the medulla simply fails to issue breathing commands.

A decreased activation of the respiratory oscillator is normal at sleep onset and throughout NREM sleep. At the

same time and for the same reason, the muscle tone of the airway declines leading both to snoring and less efficient blood oxygenation. The partial pressure of O₂ may decline and that of CO₂ may rise at the same time that brainstem responsiveness to those blood gas levels declines. The result may be central hypoxia and/or hypopnea (Figure 3).

With the onset of REM sleep, there is further aminergic demodulation. There is a concomitant increase in activation probably mediated by cholinergic systems

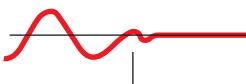

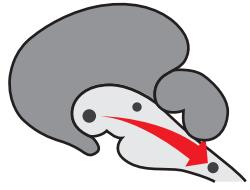

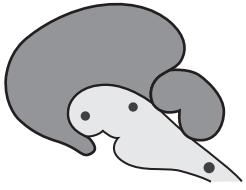

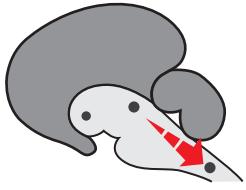

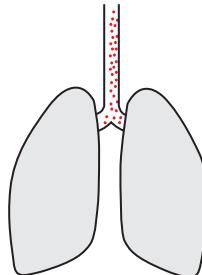

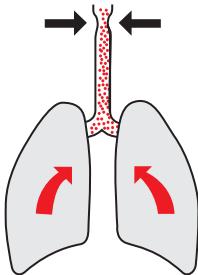

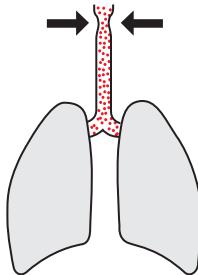

State	Wake	NREM sleep	REM sleep
Breathing pattern	Eupnea/hyperpnea	Hypopnea/apnea	Hyperpnea/apnea
	 Voluntary or metabolic response	 Obstruction	 Desynchronization of respiratory oscillator
Central component	Strong tonic neural drive	Decreased tonic neural drive	Increased tonic and phasic neural drive
			
Peripheral	Muscle tone high Airway patent	Muscle tone decreased Airway collapses	Muscle tone absent Airway collapses
			
		Forced expiration causes obstruction	

Figure 3 Pathophysiology of the sleep apnea syndrome. During waking, the respiratory oscillator of the medulla receives tonic drive from other neural structures and can respond to voluntary and metabolic signals to change the breathing pattern. Tonic drive to the oropharyngeal musculature actively maintains the airway and assures ventilation. In NREM, disinhibition decreases tonic drive on both the respiratory oscillator and the peripheral muscles, thus diminishing respiratory rate and amplitude as well as predisposing the airway to collapse. If obstruction occurs, the forced expiratory effect may actually aggravate this cycle and cause prolonged apneas with marked hypoventilation and hypoxia. During REM sleep, tonic and phasic drive from the pontine generator neurons may desynchronize the respiratory oscillator, leading to hyperapnea and/or apnea. Worse yet, the medullary oscillator can become unresponsive to metabolic signals. These processes may multiply the deleterious effects on ventilation, especially in those patients who are subject to airway collapse.

which are disinhibited as aminergic activity plummets. Neurons, sensitive to O₂ or CO₂ levels in waking, no longer have that propensity and the very definition of inspiratory and expiratory neurons may change or even reverse! With the genesis of REMs and ponto-geniculocolic (PGO) waves, unexpected impingements of neuronal signals may activate or block the respiratory oscillator producing ineffective ventilation via hypopnea or apnea of central origin.

Obesity, male gender, and age conspire to make matters worse. The airway may collapse and obstruct when

breathing efforts attempt to overcome anoxia. The number of microarousals may run to 400 per night and are entirely unrecognized by the patient. Cardiovascular complications arise early and frequently in the course of the disorder. They range from hypertension, cardiac arrhythmia with increased risk of metabolic syndrome, coronary artery disease, and stroke. Because the sleep-apnea subject wakes up often to breathe, he may suffer from extreme daytime sleepiness or he may consider himself insomniac. In fact, he is both! Given this grim picture, it is a wonder that anyone benefits from a night of sleep!

The grunting sound of forced expiratory effort against the obstructed airway can be imitated or tape-recorded by allies of the patient. Bed partners can also turn on the light or use a flashlight to determine if cyanosis is yet present. Any such severely affected subject should be referred on an emergency basis to a sleep laboratory for definitive diagnosis and treatment.

Sleep apnea is effectively countered by continuous positive airway pressure (CPAP), which helps to hold the airway open and by dietary weight reduction. Maxillary surgery may be specifically indicated for patients with relevant local anatomic factors impinging on airway patency. The success of these interventions is greatly increased by a team effort which involves bed partners and family members. Sleep apnea may sometimes overlap with chronic obstructive pulmonary disease – a condition predisposing to severe desaturation during REM sleep when the accessory respiratory muscles are silent and cannot help to diminish the airway deficiency.

Central sleep apnea refers to a recurrent cessation of breathing during sleep. It is thought to be linked to the instability of the respiratory control system in the transition from wakefulness to sleep. It is mainly seen either in elderly patients or in individuals with heightened ventilatory responsiveness to CO₂.

Wrong Kind of Sleep: The Parasomnias

The term parasomnia refers to unusual motor phenomena accompanying sleep. These abnormal movements are either linked to specific sleep stages such as NREM (disorders of arousal such as enuresis, night terrors or sleep walking, etc.) or to REM (such as REM behavior disorder (RBD), nightmares, and sleep paralysis). Some parasomnias have a preference for sleep-stage transitions (such as enuresis and grunting respiration).

A variety of disorders, commonly seen in adolescents, evince what Roger Broughton has called “disorders of arousal.” Awakening from deep NREM sleep is fraught with difficulty because of sleep inertia – a process identified by David Dinges as related to a persistent NREM-sleep drive that counteracts the effort to wake up from deep sleep. Thus, sleep-walking, sleep-talking, enuresis, and night terrors are all sensorimotor disturbances related to this difficulty in waking up. In these conditions, the brainstem and corticothalamic mediators of motility and perception show timing errors with respect to each other.

As stressed by Mark Mahowald, the parasomnias are dissociations by definition and par excellence. For example, in sleep-walking, subjects are awake as far as lower brain centers are concerned but asleep in their upper brains. In sleep-walking, subjects may navigate quite well despite the effect that their cortical

electroencephalogram (EEG) remains in stage IV SWS throughout the episode. Children who awaken, in panic, and evince night terrors, experience intense and unopposed autonomic activation without being able to become fully awake. Less activation with more complex behavioral and cognitive abnormalities are experienced during confusional arousals – another form of commonly occurring sleep disorder, especially in older adults and following sleep deprivation. Disorders of arousal tend to have a familial occurrence and a high prevalence in childhood. They all tend to occur in the first part of the night when NREM sleep prevails.

REM Sleep Behavior Disorder

The most typical and disrupting behavior among the REM parasomnias is RBD. In contrast to sleep-walking, this sleep disorder occurs in REM sleep and represents the unopposed read-out of motor commands normally quelled by the REM inhibition of spinal motoneurons that results in electromyogram (EMG) suppression and sleep atonia. This condition is most commonly seen in middle-aged males whose sleep is suddenly and dramatically interrupted by dream enactment. The movements may be fragmentary or behaviorally complex and are often associated with dreams of threat or attack. The precise details of the association of specific movements to specific aspects of dream content remain to be determined.

A similar condition can be produced in experimental animals by making lesions between the pontine locus ceruleus and pontine motor-pattern-generator centers. Cats with such lesions which enter REM sleep may suddenly jump up and express what appears to be a series of defense and attack postures. Experimental RBD was first described by Jouvet and Delorme. Morrison, who confirmed this observation, called this state REM sleep without atonia. It is another, striking example of a radical state-dissociation.

Males suffering from RBD may develop the condition spontaneously or they may have a history of exposure to SSRI medication or some other REM-sleep-suppressing pharmacological agent. RBD may also be secondary to several neurological conditions including multiple sclerosis, brainstem tumor, Alzheimer’s disease, cerebrovascular disease, and the synucleinopathies. Among the latter, Parkinson’s disease and multiple system atrophy are particularly prevalent. RBD may anticipate clinical parkinsonism by several years. Dopamine transporter (DAT) scans may reveal bilateral alterations intermediate between parkinsonism and normality. Diagnostic screening must include video-enhanced polysomnography to record both the lack of REM atonia and the excessive muscle phasic activity during REM sleep leading to violent behavior outbursts during sleep. Clonazepam, a benzodiazepine

with serotonergic properties, is the drug of choice for RBD but desipramine, melatonin, and dopaminergic agents have also been employed successfully.

Movement Disorders of Sleep

One of the great surprises of basic sleep research is that dopaminergic neurons do not obey the general rule of slowing in NREM sleep and firing arrest in REM sleep. Instead, the dopaminergic neurons of the substantia nigra continue to discharge throughout both NREM and REM sleep. The descriptive details and significance of this exceptional finding remain to be investigated but there are several sleep disorders which may reflect an alteration of dopamine itself or dopaminergic interaction with the other aminergic neuromodulators. The co-activation of cholinergic and dopaminergic neuromodulators in normal motor control is well known.

Sleep-related movement disorders include bruxism (tooth grinding), rhythmic movement disorder (head and body rolling), and periodic leg-movement disorder (PLM). One observes 5–90-s interval, brief (0.5–5 s) movements of the limbs in PLM which cause severe disruption of sleep continuity. As a consequence, there

is an impairment of daytime vigilance as well as interruptions of nocturnal sleep (Figures 4 and 5).

Restless Legs Syndrome

Restless leg syndrome (RLS) is characterized by an irresistible urge to move the legs accompanied by uncomfortable paresthesias. It impairs a smooth sleep transition, severely delaying sleep onset and often interfering with sleep maintenance. Once sleep is finally established, RLS may promote multiple arousals. Abnormal iron metabolism, dopamine levels, and genetics appear to contribute to the pathology of RLS.

Familial forms of RLS tend to occur early in life and are transmitted via an autosomal dominant genetic pattern. Iron deficiency is one of the most common secondary causes and brain iron deficiency may be a primary factor for the occurrence of RLS. There are a few direct and many indirect signs pointing to altered DAT in RLS. Both DAT scan and postsynaptic alterations have been reported.

Dopamine-promoting agents represent the therapy of choice (via drugs like pramipexole, ropinirole, and rotigotine). Gabapentin, pregabalin, and opioids are still used especially in secondary RLS, such as is seen in diabetes or end-stage renal disease. The differential diagnosis of RLS

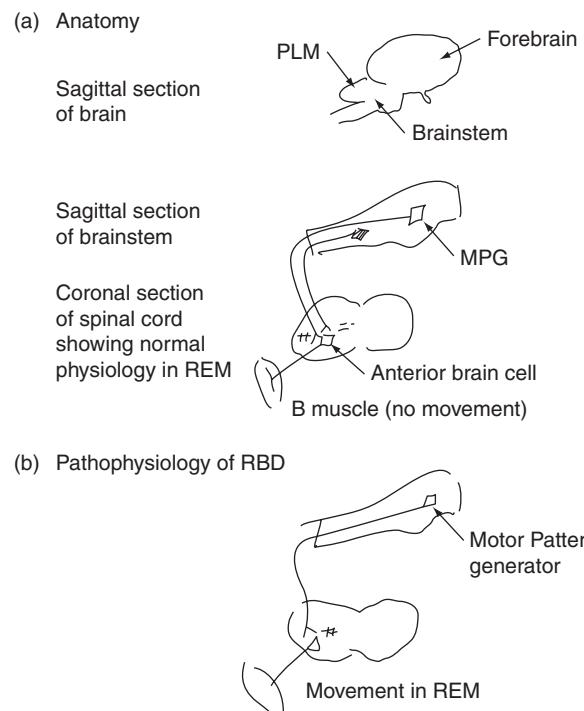

Figure 4 REM sleep behavior disorder (RBD). In the RBD, as in experimental REM sleep without atonia, there is a failure to inhibit final common-path motoneurons in the spinal cord and/or a facilitation of motor-pattern generators in the pontomedullary brainstem. In both cases, the result is a failure to effect the motor paralysis which normally prevents motor behavior in REM. In both cases, there is likely to be a loss of interaction between motor-pattern-generator neurons (MPG) and aminergic neurons (LC).

Conditions	EMG
Bruxism	(submental muscles)  Repetition but aperiodic
Rhythmic movement disorder	(neck muscles)  Repetition and periodic
Periodic leg movement	(anterior tibialis muscles)  Periodic with long silent epochs
Restless legs syndrome	(anterior tibialis muscles) Wake Sleep  Aperiodic Periodic

Figure 5 Sleep-related movement disorders. Note that recordings of EMG are from different muscles and that the patterns differ among conditions.

includes secondary forms. Leg cramps (akathesia) and positional leg discomfort are experienced. RLS is a risk factor for depression, hypertension, and cerebrovascular disease and is comorbid with several dopaminergic disorders including attention-deficit disorder, migraine headaches, sleep-related eating disorder, narcolepsy, and Parkinson's disease.

Diagnosis and Treatment of Sleep Disorders

Further details of pharmacological treatment of the conditions discussed here may be found in relevant medical texts. In this section, instead, we emphasize a natural history approach to the understanding and treatment of sleep disorders.

Home-Based Evaluation versus Sleep-Lab Diagnosis

Most sleep disorders including the most severe and life-threatening sleep apnea syndromes can be assessed by the astute clinician with the help of observant bed partners, family members, and self-observation training. Sleep logs and simple devices such as flashlights, sleep logs, and hand-held-type recorders are useful. Home-based electrographic studies can also be evaluated using portable polygraphic and movement-based measurement systems such as the Nightcap.

Sleep-Lab Referral

Severe cases, especially patients with narcolepsy, sleep apnea syndromes, RBD, and RLS are best evaluated and treated in sleep disorders centers at tertiary care facilities. Most sleep disorders will, nonetheless, be managed by family doctors in group or solo practice. Since much of the knowledge of sleep medicine is new and increasing every day, it will help all healthcare deliverers to understand sleep and manipulate its hygiene, whenever possible, by natural means.

Behavioral and Cognitive Therapy

Instead of reaching for a prescription pad, the informed and wise caretaker should consider behavioral and cognitive intervention at least for insomnia. Most clients who consider themselves to be sufferers from sleep disorders are the myriad walking-wounded of hospital outpatient departments everywhere. They are a mixed bag of anxiety disorders, character pathology, and poor health habits. Medication is not always, or even often, indicated for these unfortunate patients. Rather, a vigorous behaviorally and sophisticated educational program is in order. This is the natural task of the health educator, the clinical psychologist, and the nurse practitioner. It is for those people, not the sleep disorders specialist, that this article is written.

Glossary

Anterograde amnesia – The inability to recall or recognize events and facts that were encountered after the onset of amnesia (postmorbidity).

Confabulation – A false production of memory provided by a patient who is unaware of its falsehood. Confabulations range from plausible responses given in response to questions, apparently to fill a gap in memory, to fantastic imaginary events produced spontaneously and held with great conviction.

Consolidation – The processes by which memories are assimilated and stabilized. Consolidation includes both fast processes operating at a cellular level and slow processes operating at a systems level. At the cellular level, consolidation entails synaptic remodeling and growth that lead to the formation of a stable and long-lasting memory. At the systems level, consolidation involves reorganization, such that memories that were initially dependent for encoding and retrieval on the hippocampus and related medial temporal lobe (MTL) structures can be retained and retrieved neocortically, without reliance on MTL structures.

Declarative memory – A form of memory characterized by the ability to consciously bring to mind (recollect) information. Both episodic memory and semantic memory are forms of declarative memory. Declarative memory depends on the integrity of brain structures and connections in the MTLs and diencephalon – regions that are implicated in amnesia.

Episodic memory – Memory for personally experienced events. Episodic memory enables the mental reliving of an experience in the past. It is a form of declarative memory.

Nondeclarative memory – A variety of forms of memory in which learning is expressed through performance rather than recollection. These include simple classical conditioning, skill learning, and repetition priming. Nondeclarative memory is intact in amnesia.

Repetition priming – An unconscious expression of memory that takes the form of an improvement or bias in processing a stimulus that results from previous exposure to that stimulus. It is a form of nondeclarative memory.

Retrograde amnesia – Inability to recall or recognize experiences and information acquired before the onset of amnesia (premorbidity).

Semantic memory – Memory for facts and concepts. Semantic memory enables the retrieval of information in the form of impersonal knowledge. It is a form of declarative memory.

The Amnesic Syndrome

Global amnesia refers to a dense and a circumscribed disorder of memory in the context of preserved general intelligence and other cognitive abilities. Patients with amnesia have a severe impairment in anterograde memory – the ability to recall and recognize events and facts encountered after the onset of illness. The memory impairment is global, in that memory is affected regardless of the nature of the material (i.e., verbal or visuospatial) or the modality of presentation (i.e., visual or auditory). Typically, the ability to bring to mind experiences or information acquired before the onset of illness (retrograde memory) is also affected, although the extent is more variable. Some cases of isolated or focal retrograde amnesia have been described, but the existence of this syndrome is less well-established, as the absence of anterograde memory loss is not always clearly documented and in some instances, the selective nature of the retrograde amnesia may reflect faster recovery of initially impaired anterograde memory.

Much of our current clinical and theoretical understanding of global amnesia finds its origin in the study of patient HM, who in 1953, at the age of 27, underwent resection of the medial temporal lobes (MTLs) bilaterally for the relief of intractable seizures. As a result, HM was left with a profound inability to consciously learn and remember new information. In daily life, he was not able to recall the gist of a conversation he had with a visitor 30 min ago, nor did he remember whether someone actually visited. In the laboratory, he exhibited severe impairments in word and picture recall, in cued recall of paired associates, and in recognition memory. He also evidenced impaired recall of memories predating the surgery, and most of his personal memories were from the age of 16 or earlier.

Many other patients with amnesia have since been described, and although it is now clear that the amnesic syndrome is functionally heterogeneous, some general

characteristics can be identified. In particular, despite the pervasive nature of the memory impairment exhibited by amnesic patients, it is striking that some aspects of memory remain intact. Patients show normal performance on many tasks of immediate memory and working memory, such as the ability to repeat a string of digits or spell a word backwards. The ability to hold and manipulate information online is essential for the performance of many cognitive tasks, ranging from language comprehension to simple arithmetic. Although the integrity of working memory has long been taken as a given, there is mounting evidence that the ability to hold information in mind may at times be impaired, especially for nonverbal information. Whether this reflects a true impairment in working memory or the fact that maintenance of nonverbal information depends on long-term memory processes is still unclear. Patients with amnesia are also able to retrieve overlearned semantic memories, as evidenced by their knowledge of word meanings and their good fund of general knowledge. Finally, even within the domain of new learning, there is evidence for preservation of skill learning, classical conditioning, and repetition priming – forms of learning often collectively referred to as nondeclarative memory. The distinction between preserved and impaired forms of learning in amnesia has guided much research into the cognitive and neural organization of various components of memory.

Etiologies of Amnesia

Although amnesia can have a psychogenic origin, the focus here is on organic amnesia due to structural brain damage. Amnesia can result from lesions of the MTL (the hippocampal formation and adjacent entorhinal, perirhinal, and parahippocampal cortices), the diencephalon, and the basal forebrain, as well as from disruption of some of their connections such as the fornix. A range of vascular, infectious, and traumatic disease processes can cause such lesions. The most common ones are discussed in the following sections.

Herpes Simplex Encephalitis

Patients with herpes simplex encephalitis (HSE) may initially present with profound confusion and disorientation, amnesia, agnosia, and aphasia, but over time these symptoms may resolve so that the patient is left with a selective, dense amnesia. HSE typically affects MTL regions, including the hippocampus and adjacent entorhinal, perirhinal, and parahippocampal cortices. Damage may also extend anteriorly into the insular cortex and basal forebrain. Damage to the anterolateral and inferior temporal lobes may be responsible for persistent aphasia and agnosia in some patients. Lesions may be

asymmetrical: greater damage to right temporal regions has a more pronounced effect on nonverbal/visual memory, whereas greater damage to left temporal regions has a more pronounced effect on verbal memory. Extensive retrograde amnesia is typically seen in association with lesions extending into lateral temporal regions.

Anoxia

Reduced oxygen to the brain can result from cardiac arrest, respiratory distress, or carbon monoxide poisoning. The MTL region is particularly sensitive to oxygen deprivation, and as such, anoxia can result in selective memory impairment. The severity of memory impairment, both in the anterograde and retrograde domains, can vary from mild to very severe, depending on the extent of MTL damage. Anoxic brain damage is not always limited to the MTL region, but can involve the basal ganglia, thalamus, and diffuse cortical areas. In such cases, other cognitive and perceptual abilities may be affected. Anoxic episodes shortly after birth can lead to a relatively selective form of developmental amnesia.

Wernicke–Korsakoff Syndrome

Patients with Wernicke–Korsakoff syndrome (WKS) develop amnesia as a result of the combined effects of alcohol abuse and thiamine deficiency. In the acute phase, patients exhibit a confusional state, oculomotor problems, and ataxia. The chronic phase is characterized by dense amnesia, which is thought to be due to damage to the anterior and dorsomedial nuclei of the thalamus and the mammillothalamic tract. Additional frontal dysfunction may account for some of the unique characteristics of WKS amnesia, including superficial encoding strategies, confabulation, and source memory errors. Retrograde memory loss is common, but its interpretation is complicated by the fact that (1) patients' premorbid lifestyle may have interfered with the establishment of salient remote memories that serve as anchors for retrieval; and (2) frontal dysfunction may interfere with the strategic search of memories from the past.

Cerebrovascular Accidents

Bilateral posterior cerebral artery (PCA) infarction is a well-known cause of amnesia, and is due to lesions in the posterior parahippocampus or collateral isthmus (a pathway connecting the posterior parahippocampus to association cortex). Reading and visual naming problems may complicate the clinical presentation, and these are thought to be due to disconnection of posterior occipital regions from the left hemisphere language areas. Memory problems also can occur following unilateral (primarily

left) PCA lesions. The extent of retrograde amnesia is variable.

Thalamic strokes, due to infarction of the tuberothalamic and paramedian arteries, also can lead to significant memory loss. Severe amnesia is usually associated with lesions of the anterior thalamic nuclei or the mammillothalamic tract, whose fibers project to the anterior nucleus. Lesions of the dorsomedial thalamic nuclei typically lead to milder memory disturbances. As in WKS, executive dysfunction frequently accompanies the memory impairment. Unilateral lesions lead to material-specific deficits. There is variability in the persistence and extent of retrograde amnesia.

Anterior Communicating Artery Aneurysms

Memory impairments following anterior communicating artery (ACoA) aneurysm result from damage to the basal forebrain, the striatum, and frontal lobes. Several basal forebrain nuclei are rich in cholinergic neurons that innervate the hippocampus. Thus, amnesia may be due in part to disruption of hippocampal functioning, but additional frontal damage will also impact the nature of the impairments. In the acute phase of the disorder, patients often present with severe confusion; once this clears, significant impairment in new learning becomes apparent. Because of the variability in the locus and extent of lesion, there is considerable heterogeneity in the nature and severity of impairment, but a common feature is much worse performance on tasks of recall than of recognition. This may reflect impairments in the strategic search of memory secondary to frontal lesions. Confabulation, lack of insight, and severe retrograde amnesia also tend to be associated with frontal lesions.

While the etiologies reviewed above typically lead to permanent amnesia, other conditions can cause transient selective memory impairment. For instance, severe memory problems are often associated with electroconvulsive therapy, a procedure used for the treatment of severe depression, but good recovery of memory occurs with time. Another condition, termed transient global amnesia, refers to a circumscribed memory deficit of limited duration (<24 h) that typically resolves in the weeks or months after the episode. Common causes include seizure activity, migraine, or temporary disruption of the vascular supply.

Features of Anterograde Amnesia

Amnesic patients are severely impaired at intentionally remembering information to which they were exposed after the onset of their illness. This deficit encompasses both personally experienced events (episodic memory) and impersonal facts and concepts (semantic memory).

These forms of memory are referred to collectively as declarative memory.

The ability to bring to mind previous experiences or facts depends on a series of processes, including the initial processing and representation of information, its storage in long-term memory, and its subsequent retrieval. Amnesic patients are able to process and register information, as evidenced by their normal intelligence and their ability to repeat information immediately after presentation, and thus, their memory impairments are unlikely to reflect deficient intake of information. There is also little evidence for a generalized retrieval deficit, as patients typically are able to retrieve highly overlearned information that was acquired many years prior to the onset of amnesia. Further, a retrieval deficit would predict that in patients with transient amnesia, resolution of the amnestic episode would lead to recovery of the memories that were lost, but such is not the case. Rather, there is a permanent gap in memory. Consequently, it is generally assumed that the amnestic deficit reflects a problem with the consolidation of information into memory. The MTL, through interactions with neocortical regions, plays a central role in consolidation. It is not the site of permanent storage, but is thought to bind together into a coherent representation the different aspects of an event that are neocortically represented.

Depending on the nature and extent of the MTL lesion, different aspects of declarative memory may be differentially impaired. A critical consideration is whether the MTL lesion is limited to the hippocampal formation, or extends into surrounding cortical regions. Some patients with lesions limited to the hippocampus have been described as those who have impaired performance on recall tasks, but intact performance on item-recognition tasks. Such a dissociation has been interpreted with reference to two qualitatively distinct processes (i.e., recollection and familiarity) that can support declarative memory. Recollection refers to an intentional, effortful process by which aspects of an episode are recovered. Familiarity, in contrast, refers to a subjective feeling that arises when information is processed fluently and comes to mind easily. While performance on recall tasks depends on recollection of contextually appropriate information, performance on item-recognition tasks can be supported by either recollection or familiarity. Thus, the pattern of performance of these patients with limited hippocampal lesions has been interpreted as reflecting impaired recollection, but preserved familiarity. Consistent with this notion, when given recognition memory tests that assess memory for contextual information (where or when) or for the relationship among items, a form of recognition that cannot be supported by familiarity of individual cues, these patients again perform poorly. This pattern of impaired recollection and preserved familiarity in patients with limited hippocampal

lesions accords well with findings from neurophysiological and neuroimaging studies that suggest that the hippocampus is critical for recollection, whereas familiarity is supported by perirhinal cortex. It should be noted, however, that this pattern has not been obtained consistently, and some patients with limited hippocampal damage have been reported to have comparable deficits in recollection and familiarity. However, in the absence of histological evidence, it is always possible that the familiarity deficit is due to undetected damage outside the hippocampus proper.

Patients with more extensive MTL lesions show more severe impairments in declarative memory that are evident in recall and in recognition tasks. Their performance reflects impairments in both recollection and familiarity, although occasional reports that these patients can perform simple recognition tasks relatively well suggest that the impairment in recollection may be more severe than the impairment in familiarity. From a clinical perspective, any effort to provide new information to the patients with extensive MTL lesions should capitalize on their remaining ability to use familiarity to support performance.

Differences in performance depending on the extent of MTL lesion are also evident in the domain of new semantic learning. Patients with extensive MTL lesions show minimal ability to acquire new facts or concepts. For instance, HM was unable to acquire the meaning of any new words that entered the vocabulary since the onset of his amnesia. In contrast, patients with limited hippocampal lesions are able to acquire some degree of new semantic knowledge including vocabulary words, and may perform quite well when tested with recognition tasks. Even more extensive semantic learning has been documented in patients with developmental amnesia who, secondary to an anoxic event in early childhood, have damage limited to the hippocampus. Despite severe episodic memory problems, these patients have been shown to acquire language normally and to perform well on scholastic tests, demonstrating a level of learning well beyond that shown by adult amnesic patients. This may reflect the greater opportunity for functional reorganization or compensation associated with early hippocampal damage.

While the above evidence points to differences in the nature of the anterograde memory impairment depending on the extent of MTL lesion, even more striking qualitative differences are seen when nonobligatory frontal deficits are superimposed on the core amnesia. In amnesic patients with frontal lesions, impairment in executive processes that contribute to memory may lead to additional encoding deficits, reflecting an inability to mentally manipulate and organize incoming information. Similarly, additional retrieval deficits are often seen, reflecting impaired initiation and evaluation of memory search. These deficits can lead to impairments in source memory

or temporal memory, and are responsible for unusually high levels of intrusions in recall or false alarms in recognition, a phenomenon known as enhanced susceptibility to false memory.

As noted above, anterograde amnesia involves declarative memory, but leaves unaffected several forms of nondeclarative memory. For instance, amnesic patients show intact procedural memory: they are able to acquire new skills and habits (e.g., operating a cell phone or learning to type), even though their declarative memory (i.e., their knowledge of having been exposed to the information) is severely impaired. Similarly, they show evidence of normal eyeblink conditioning, provided that the conditioned stimulus and unconditioned stimulus are temporally overlapping. These two forms of nondeclarative memory are thought to depend on the basal ganglia and the cerebellum, respectively. A third form of nondeclarative memory is repetition priming. In contrast to procedural memory and conditioning, which are acquired gradually across many presentations, repetition priming requires only a single study exposure. In a typical repetition-priming task, patients are exposed to a series of words or pictures (e.g., the word tulip). During a later test phase, they are asked to perform a seemingly unrelated task, such as reading briefly flashed words or generating as many words as possible when cued with the semantic category flowers. Priming is measured as the enhancement in task performance for stimuli presented in the study phase, compared to stimuli that were not presented. Repetition priming can be due to facilitation of perceptual processes that are reinstated at test (i.e., enhanced accuracy in identifying the word tulip), or to reinstatement of conceptual processes (i.e., enhanced generation of tulip as an exemplar of flowers). In either case, patients with global amnesia show intact priming in such tasks. Such priming does not depend on MTL or diencephalic regions, but is rather mediated neocortically, by those very regions involved in visual or semantic processing.

Features of Retrograde Amnesia

Retrograde amnesia can involve impaired memory for events (episodic memory) as well as for facts and concepts (semantic memory) to which patients were exposed prior to the onset of their illness. A further distinction concerns memory for personally relevant information compared to general, public information. Personal memory for specific events, often referred to as autobiographical memory, entails re-experiencing of personal episodic detail, and thus forms the prototype of episodic memory. It is often tested by asking patients to describe in as much detail as possible an event in response to a cue word provided by the examiner. On the other end of the spectrum, memory

for general information such as famous faces or of vocabulary provides the prototype of semantic memory.

Although many patients show impairment in both forms of memory, retrograde deficits in episodic and semantic memory can be dissociated, as some patients have severe autobiographical memory impairments but relatively preserved memory for facts and concepts, whereas other patients show the opposite pattern. Dissociations between autobiographical and semantic retrograde memory are clear cut when memories reflect exclusively autobiographical or semantic memory, but practically such dissociations are harder to observe because memories often reflect a combination of autobiographical and semantic information: memory for a public event may entail both the fact of the event and information regarding one's personal circumstances at the time of the event. In a similar vein, some personally relevant memories, such as names of schoolteachers or addresses of previous places of residence, are not tied to singular events and likely reflect a combination of autobiographical and semantic information. Such memories are referred to as personal semantics.

A classic finding in retrograde amnesia is the fact that remote memories are better preserved than memories for events or facts to which the patient was exposed shortly before the time of brain injury. The presence of such a temporal gradient is very common, but the extent of retrograde amnesia can vary greatly, from a relatively restricted impairment encompassing only a few years predating the illness (with a steep gradient) to a very extensive impairment encompassing 30 years or more (with a relative flat gradient). The nature of the gradient is multidetermined, with the primary determinants being the location and extent of brain damage and the type of memory test administered.

Many studies of patients with MTL lesions have documented a limited temporal gradient, with the gradient becoming progressively more extensive with larger MTL lesions. This pattern of memory loss has been interpreted in the context of standard consolidation theory, according to which the hippocampus and surrounding MTL areas play a time-limited role in memory: the hippocampus initially serves as an index to the various neocortical sites in which information is processed, but over time, direct interconnections among neocortical sites are forged and the hippocampus is no longer needed for memory retrieval. Thus, older memories can be retrieved directly through reactivation of neocortical traces even in the face of hippocampal lesion, whereas newer ones that are not yet consolidated cannot.

While a limited temporal gradient adequately characterizes the semantic memory loss in MTL patients, it is now apparent that earlier studies may have underestimated the extent of impairment in autobiographical memory because they did not sufficiently probe for

event details. Recent studies evaluating both the number and quality of event details have revealed that patients with MTL lesions have extensive autobiographical memory loss that may cover 30 years or more. Such an extensive temporal gradient is problematic for a consolidation view, as it suggests that the loss of autobiographical memory extends well beyond a time frame during which biological consolidation is likely to operate. In light of these findings, an alternative view, referred to as multiple trace theory, has been proposed, which postulates that retrieval of personal event-specific details (which are critical for autobiographical memory) continues to depend on the hippocampus, irrespective of the age of the memory. According to this view, every time a memory is retrieved, it is re-encoded and a new hippocampal trace is formed. The relative preservation of older memories compared to more recent ones reflects the fact that older memories, which presumably have been re-activated more frequently, are represented by more hippocampal traces, and are therefore more resistant to partial MTL damage. Complete MTL damage, however, can lead to a complete inability to recollect autobiographical details of one's past. Unlike autobiographical memories, semantic memories lose their dependence on specific details as they are gradually formed through extraction of the commonalities among episodes. Thus, although they may initially be supported by MTL-mediated recovery of specific details, they lose their dependence on MTL structures over time so that they can be retrieved directly through neocortical connections and are therefore resistant to MTL lesions. A similar distinction between retrieval of semantic/generic representations and specific detail also applies to the domain of spatial memory: when evaluating memory for an environment known long ago, intact memory for general spatial layouts, but impaired access to highly detailed spatial representations, has been found in some amnesic patients.

In patients whose lesion extends beyond the MTL to involve the anterolateral temporal lobes, very extensive retrograde amnesia with a flat gradient is typically seen, and this may encompass not only autobiographical, but also semantic memory. This is thought to be due to damage to the temporal neocortex, which directly disrupts neocortical storage sites or disconnects these sites from the hippocampi. Impairments in semantic memory appear to be more prominent following left temporal lesions, a finding that is likely tied to the role of the left hemisphere in verbal lexical–semantic processing. Impairments in autobiographical memory appear to be more prominent following right temporal lesions, and may reflect the fact that autobiographical memory relies heavily on the ability to conjure up visual images.

Finally, extensive retrograde impairments can also be seen in patients with frontal lesions. These impairments may encompass both semantic and episodic memory, but

they are particularly evident when the demands on self-initiated retrieval are high, as is the case for autobiographical memory. In these patients, retrograde amnesia is closely linked to frontal executive impairments. Confabulatory responses may also be prominent, and these are thought to reflect impaired monitoring of retrieved information.

Clinical and Theoretical Implications

Amnesic syndromes are functionally heterogeneous, but they share the fundamental characteristic of a relatively isolated impairment in memory, with both anterograde and retrograde components. Clinically, the impact of such memory impairment on functional activities that require retrieval of recent information or maintenance of information in the face of distraction is self-evident, as is the wider psychosocial impact of the inability to reminisce about the past. Equally important and perhaps less well-recognized, however, is the impact of severe memory impairment on the ability to plan and envision future scenarios. Recent studies suggest that there is extensive overlap in the brain regions involved in remembering the past and those involved in thinking about the future, and evidence is now emerging that amnesic patients have great difficulty imagining new experiences. It is possible that richly envisioning future scenarios requires flexible retrieval and recombination of details from the past, drawing on the same processes of (re-)construction as does remote memory. The impact of this impairment on a range of abilities from problem solving to creativity remains to be explored. In a similar vein, much remains to be learned about the effect of amnesia on the ability to maintain an updated sense of self and to develop goals that are appropriate to one's personal history.

On a theoretical level, neuropsychological studies of patients with amnesia have contributed greatly to our understanding of memory processes and the brain regions that mediate them. Within the domain of new learning, striking dissociations in amnesia between declarative memory and different forms of nondeclarative memory have reinforced the notion that memory is not a unitary phenomenon, but rather, that there are multiple memory systems and processes that are mediated by distinct neural systems. It has long been held that the MTL-diencephalic memory system that is lesioned in patients with amnesia is involved only in long-term memory, but recent findings raise the possibility of a similar role in the maintenance of some forms of short-term memory. Within the domain of retrograde amnesia, much continues to be learned from patients with selective impairments in autobiographical or semantic memory, and the existence of distinct gradients for these two forms of remote memory suggests that

the storage and retrieval of autobiographical memories and of semantic information are functionally and neuroanatomically distinct. These theoretical advances in turn make possible the development of more sophisticated methods of memory assessment of patients with amnesia, and may lead to the development of memory rehabilitation approaches that capitalize on preserved memory processes.

Agnosia

L A Baugh, L Desanghere, and J J Marotta, The University of Manitoba, Winnipeg, MB, Canada

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Apperceptive agnosia – A form of visual agnosia in which a person cannot reliably name, match, or discriminate visually presented objects, despite adequate elementary visual function (visual fields, acuity, and color vision).

Associative agnosia – A form of visual agnosia in which a person cannot use the derived perceptual representation to access stored knowledge of the object's functions and associations but is able to copy and match the drawing even though unable to identify it.

Balint's syndrome – Agnosic syndrome that results from large bilateral parietal lesions and is composed of three deficits: (1) paralysis of eye fixation with inability to look voluntarily into the peripheral visual field, (2) optic ataxia, and (3) disturbance of visual attention such that there is neglect of the peripheral field.

Dorsal simultanagnosia – An inability to detect more than one object at a time, with difficulty shifting attention from one object to another.

Dorsal stream – The stream of cortical visual projections from primary visual cortex to posterior parietal cortex, concerned primarily with the visual control of action.

Inferotemporal cortex – Inferior surface of the temporal lobe that is particularly important for object recognition.

Integrative agnosia – A form of visual agnosia in which one retains the ability to recognize elements of objects but is unable to integrate these elements together into comprehensible percept.

Optic aphasia – A condition in which a person cannot name a visually presented object, despite being able to indicate the identity of the object through gesture and sort the visual stimuli into categories.

Prosopagnosia – A form of visual agnosia in which a person cannot recognize familiar faces, despite adequate elementary visual function (visual fields, acuity, and color vision).

Ventral simultanagnosia – A reduction in the ability to rapidly recognize multiple visual stimuli, such that recognition proceeds in a part-by-part fashion.

Ventral stream – The stream of cortical visual projections from primary visual cortex to the inferotemporal cortex, concerned primarily with representing the identity of stimuli by characteristics such as shape and color.

Introduction

Visual agnosia can be broadly conceptualized as an impairment in the higher visual processes necessary for object recognition, with relative preservation of elementary visual functions. This impairment occurs in the absence of dementia or a general loss of knowledge about objects as patients are typically able to recognize objects through other modalities such as through touch, audition, or verbal descriptions. Historically, Lissauer in 1890 suggested that there were two general categories of object recognition deficits following brain damage, apperceptive and associative agnosia. Patients with apperceptive agnosia were described as having early perceptual processing deficits that caused an inability to form a complete conscious percept of the stimulus. Associative agnosics, on the other hand, were characterized by an inability to recognize objects, despite having intact early level representations. Typically, these impairments were assessed by having the patients copy simple pictures of objects. Individuals with apperceptive agnosia were unable to copy or identify the picture while individuals with associative agnosia could produce a copy of the presented object but were unable to recognize or name it (Figure 1).

Although Lissauer's classifications of agnosia remain in current neuropsychological theories of object recognition today, we are now aware that the simple dichotomy of associative versus apperceptive agnosia cannot account for all forms of object recognition deficits reported in the literature. The neural mechanisms supporting different aspects of perception have been well explored, and depending on the specific area of damage, diverse agnosic characteristics have been shown. Although this article limits the topics to object recognition agnosias, tactile, auditory, face (prosopagnosia), and color agnosia have been reported in the literature.

Neuroanatomy

Diverse methodology, including animal, lesion, functional magnetic resonance imaging (fMRI), and behavioral studies, have been employed to identify the underlying visual mechanisms involved in object perception and recognition. Indeed, two distinct, but interconnected, cortical visual pathways have been shown to process the visual information needed for visual perception and visually guided action. The dorsal stream, projecting

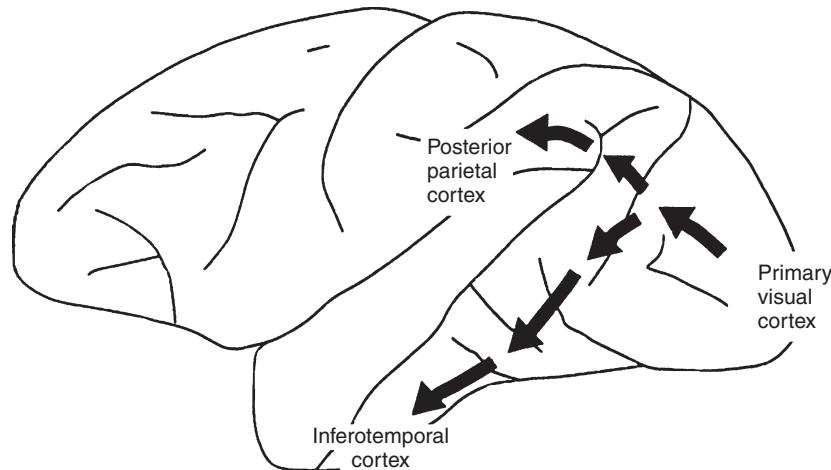

Figure 1 Two streams of visual processing in the primate cerebral cortex. The brain illustrated is that of a macaque monkey. Reproduced from Milner DA and Goodale MA (2006) *The Visual Brain in Action*, 2nd edn. Figure 1.9 (pg. 23), with permission from Oxford University Press.

from the primary visual cortex (V1) to the posterior parietal lobe, deals with moment-to-moment information about the location of objects and is primarily involved in the visual control of skilled movements directed at those objects. The ventral stream, on the other hand, projects from V1 to the temporal lobe, provides us with our visual perceptions of objects and events in the world and codes this information for storage and for use in cognitive processes such as imagining, planning, and recognition (**Figure 2**).

Ventral stream function is associated with object recognition and form representation. Investigations with nonhuman primates have shown that this system has strong connections to the medial temporal lobe (which is associated with long-term memories) and the limbic system (which is involved in emotional processes). Thus, the role of the ventral stream seems to be to form our

perceptual and cognitive representations of the world, providing both the characteristics of objects and their significance to us.

The primary pathway of ventral information from V1 is through visual association areas V2 (involved in the processing of simple properties such as orientation, color, and spatial frequency), V4 (tuned for properties such as orientation, spatial frequency, color, and simpler geometric shapes), and finally to the inferior temporal lobe. fMRI studies in normal individuals have shown activations in the ventral stream during identification of form, texture, and color, as well as during recognition of objects and faces.

As information moves from the visual association areas to the temporal lobe, the cells show remarkable specificity in their responses to visual stimuli. For example, the lateral occipital complex (LOC), which is a region located

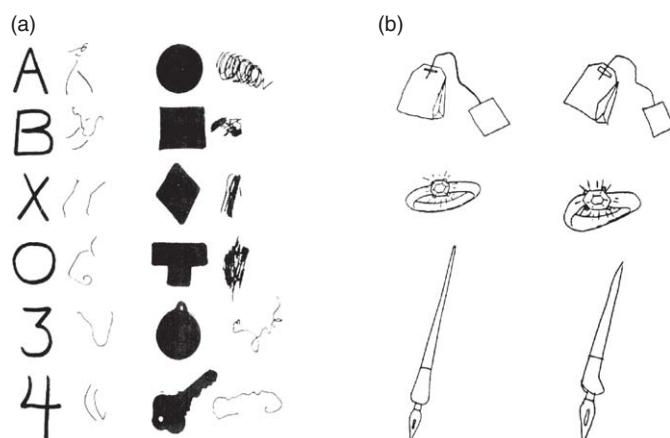

Figure 2 The copying abilities of individuals with (a) apperceptive agnosia and (b) associative agnosia. Reproduced from Farah, MJ. Visual Agnosia, 2nd edn., Figures 2.1 (p. 14) and 6.2 (p. 73), ©2004 Massachusetts Institute of Technology, with permission from the MIT Press.

bilaterally on the occipitotemporal cortex, is more activated when viewing objects when compared to viewing textures or scrambled objects. Within the temporal lobe, many of the cells have large receptive fields, which allow for generalization across the visual field and the coding of intrinsic object features, independent of object location. Lesion studies in monkeys provide further evidence for the role of the ventral stream in object perception. For example, when monkeys have lesions to the temporal cortex, performance on shape discrimination tasks is compromised.

This article examines some of the more profound and, in our opinion, more interesting forms of agnosia that have been reported. While our discussion is primarily limited to agnosias within the visual domain, it is important to note that cases have been reported in other sensory modalities as well (such as auditory and tactile). A broad approach has been undertaken, highlighting key findings in all disciplines of behavioral neuroscience, including case studies, animal models, lesion studies, and systems theory. It is expected that by offering such a broad treatment, the reader will develop an accurate depiction of the current state of knowledge about agnosia, and what it has taught us about the human visual system.

Apperceptive Agnosia

Individuals with apperceptive agnosia are characterized by a difficulty forming a complete visual percept. In extreme cases, termed visual form agnosia, even simple shape discriminations cannot be made as these patients lack the ability to group local visual elements into contours, surfaces, and objects. This type of agnosia is associated with diffuse bilateral damage to the lateral occipital lobes, critical structures involved in visual perception. Individuals with such diffuse damage typically have preserved visual acuity, brightness discrimination, and color vision, and are able to maintain fixations on objects. However, despite the preservation of these elementary visual functions, their ability to point to objects in the environment and match, copy, or discriminate simple and complex geometric shapes is often compromised. Impairments in object identification do not, however, reflect a general impairment in object recognition as patients are still able to accurately identify objects upon tactile presentation and verbal descriptions. In addition, object identification improves when these patients are looking at real objects where cues such as color and texture can aid in recognition.

Despite general impairments in object perception, patients with apperceptive agnosia have been reported to recognize actions depicted in line drawings, such as someone pouring water into a glass, objects whose functions are pantomimed by an experimenter and objects either in motion or drawn in front of them. The

dissociation between impaired perceptual representations of static objects and a preserved ability to perceive motion in these individuals is likely the result of intact parietal and parietofrontal visual networks. As previously described, visual processing in the dorsal stream deals with information about the location of objects and is primarily involved in the visual control of skilled movements and motion perception. In addition, this network forms connections with frontal areas critical for understanding actions performed by others. Despite obvious perceptual deficits, individuals with apperceptive agnosia retain the ability to accurately interact with objects around them and maneuver through their environment. For example, DF, one of the most extensively tested patients with visual form agnosia, clearly demonstrates intact visuomotor control for manual actions on the basis of object size, orientation, and shape, despite her inability to consciously perceive these same details. Indeed, DF can use these intrinsic object properties to accurately scale her grasp when picking up objects with accuracy equal to that of normal controls. Since DF's ventral stream is severely compromised, it is likely that her preserved visuomotor abilities are mediated by intact mechanisms in the dorsal stream, thus allowing accurate visuomotor abilities in the absence of conscious perceptual detail.

In addition to apperceptive patients with severe perceptual deficits, such as those with visual form agnosia, there are individuals that present with higher-order apperceptive impairments known as perceptual categorization deficits. While these patients can typically recognize most objects, their perceptual deficits become apparent when trying to recognize or match objects seen from unusual orientations or under poor lighting conditions. In the past, this impairment has been attributed to the breakdown of the mechanisms involved in object shape constancy. Such mechanisms allow us to recognize objects presented at any orientation or in degraded lighting conditions. However, others have disputed this interpretation. Since patients with this deficit do not have problems with everyday object recognition, and only object recognition at some, rather than all, perspectives is impaired, the deficit may reflect a general loss of visual problem-solving abilities rather than impairment of shape constancy mechanisms.

Simultanagnosia

Simultanagnosia is characterized by an inability to appreciate the overall meaning of a complex picture or stimulus, with preserved perception of isolated elements or details within the stimulus. Patients with simultanagnosia present some visual deficits similar to those seen in apperceptive agnosia, such as an inability to identify an array of stimuli or a tendency to look at parts of an object to guess the object's identity on the basis of local features.

However, unlike apperceptive agnosics, patients with simultanagnosia can use shape information to aid in identification. Two broad classes of simultanagnosia (dorsal and ventral) have been established by Farah in 1990 based on both the presentation of the disorder as well as the corresponding lesion sites to the dorsal and ventral cortical visual pathways.

Despite being able to recognize most objects, patients with dorsal simultanagnosia cannot detect more than one object at a time and have difficulty shifting attention from object to object. For example, when presented with a series of overlapping line drawings, such patients may only report seeing one of the objects. These patients are often confused with blind individuals as they frequently walk into objects and grope for things as if they were in the dark. Attentional impairments, resulting from impaired spatial attention systems, have been shown to be the root underlying cause of dorsal simultanagnosia. Such impairments result in an inability to disengage attention from a specific object or a region of space; thus, these patients can only attend to one stimulus at a time. However, if individual objects are placed close enough together, dorsal simultanagnosics can combine the individual elements to recognize the larger 'global' structure and, in rare cases, perceive multiple objects. This perceptual impairment is typically resultant from bilateral lesions to the posterior parietal cortex and occipital regions and frequently occurs in the context of Balent's syndrome where impaired visuomotor control (optic ataxia), eye movements, and spatial coding deficits are observed.

Ventral simultanagnosia, on the other hand, is characterized by the reduced ability to recognize multiple visual stimuli rapidly. Although these patients are able to see multiple objects at once, like individuals with dorsal simultanagnosia they are only able to recognize one object at a time and often do this on a part-by-part basis. That is, while patients with dorsal simultanagnosia have mainly deficits in perceiving more than one stimulus, patients with ventral simultanagnosia have deficits in recognizing more than one stimulus, even though other objects are seen. Indeed, patients with this visual disorder are most noticeably impaired while reading as they must identify each word letter by letter. The underlying cortical damage for this disorder has typically been associated with left posterior temporal or temporo-occipital cortical lesions.

Associative Agnosia

In comparison to apperceptive agnosia, an associative agnosic can adequately perform figure-copying tasks, even though they may be unable to identify the very picture they just copied. Further, associative agnosics usually perform significantly above chance at matching

tasks. A third similarity, both apperceptive agnosics and associative agnosics are affected by the quality of the stimulus they are trying to identify, with performance on three-dimensional objects superior to two-dimensional photographs, and line drawings being the poorest performance. Unlike apperceptive agnosics, a person with associative agnosia can use shape cues to try to identify the presented object (as opposed to color and texture). Therefore, an associative agnosic is likely to mistake an object for one that is similar in shape. Patient FZ is known to have misidentified a drawing of a baseball bat as a paddle, knife, and thermometer (all objects that have a shape similar to a baseball bat). Since form information seems to be, at least partially, intact, there must be a failure of the structured perception to appropriately activate the network of knowledge about the functional, contextual, and categorical properties of objects that aid in their correct identification.

Of course, one of the highlighted symptoms of associative agnosia is that perception remains intact, that is, it becomes inaccessible. However, recent research has demonstrated that, at least some, associative agnosics do indeed have at least some form of visual impairment. For instance, patient CK's figure copying was quite adept in terms of final product; however, the process employed to reach that point was substantially different from what would normally be observed. CK was slow, and often lost his place if he had to take his pen off the paper. Levine and Calvanio reported further perceptual difficulties observed in patient LH, who was significantly slower in matching tasks and visual search tasks. While in comparison to other agnosics it may seem that those suffering from associative agnosia are displaying 'perception without meaning,' as coined by Teuber few would wholly subscribe to the notion that these patients have fully intact perceptual abilities.

An interesting subset of associative agnosia may manifest in some which recognition is not equally impaired for all classes or categories of object. Category-specific visual agnosia (CSVA) usually distinguishes between biological and nonbiological objects, with patients showing preserved recognition for all categories and a deficit for the biological objects. For example, someone with CSVA may have correct recognition of tools, but demonstrate marked difficulties in recognizing fruit and vegetables. Similar to associative agnosia, it is thought that the deficit is rooted in a dissociation between the mechanisms underlying visual perception and those that provide access to the semantic information associated with objects. However, the exact mechanisms are at present not fully understood. Some have theorized that the split in performance between biological and nonbiological items may be a result of biological items depending on specialized neural mechanisms that are unused (or underused) when recognizing nonliving. Neurological evidence has for the most

part substantiated this line of theory, with deficits in identifying biological objects following inferior-temporal lobe damage.

Integrative Agnosia

While Lissauer's pioneering work dichotomizing forms of recognition disorder (apperceptive vs. associative) is still often cited, we are now fully aware that object recognition is a far more complicated process than Lissauer could have intuited. Rather than simply matching stimuli coded in terms of primitives (like line orientation) to previously acquired knowledge, the visual system must code the spatial relations between lines and features, the object must be parsed from the background, and individual parts of the object need to be related to one another. Problems with this intermediate level of vision can result in poor overall perceptual integration of form information. Perhaps the best-studied patient was described in detail by Riddoch and Humphreys, H.J.A., who had bilateral occipitotemporal damage following an infarct of the posterior cerebral artery. Following the lesion, H.J.A. demonstrated profound impairments in a number of higher-level visual tasks, including face recognition, word recognition, and visual navigation. When attempting to identify objects, H.J.A.'s descriptions generally consisted of fragmented reports of various form-based features, with correct identification of an object seemingly hinged on either an elongated process of deduction or the presence of a highly diagnostic feature. For example, when asked to identify a line drawing of a pig, H.J.A. began identifying features such as having four short legs and a powerful body. Once he realized the mystery animal possessed a small curly tail, he was quick to correctly identify the stimulus. Typically, integrative agnosics over-segment stimuli, with parts of the same object being classified as separate. For example, while describing a paintbrush, H.J.A. suspected there may be two objects close together, rather than the single paintbrush presented. These patients typically perform best when

identifying real-world objects than still photographs, and have the poorest performance when required to identify line drawings. Such findings suggest that the addition of surface information and depth information appears to increase performance via benefiting the processes involved in integrating elements of the stimuli into a perceptual whole. Interestingly, when H.J.A. incorrectly named an object, his errors were visually related to the target objects and never seemed to be a result of semantic association, suggesting a deficit before access of item-specific stored knowledge has been retrieved. This notion is furthered by findings that integrative agnosics are unable to perform matching tasks that require semantic information or, to gesture, the correct use of misidentified objects. In sum, the deficit truly is one of object identification, rather than object naming. Although the disruption in processing is undoubtedly before higher visual processes, such as the attachment of meaning, most integrative agnosics perform quite well on standardized test of early perceptual processing. For example, H.J.A was able to accurately reproduce etchings presented to him, as can be seen in **Figure 3** (although his order of drawing lines was abnormal).

In addition, H.J.A. performed well on a task requiring the perceptual discrimination of objects that are matched for overall area and brightness, which patients suffering from impairments in the encoding of basic visual properties could not. In order to account for all features of performance found in integrative agnosics, basic, local visual elements are thought to be processed in a normal way, but the integration of these elements into unitary wholes is impaired. In more concrete terms, integrative agnosia appears to be a deficit located between the stage of visual processing concerned with shape processing and the visual access to memory representations. Since the human visual system is limited recognizing one object at a time, any deficiencies in the ability to properly segment/group the visual field will lead to the deficits observed in integrative agnosia by way of perception breaking down into a parts-based analysis of objects.

Optic Aphasia

Optic aphasia is typically described as having an inability to name a visually presented object, despite being able to identify the object through alternate means such as gesturing the appropriate use. With associative agnosias and optic aphasias often displaying similarities in their deficits, some have argued a classification of a single syndrome, perhaps allowing for varying degrees of severity. Both of these patient populations have profound difficulty in naming visually presented objects, with intact recognition persevering within the other senses, such as touch or sound. Additionally, both 'types' of patients have relatively intact low-level visual processing and an ability to copy presented line drawings. When examining optic aphasics, however, a number of important distinctions are readily apparent. First, and perhaps most importantly, optic aphasics are able to nonverbally identify an object through gesturing the intended use, a skill associative agnosics lack. Patient Jules, who was extensively studied after suffering a posterior left hemisphere stroke, would often pantomime the use of an object correctly, even if his verbal identification was incorrect. For instance, when shown a picture of a boot Jules correctly mimed putting the boot on his foot, but incorrectly identified the object as a hat. The nature of the disorder is further elucidated when one examines the types of errors seen in optic aphasia in comparison to associative agnosia. An associative agnosic commonly makes errors related to visual dimensions of the target object, whereas an optic aphasic is likely to make errors with a semantic underpinning. As is evident from the example above, Jules chose a response from a similar semantic category (clothing, for example), even though a hat and a boot share few visual features in common. Another common finding associated with optic aphasia, although much less frequently observed in associative agnosias, is an insensitivity to the visual quality or nature of the stimulus. That is, optic aphasics perform equally well (or equally poorly) on identifying photographs, three-dimensional pictures, and line drawings of objects. Finally, optic aphasics are far more likely to perseverate once an answer is produced, repeating error responses from previous trials. It is important to close with a caveat regarding the dichotomy created between optic aphasia and associative agnosia: there have been a number of reported cases where both conditions seem to be present in a single patient; indeed, even Lissauer's seminal patient had features of both apperceptive and associative agnosias preventing his categorization.

Summary

This article has served as a brief introduction to the collection of disorders termed visual agnosia. Despite relatively normal visual perception, attentional mechanisms,

intelligence, and language, these patients have a marked deficit in the recognition of previously known visual stimuli. The condition is modality specific, with the other senses (touch, hearing, etc.) providing a route to relatively unimpaired recognition performance. Despite the pedagogical role these interesting cases can fulfill, there is another, arguably more useful role for the study of visual agnosia within neuropsychology. As should be apparent from the provided discussion of neuroanatomy, the visual system as a whole is far more complicated than one would intuit. Indeed, one of the primary impediments to understanding how object recognition is achieved is the contradiction between how easily we accomplish it and the underlying complexity. By studying individuals who demonstrate impairment, we have been able to not only identify major distinctions between stages of object recognition, but also verify the modular organization of the visual system. The dissociations seen within the various subtypes of agnosia discussed here are compelling cases of how distinctions between 'early,' 'intermediate,' and 'late' stages of object recognition can have explanatory power in accounting for the many, seemingly distinct, forms of agnosia one may encounter. Of course, this relationship is two directional, with the study of patients with visual agnosia guiding our investigation of the visual system as a whole.

Glossary

Action semantic system – Component of the gesture-processing architecture that contains the conceptual attributes of a gesture, including conceptual attributes related to the knowledge of functions and actions in relation with tools and objects, to the knowledge of actions independently of tools and objects (e.g., arbitrary communicative gestures) but in which objects and tools can be incorporated, and to knowledge related to the gathering of simple actions in a sequence.

Conceptual apraxia – Formerly known as ideational apraxia, it is now proposed to use the term ‘conceptual apraxia’ for alterations that directly affect semantic knowledge about functions and actions related to tools and objects, and about arbitrary actions performed independently.

Ideational apraxia – The term was formerly applied to all disturbances in the action semantic system. It is now proposed to keep the term ‘ideational apraxia’ for disorders of the sequential organization of movements.

Melokinetic apraxia – A form of motor apraxia characterized by difficulties in carrying out successive small digital movements.

Motor apraxia – A form of limb apraxia that induces disorganization of the elementary motor activities that constitute a movement.

Praxicons – Recipients where visuo-kinaesthetic engrams are stored.

Visuo-kinaesthetic engrams – Abstract codes about the physical attributes of a to-be-performed or a to-be-perceived action.

variety of apraxic patterns. Principles and guidelines are provided for the assessment of limb apraxia, still too often overlooked in standard clinical examination.

A Brief History of Limb Apraxia

Conceptual bases for the study of apraxia originate with Hugo-Karl Liepmann (1863–1925) who described the seminal case of MT, an Imperial Counselor hospitalized with a diagnosis of aphasia and dementia following a syphilis attack. Intentional motor activity of the right hand was severely disturbed in MT, as well as global head, face, and tongue movements. Notwithstanding, Liepmann observed that after immobilization of the right hand, which was interfering with contralateral movement production, MT was actually flawlessly able to imitate and execute on verbal command simple movements with his left hand, including pantomiming the use of several objects. Because performance was so strikingly different between the two hands, Liepmann logically deduced that left-hand motor difficulties were not attributable to a deficit in object recognition or understanding, because these deficiencies should have equally affected performance on both hands. He therefore proposed to name this pattern motor apraxia to establish a firm distinction between apraxia and asymbolia, the disorder of symbolic representations that was deemed at that time to encompass aphasic, apraxic, and agnosia symptoms.

Liepmann must also be credited for conducting one of the first group studies in neuropsychology. He investigated apraxic symptoms using movements’ imitation and execution on verbal command in 89 patients with unilateral right or left hemisphere lesions. The outcome was that most left-brain damaged patients were exhibiting apraxia of the left upper limb (the right limb most often being paretic), whereas right-hemisphere lesions were not associated with movement disorders. Given that a cerebral hemisphere controls for motor activity in the contralateral part of the body, Liepmann reasoned that the left cerebral hemisphere should play a predominant role in programming and controlling voluntary movements, as it plays in language, and that movement information processed in the left sensorimotor area is transferred to the right sensorimotor area via the corpus callosum for controlling the left hand. He also proposed a first anatomo-functional model of praxis processing, with the assumption that gestures production passes through a

Outline

Limb apraxia is a cerebral disorder that affects the processing of voluntary movements in the absence of elementary sensorimotor, psychological, or cognitive deficiencies able to explain the observed deficit. Current models of limb apraxia have provided a theoretical framework that globally conceives gesture processing as the result of neural activity in dedicated modules for the treatment and storage of movement-related information. These cognitive and neuropsychological models offer the advantage of a unified explanatory framework for a large

conceptual stage, that is, the development of the idea of the movement, located in the occipito-temporal cortex, followed by a production stage where the appropriate motor programs (also called visuo-kinesthetic engrams) are selected in the sensorimotorium, which includes the sensory parietal area and Brodmann's motor areas 6 and 8. Liepmann's constructs have strongly influenced the clinical practice, to the point that his classification of limb apraxia (ideational, ideomotor, and motor) is still found nowadays in many textbooks, in a barely modified phrasing.

Current Understanding of Apraxia

Nowadays, apraxia is still considered one of the major classical neuropsychological syndromes, along with aphasia, agnosia, and amnesia. It is generally defined as a cerebral disorder that affects the processing of voluntary movements, after having excluded perceptual and motor elementary deficits, paralysis, agnosia, and intellectual or linguistic comprehension disabilities that may explain the observed disturbances. Exclusion criteria are particularly important for the diagnosis of apraxia because disorders of high-order cognitive functions are established only after having ensured that other deficits cannot be responsible for a similar symptomatic. This can be especially difficult in the case of apraxia because apraxic problems are diagnosed throughout a continuum ranging from motor to conceptual disturbances in the processing of gestures. For instance, observing a patient who uses a spoon for combing his hairs should evoke alterations in an action semantic system, because the physical features of the object have been erroneously associated with the functions normally devoted to another object. However, this error can be deemed genuinely apraxic only if conceptual misattributions are proven specific to intentional gestures, and are not observed in many other domains of cognition, in which case a global intellectual deterioration should rather be diagnosed. At the other extreme of the continuum, manual dexterity impairments in buttoning a shirt or holding a pencil may lead the clinician to evoke the possibility of a melokinetic apraxia (see later on), unless a neurological examination evidences a digital sensitivity deficit, which actually entails coarse handling of objects due to the impoverishment of the afferent information necessary to create the appropriate motor programs. On the other hand, it should be kept in mind that the mere presence of an exclusion criterion does not automatically exclude the diagnosis of apraxia. Indeed, the crucial argument must be that the observed deficit should be capable of explaining both the extent and the qualitative features of the apraxic symptomatic. Referring to the example above, it is obvious that a digital sensitivity deficit can harm fine manipulation of small objects, but cannot

explain an incorrect positioning of the whole arm in space, as for instance, positioning its hand behind the head instead of touching the nose.

Although many patients may suffer from apraxia at various levels, its evaluation remains too often overlooked in standard neuropsychological examination. This means that apraxia diagnosis is too often taken into consideration only when symptoms are really obvious during the testing, or whenever the patient spontaneously complains about movement difficulties in everyday life. This relative disinterest comes from various reasons. First, many clinicians still believe that a definite feature of apraxia is the automatic–voluntary dissociation proposed by Jackson (1878), by which apraxic disorders are laboratory symptoms revealed in the course of a specific and effortful examination, but do not impact on routine and automated activities of everyday life. Still popular nowadays, this misconception is challenged by more subtle studies having demonstrated that apraxic patients actually experience concrete difficulties even when performing highly familiar activities such as slicing bread, dialing a phone number or grasping tiny objects. Second, although apraxia and aphasia are separate entities, a mutual predominance of the left hemisphere for language and gesture functions in most right-handed individuals entails a relatively high co-occurrence of the two disorders, from 27% to 80% according to studies, in which case the aphasic symptoms are likely to obscure the presence of an associated apraxia. Third, our understanding of the cerebral and cognitive mechanisms underlying the representation and programming of movements in man is still fragmentary. Despite several proposals for cognitive and neuroanatomical models of limb apraxia in the past 20 years, empiricism still prevails in clinical assessment, which makes conclusions rather uninformative. Finally, clinical evaluation justifies itself by the fact that it is a first step toward therapeutic intervention. Unfortunately, published revalidation studies still remain scarce and have not always been conclusive, which does not encourage neuropsychologists and neurologists to invest much time in a rigorous and exhaustive evaluation of apraxia. This creates a vicious circle that must be broken, as there is convincing evidence that everyday activities can be rehabilitated with a certain success in apraxic patients, for instance, when using error-free training procedures.

Cognitive and Neuropsychological Modeling of Limb Apraxia

Current neuropsychological and cognitive approaches of limb apraxia have provided a theoretical framework that globally conceives gesture processing as the result of neural activity in dedicated modules for treatment and storage of specific information. From this perspective,

limb apraxia is viewed as the behavioral outcome of dysfunctions in the cerebral structures that underlie these various levels of processing. Here, we briefly describe such a cognitive neuropsychological model of limb apraxia, partially adapted after the popular model proposed by Rothi and colleagues to account for the complex processes involved in the production and reception of gestures under various modalities.

In this model illustrated by **Figure 1**, the visuo-gestural analysis stage corresponds to the high-level perceptual visual analysis of human gestures, that is, the elaboration of a structural description of the visually perceived gesture, which is segregated from the visual analysis of objects. At the following step, visuo-gestural information is forwarded to the input praxicon stage, in which visual descriptions are compared with canonical representations of well-known and meaningful gestures stored in memory. This intermediary stage is mandatory for discriminating between familiar and novel gestures, and for meaningful gesture recognition and naming upon access to the action semantic system, where conceptual attributes of the gesture are retrieved. These conceptual attributes relate to the knowledge of functions and actions in relation with tools and objects, to the knowledge of actions independently of tools and objects (e.g., arbitrary communicative gestures) but in which objects and tools can be incorporated, and to knowledge related to the gathering of simple actions in a sequence. Besides the

input praxicon, the output praxicon is proposed to contain complementary codes about the physical attributes of a to-be performed action, at variance with the input praxicon that contains the codes about the physical attributes of a to-be perceived action. Access to the output praxicon stage and its visuo-kinaesthetic engrams or codes for to-be-performed actions is mandatory in order to pantomime gestures upon verbal command, a task in which the movement can only be evoked from memory. In collaboration with the input praxicon, it is also assumed that the output praxicon provides a processing advantage for imitation of familiar gestures, in that it avoids the cost to compute on-the-fly all the parameters needed to analyze and implement the spatial and temporal features of the skilled movement at each imitation attempt. The relatively abstract information provided by the output praxicon is then implemented in its motor form at the innervatory pattern stage for effective gesture production. Disturbances in one or more of these cognitive components will thus result in specific deficits in imitating, performing upon verbal command or presentation of an associated object, and discriminating or naming familiar gestures. On the other hand, imitation of meaningless, novel gestures is a particular case in that no corresponding representation is previously available in memory.

It has been long believed that imitation of novel, unfamiliar gestures is processed through direct transposition

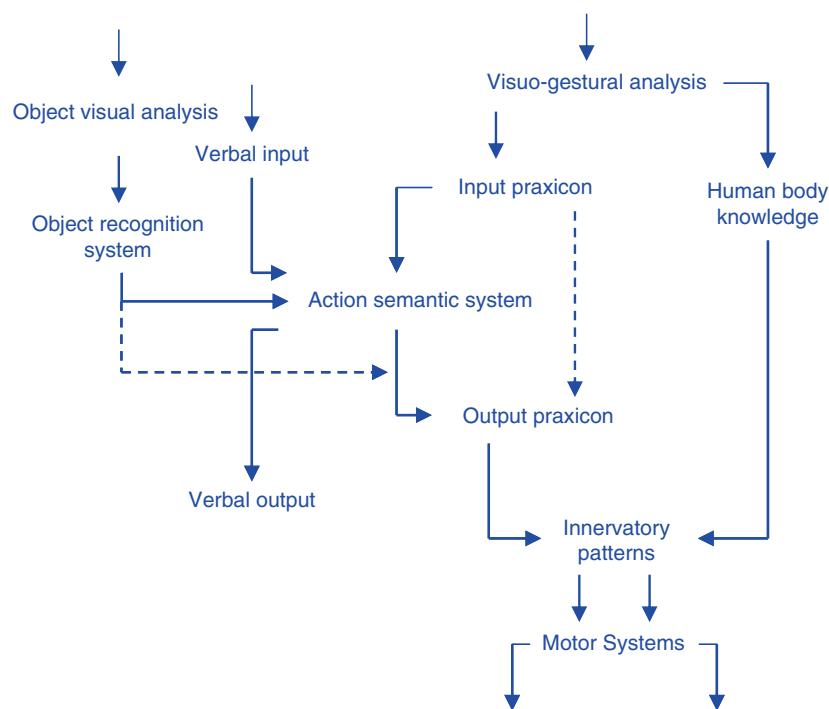

Figure 1 Cognitive neuropsychological model of limb praxis processing. Adapted from Peigneux P, Van der Linden M, Andres-Benito P, et al. (2000) Exploration neuropsychologique et par imagerie fonctionnelle cérébrale d'une apraxie visuo-imitative. *Revue Neurologique* 156(5): 459–472.

between visual analysis and motor implementation. However, neuropsychological evidence indicate that after demonstration of a nonfamiliar gesture, an intermediate representation is build after the visuo-gestural analysis stage into the human body knowledge system, which specifies the possible relationships between the main body components (for instance, the relative position of the upper arm, the arm, and the hand). This operating step creates a schematic representation which is more easily held in working memory and manipulated, and is subsequently conveyed toward the innervatory pattern stage for motor implementation. Thus, human body knowledge coding facilitates the transition between visual analysis and motor execution in that it reduces the complexity of the visuo-motor transformations needed to imitate a previously unknown gesture.

As compared to classical taxonomic approaches of limb apraxia, this type of modeling offers the advantage of a unified explanatory framework for a large variety of limb apraxic patterns. Indeed, if one or more specific processing modules are involved in the completion of each given task according to specific modalities (e.g., imitation, verbal command, recognition, etc.) and to the nature of the movement to process (familiar, novel, etc.), each apraxic pattern should be associated with alteration in one or more cognitive components. Identification of altered and preserved components may therefore be achieved by (1) making a comparison of the performance patterns under different conditions using comparable stimuli (e.g., imitation versus execution on verbal command of familiar gestures), (2) making comparison of performance patterns for specific categories of stimuli with identical task settings (e.g., imitation of familiar versus novel gestures), and (3) through the qualitative analysis of errors made during gesture processing.

Assessment of Limb Apraxia

Assessment of limb apraxia should take into account the diversity and specificity of apraxic patterns highlighted above. We will provide here some principles to guide the examination of limb apraxia for the interested reader. It should be stressed, however, that a detailed investigation of apraxia may take up to several hours and should be carried out by a trained neuropsychologist familiar with these specific assessment methods. Notwithstanding, it is also important for other professionals to apprehend apraxia examination and apply similar principles in standard investigations aiming at evidencing possible apraxic disorders. In addition, it must be reminded that the diagnosis of apraxia can be established only after having excluded the possibility that the observed symptoms are caused by other factors. Therefore, thorough neurological and neuropsychological examinations should be

performed beforehand to leave out other psychological, cognitive, or sensorimotor deficiencies that could account for an probable apraxic deficit.

Examination Conditions

In the assessment of limb apraxia, the variety in testing conditions aims at highlighting dissociations of performance that may point toward specific deficits. In the evaluation of gesture production, the examiner should always present the patient with at least three pantomime conditions: (a) executing familiar gestures on verbal command, (b) imitating familiar gestures, and (c) imitating novel, unfamiliar movement patterns. Those conditions are best suited to highlight the most frequently observed dissociations in performance. Whenever possible, however, the examination will be complemented with pantomimes performed upon (d) visual and (e) tactile presentation of man-use objects associated with specific actions (e.g., hammer, comb, screwdriver, etc.), and (f) concrete manipulation of the same objects. Gesture reception should also be carefully assessed using at least (g) denomination of visually presented familiar gestures, and (h) reasoning tests in which functional knowledge about tools and associated actions is probed. In the latter case, this can be achieved, for instance, by asking the patient to decide whether a hammer and a nail works together (i.e., probing functional associations between two objects), or whether a hat may be a replacement for a bucket to carry some water on a short distance (the answer here being 'Yes' since both objects are potential containers even if the hat will not hold water for very long).

Referring to the cognitive neuropsychological model described above, each of these tasks usually involves direct access to more than one processing module. Therefore, any hypothesis about the functional localization of the observed deficit will be made based on differential patterns of performance across the different tasks. For instance, a common deficiency in the imitation and execution on verbal command of familiar gestures would be potentially attributable to deficits affecting the action semantic system, the output praxicon, or the innervatory patterns. However, if it can be established that gestures denomination is preserved, this positive result will demonstrate the integrity of the action semantic system, which is mandatory for attribution of the correct conceptual label to the proposed action. Having excluded an action semantic system deficit, it remains to differentiate further whether the deficit is located at the output praxicon or the innervatory patterns levels. In this case, flawless performance on novel gestures imitation will be sufficient to certify the integrity of innervatory patterns, knowing that successful imitation always requires access to the innervatory pattern stage. In such a case, it may be

concluded that it is an output praxicon deficit which is responsible for this disorder predominantly affecting the production of familiar gestures. When confronted with a patient exhibiting deficits in novel gesture imitation, an additional test can be proposed, which is the reproduction of the same unfamiliar limb postures on a manikin or a collaborator. The rationale behind this test is to highlight disorders of the human body knowledge component. Indeed, if similar errors are produced when imitating a novel gesture or having to reproduce the same pattern on another body structure, despite strikingly different motor demands, then this will indicate that the imitation deficit lies in the ability to create a coherent representation of the perceived posture with reference to the topographical organization of the human body.

Examination Procedures

Before and during the course of apraxia assessment, it is essential that the instructions provided by the examiner strongly emphasize the need to produce and analyze gestures in a most precise as possible manner. Similarly, it must be carefully ensured that the patient has an adequate understanding of the performance levels that

should be targeted, systematically using training items and providing examiner's feedback. Most importantly, at least a second trial should be systematically proposed after failure to process a gesture, in order to ensure the consistency of the observed deficit. Indeed, many examiners overlook the fact that apparently apraxic errors may be produced due to the influence of various nonspecific cognitive factors, for instance following attentional and working memory deficits. Such nonspecific errors are usually corrected by the patient if allowed a second attempt, demonstrating preserved access to the underlying praxis system.

This is why a difference should be made between simple and consistent errors. Simple errors are observed at the first attempt in performing a gesture, but corrected in a subsequent attempt, even if this correction is sometimes associated with the production of a qualitatively different error. These simple errors may suggest a limitation in processing capabilities, but cannot ensure the genuine apraxic characteristic of the deficit. On the other hand, consistent errors are errors repeated at consecutive attempts, despite the fact that the patient's attention has been drawn towards the previously committed error (**Figure 2**). Consistent errors are thus more

Figure 2 Consistent spatial error produced by patient R.M. during imitation of a meaningless gesture (i.e., to put the back of the right hand on the left ear). At first attempt (top left picture), a spatial configuration error is observed as R.M. put the palm of her right hand on the ipsilateral cheek instead of the contralateral one. The examiner then attracted her attention on the incorrectness of the gesture, and a second attempt was allowed. After marked hesitations (illustrated on middle picture), R.M. produced a second spatial configuration error (bottom picture) in putting the back of the right hand was on the ipsilateral cheek. Thus, spatial configuration errors are consistently produced across trials, suggesting genuine apraxic difficulties to elaborate an appropriate representation of the gesture to imitate (see main text). Left inferior drawing represents the posture demonstrated by the examiner. Reproduced from Peigneux P, Van der Linden M, Andres-Benito P, et al. (2000) Exploration neuropsychologique et par imagerie fonctionnelle cérébrale d'une apraxie visuo-imitative. *Revue Neurologique* 156(5): 459–472.

likely to be genuinely apraxic, because reproduction of the same error despite reinstruction provides more confidence that this error reflects a specific alteration in the movement-processing system. All these precautions are especially important in apraxia assessment because there is a large, natural variability in the way movements are produced among different individuals. Owing to this fact, relatively vague attempts to produce gestures may be erroneously classified as correct or flawed when these exigency levels are not made perfectly clear to the patient. Further, to prevent facilitation of performance by an order effect between the various conditions of gesture production (e.g., production of same or similar gestures on imitation vs. verbal command), presentation order of the testing items should be randomized across these conditions, unless other cognitive problems (e.g., an executive dysfunction characterized by altered flexibility) make it difficult for the patient to switch from one condition to another. On another note, apraxia should be as much as possible systematically investigated at both limbs, taking in account the normal asymmetry of performance between the right and left hands in interpreting the results. Finally, bimanual gestures may also be administered to probe limb-coordination difficulties.

Qualitative Error Analysis in Gesture Production

The most accurate manner to assess gesture production is to record the patient's performance on videotape, allowing delayed in-depth analysis by one or more independent evaluators. Although not always attainable in clinical settings, this procedure largely facilitates the qualitative analysis of gesture-production errors, which is an essential complement to the quantitative analysis of performance dissociations presented above. Indeed, the mere usage of quantitative scores computed based on a number of successfully performed items, or on the number of trials needed to achieve the correct execution of gestures, provides only crude information about the mechanisms underlying disturbed performance. Such measures completely obscure the fact that individuals with qualitatively different deficits can obtain identical quantitative scores. For instance, it is very different to perform a gesture on verbal command in a seemingly recognizable way, but inadequately positioned in space (e.g., combing on the shoulder instead of on the head) than producing a perfectly performed gesture, but which is not the one required by the examiner (e.g., playing piano instead of playing violin). In the first case, the error suggests that either the visuo-kinesthetic representations of gestures in the output praxicon or their motor transcription in the innervatory patterns are altered, whereas the action semantic system is preserved. In the latter case, flawless motor production of a gesture with an inadequate meaning suggests the opposite profile, that is, a deficit in

the action semantic system coupled with preserved functioning of the output praxicon and innervatory patterns. These conclusions will complement congruent findings of performance dissociations between tests performed under various conditions and using different stimulus type. For instance, an action semantic deficit should lead to marked differences in performance between defective gesture production on verbal command and preserved imitation of these same gestures, the latter being made possible by a direct link between the input and output praxicons that bypasses the action semantic system, or by accessing the alternative imitation route and processing familiar gesture to imitate in the same manner as novel gestures, through access to the human body knowledge system.

A Brief Taxonomy of Limb Apraxic Disorders

A recurrent problem with taxonomies of limb apraxia is their lack of theoretical foundations. In addition, similar labels have been applied to different apraxic patterns all the way through the history of clinical practice and publications, and these concurrent labels still prevail nowadays. Still, these taxonomies remain largely in use in the clinical domain, which makes it important for the reader to be briefly informed about the main limb apraxia categories and their possible variations.

Ideational Apraxia

Ideational apraxia is a term that defines two distinct apraxic patterns that may be deemed related to the action semantic system. In its first acceptance, inherited from the French author Morlaas, ideational apraxia is a selective disturbance in the use of current objects, in which the patient cannot use any more a real object and/or produces errors in using tools, even for simple tasks that imply only one object. In most severe forms, the patient may try writing with scissors or brushing teeth using a spoon. In its second acceptance, ideational apraxia defines the inability to order the set of elementary movements that makes a complex action into their correct sequence. For instance, the patient will omit, add, or transpose elements in the sequence of movements used in pantomiming eating soup with a spoon. To avoid terminological disputes, it has been proposed to keep the term ideational apraxia for disorders of movement sequence organization, while defining under the term 'conceptual apraxia' the other alterations that directly affect semantic knowledge about functions and actions related to tools and objects, and about arbitrary actions performed independently.

Ideomotor Apraxia

Ideomotor apraxia is probably the most common form of limb apraxia, which affects a gesture production system including sensorimotor knowledge of actions and the perceptivo-motor processes required for their organization and execution. Complementary to the two main definitions of ideational apraxia, ideomotor apraxia knows at least two concurrent definitions. According to its first acceptance, again inherited from Morlaas (1928), ideomotor apraxia relates to the gesture execution component in itself, independently of the object associated to the action. The disorder will therefore be especially visible during the execution of arbitrary or symbolic movements (e.g., military salute, praying, etc.) that cannot be improved by the presence of an object. Still, deficits will be also observed during pantomime of object-use gestures, carried out in the absence of the associated object. According to the second acceptance, based on the bottom-up, hierarchical distinction between movement, action and sequence, ideomotor apraxia defines a deficit that affects action execution by itself, characterized by difficulties in performing isolated gestures or fragments of a movement sequence upon imitation or verbal command. Beyond these differences, these two forms of ideomotor apraxia have in common the description of the incorrect production of an action appropriately selected at the conceptual level. Besides supra-modal ideomotor apraxia that affects movements in all production forms, ideomotor apraxia can also be restricted to specific modalities of gesture production (imitation, verbal command, upon visual or tactile object presentation, etc.), stimulus types (object-use, symbolic, arbitrary unfamiliar, etc.), or effectors (upper or lower limb, unilateral or bilateral, etc.).

Motor Apraxia

Motor apraxia defines a disorganization of the movement that closely resembles elementary motor disorders. Motor apraxia is almost always unilateral and expressed across all gesture production modalities as manual dexterity disorder. Its best-known form is melokinetic apraxia in which small and rapid, alternated or serial movements are disturbed and carried out awkwardly. For instance, the patient may not be able to tap fingers in alternation or tinkling fingers smoothly on the edge of the table any more. Melokinetic apraxia can be distinguished from afferent or kinesthetic apraxia, characterized by a loss of selectivity (rather than by loss of dexterity) of digital movements with major difficulties in the reproduction of elementary fingers configurations.

Physical and Emotional Pain

Glossary

Active emotional coping – Integrated psychological, behavioural and physiological responses engaged to control and reduce the impact of any stress threat or pain; these responses may be either ‘proactive’ or ‘reactive’ strategies depending on the specific behavioral patterns engaged.

Anterior cingulate cortex – The cingulate cortex is found in the medial part of the cerebral cortex; it lies above and around the corpus callosum, and its anterior part is found beneath the prefrontal and frontal cortices. It is also known as Brodmanns area 24.

Conservation-withdrawal – Integrated psychological, behavioral, and physiological response engaged in response to stress threat or pain, for which ‘proactive’ or ‘reactive’ active emotional coping strategies have either failed or are inappropriate.

Midbrain periaqueductal gray – The cell dense region surrounding the canal that joins the third and fourth ventricles of the brain. It is organized into longitudinal columns of cells, each of which plays an important role in the mediation of integrated psychological, behavioral, and physiological responses to deal with stress threat or pain.

Passive emotional coping – Another term for conservation-withdrawal responses; however, it is sometimes, and somewhat confusingly, used to describe ‘reactive’ active emotional coping by some scientists.

c-fos – An immediate early gene, whose expression has been used quite extensively by neuroscientists, to identify recently active neurons in post-mortem histological sections of nervous system tissues. The gene is identified from either (1) the presence of its protein product Fos, using immunohistochemical techniques, or (2) the expression of c-fos mRNA, using *in situ* hybridization techniques.

To expand on this idea, what is being stated is that should we be able to describe precisely, in both structural and functional terms, the pathway from the peripheral receptor (nociceptor) via the sensory ganglia, and along through the spinal, thalamic, and cortical pathways, our understanding of the pain experience would be both incomplete and inadequate to explain the clinical presentation of the pain patient.

A similar fundamental view permeates some of the writings of Patrick Wall, another scientist at the vanguard of modern pain research. In the John J. Bonica lecture of 1979, he challenged the view of many pain neurobiologists by placing the definition of ‘pain’ in a new context. He states that “... pain is better classified as an awareness of a need state than as a sensation: that it has more in common with the phenomena of hunger and thirst than it does with seeing and hearing; and that it serves more to promote healing, than to avoid injury.” In identifying an immediate, and acute and a chronic stage following pain eliciting events (i.e., tissue injury), Wall recognized that “... in each stage pain has only a weak connection to the eliciting stimulus, but a strong connection to the body state...” That is, as time passes pain may resolve or persist, and thus the drives for behavioral change will alter; however, these drives do not necessarily correlate with the presence of pain as a sensation.

What each of these authors were highlighting was that pain as a sensation is only part of an organism’s experience and that pain represents a fundamental drive for the need for behavioral change. That is, pain is better viewed as a motivational state, rather than simply sensation, and further that this need state changes over time, relative to the occurrence of the injury. On balance, each of these views arrives at the same conclusions, albeit on the bases of slightly different arguments, that to understand pain we must understand more than just the sensory pathways and that any definition of the central neural representations of pain must include the motivational or emotional state changes that it generates.

This viewpoint underpins the definition of pain offered by the International Association for the Study of Pain in 1979, “that pain is an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.” However, despite the acknowledgement of the inextricable link between sensation and emotional state change, the design and execution of most experimental studies in the neurobiology of pain remained unaltered, until recently.

Concepts of Pain

In the posthumously published works of William K. Livingstone, a pioneer of contemporary pain research, the point is repeatedly made that “... pain is not strictly a physical sensation that can be defined simply by its anatomical and physiological substrates....”

It has been appreciated for many years that pain of different origins is associated with emotional state changes with distinct and different qualities. Almost 70 years ago, it was noted by Thomas Lewis, a clinician and physician in his book *Pain*, in which he presents findings based on many years of clinical observations, that pain arising from different body structures triggers distinctive emotional behaviors. He notes specifically that pain arising from the human skin is associated with "brisk movements, with a rise in pulse rate and a sense of invigoration," whereas pain derived from deeper body structures is associated usually with "quiescence, slowing of the pulse, falling of the blood pressure, sweating and nausea." He went on to comment that the nausea is responsible for the description of deep pain being sickening, an emotional state most usually applied to pain of deep origin but seldom to that from cutaneous pain. Indeed, this sickening feeling or vaso-vagal response (which Lewis first termed vaso-vagal syncope) occurs often with pain arising from joints, muscle, periosteum, and the vasculature; it also occurs during angina, gall stones and colic, and is a major feature of testicular and bladder pain.

The clearly opposing emotional state changes triggered by pain arising from different body regions (tissues) led Lewis to state that given the differences in the emotional responses to pain of different origins, it may in fact be "unsafe to classify both states under the one unqualified term pain." Thus, it is clear that Lewis recognized the critical position of emotional state in our definition of pain.

If then, it is essential that we formulate our understanding of the neurobiology of the representation of pain in the nervous system by including an understanding of the location of brain regions mediating the emotional state changes evoked by pain. The observations made by Lewis, almost 70 years ago; the clinical reasoning presented in the writings of Livingstone; and the challenges of Wall's provocative lecture must all be integrated fully into the conceptual framework of the modern pain neurobiologist. Lewis' observations that two distinct emotional state changes are evoked by superficial and deep pain have direct implications in this regard.

Lewis was clear about the significance of his findings, when he stated that the qualities of superficial versus deep pain are so distinct, that from a clinical perspective, they challenge a unitary conceptualisation of pain. That is, the experience of superficial pain and that of deep pain share few common properties. He recognized that the distinct differences in both sensory and emotional experience between superficial and deep pain could only have its basis in differential representations within the central nervous system. He states... "we need to consider whether or not the system of fibres subserving pain derived more deeply connect basically to another distinct

part of the sensorium..." compared with those subserving superficial pain. "Although both follow the path of the anterolateral tract as shown by the abolition of both in cases in which this tract has been divided surgically, we should bear in mind the possible serious fallacy of regarding both types as being represented in a common centre." This suggests that Lewis expected distinct and separate neural representations of pain of superficial versus deep origin.

A Dilemma for the Pain Neurobiologist?

A longstanding difficulty for experimental research into the neurobiology of pain is revealed after consideration of the approaches of Livingstone, Wall, and Lewis. It becomes clear that there are two major strategies to approach the study of pain, which are well illustrated by considering how pain of cutaneous and deep origin has been investigated most recently. The most widespread and extensively published approach has been that derived from the classical paradigms of the sensory physiologist, which have been fuelled by the clinical significance and diagnostic importance of the phenomenon of referred pain. Not surprisingly from this vantage point, anatomical and (electro-)physiological experiments have focused almost exclusively on viscero-somatic convergence. That is the common representations of pain of superficial and deep origin with the central nervous system.

In contrast, the approach suggested by the writings of Livingstone, Wall, and Lewis, with their emphasis on the emotional and behavioral significance of the pain signal, suggests that consideration of the different central representations of the distinct emotional states evoked by pain of cutaneous and deep origins will reveal a deeper understanding of the brain mechanisms underlying the array of sensory and emotional state changes commonly referred to as pain.

Emotional Pain in Animals

In humans, it is clear from the findings discussed above that there are two ways in which an individual attempts to cope with pain. These emotional state changes, or emotional coping strategies, are adopted in situations other than pain states, and broadly represent the strategies engaged to deal with any major stressor challenging the integrity of the individual. The strategy engaged in response to superficial pain has been defined as an 'active emotional coping response,' and is identical to the classically defined 'fight-flight' response. This response strategy leads an individual to engage with its environment, and in particular, with the source or the location of the painful event. The response is characterized by

increased vigilance, hyper-reactivity, increased somatic activity, and increased sympathetic tone (which shows regional specificity, depending on the specific behaviors engaged in). This particular emotional state is triggered usually by painful events that can be controlled or escaped from, as well as other stressors that are perceived as escapable and/or controllable.

The second class of response, engaged during pain arising from deeper structures, has been referred to as a ‘passive emotional coping response’; it is in fact the complete opposite of the active emotional strategy. Rather than engagement with the painful stimulus and/or the environment, there is disengagement with the environment, a response termed conservation-withdrawal, in earlier studies, which focused on the coping styles evoked by other classes of stress or threat. The passive coping strategy is characterized by decreased vigilance, hypo-reactivity, reduced interest in the environment, and often a withdrawal of sympathetic tone resulting in falls in arterial pressure and heart rate. This strategy is usually engaged in response to stimuli that are, or are perceived as, inescapable. Thus, with regard to pain arising from distinct body structures, acute cutaneous pain triggers active emotional coping behaviors, whereas persistent cutaneous pain, or pain of deep somatic or visceral origin, will trigger primarily passive emotional coping behaviors. In addition, there is a transition point for pain of cutaneous origin, insofar as acute pain from superficial structures triggers initially an active emotional coping response. If this pain persists, the emotional coping response will switch over time to a passive style of response, in exactly the way Wall described some 30 years ago.

It is thus possible now to re-address the issue of physical and psychological pain, in terms of the distinct and different emotional behaviors evoked by different classes of pain. The important neurobiological questions raised by this conceptual shift are: (1) are there different neural circuits mediating active and passive emotional coping behaviors; and (2) are there different and distinct neural pathways accessing these circuits following noxious activation of cutaneous and deep body structures?

Brain Representations of Active and Passive Emotional Coping Responses: Animal Studies

In unravelling the distinct neural circuits in which active and passive emotional coping responses in experimental animals, investigations of one brain region, the periaqueductal gray (PAG) region of the midbrain, has provided an invaluable entrée point. The PAG is the cell dense structure that surrounds the midbrain aqueduct, the conduit between the third and fourth ventricles of the brain.

Studies by a number of investigators in a number of laboratories revealed that the PAG is divisible into a series of longitudinally oriented functional columns. Active emotional coping responses (fight or flight; increased arterial pressure and heart rate; and a non-opioid mediated analgesia) are evoked when neurons lying either dorsolateral (dIPAG) or lateral (IPAG) to the midbrain aqueduct are activated.

Neurons of the dIPAG are distinguished from neurons of the IPAG by the presence of a number of transmitter substances, including nitric oxide synthase, cholecystokinin, acetylcholine and Met-enkephalin, and also by the absence of cytochrome oxidase and the glycine transporter (Gly-2). The major inputs to neurons of this region arise from the medial prefrontal cortex and specific nuclei of the medial hypothalamus; however, these cells do not receive inputs from the brainstem or the spinal cord, regions which themselves receive dense inputs from nociceptive primary afferent fibres carried in: spinal nerves, the trigeminal nerve (cranial nerve V), the vagus (cranial nerve X), or the glossopharyngeal nerve (cranial nerve IX) (**Figure 1**). The predominance of cortical inputs into the dIPAG has led to the suggestion that when evoked by psychological stimuli (i.e., signals arising primarily from the cortex), active emotional strategies are mediated by neurons in this PAG column. Data from a number of animal studies support this view, for example, the threat, either potential or immediate, signaled by the odor or sight of a cat (critically though, not the physical contact) evokes an active emotional coping response and a selective activation of neurons in the dIPAG as indicated by the neuronal expression of the immediate early gene, c-fos (**Figure 4**). Thus, it may be that the psychological/emotional states, which people describe as having painful qualities, are mediated in part by neural circuitry, which may be defined by its afferent and efferent connections with dIPAG neurons.

Although a clear boundary can be defined between the dIPAG and the ventrally adjacent IPAG on neurochemical grounds, the boundary between the IPAG and the ventrally adjacent ventrolateral PAG (vIPAG) column rests primarily on functional criteria. The lateral column of the PAG receives comparatively little cortical input, comprising, for the main part, a small projection from the dorsolateral convexity of the medial prefrontal cortex; similarly, its hypothalamic projections are also modest, receiving again a small projection from nuclei of the dorsal hypothalamus. By far the largest projection to the IPAG arises from the spinal cord and the spinal trigeminal nucleus (Sp5) (**Figure 2**). These projections terminate somatotopically within the IPAG column, and arise from spinal and Sp5 laminae (Rexed’s laminae I, II, IV, and V), which contain noci-responsive neurons. These anatomical observations of a significant input from noci-responsive brainstem and spinal cord regions suggest that neurons of the IPAG play

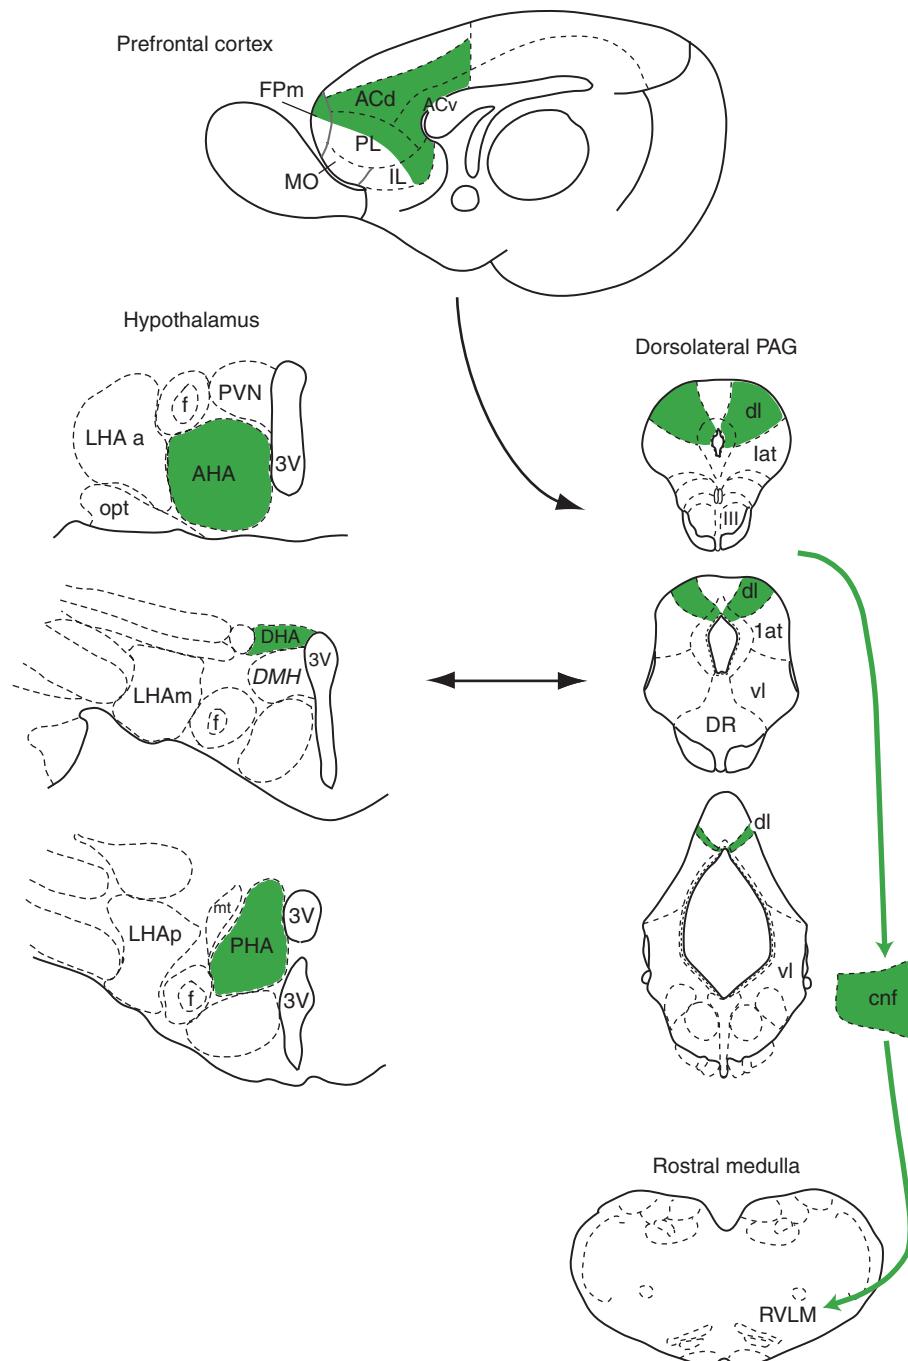

Figure 1 Schematic illustration of the major inputs to the dPAG from the forebrain and hypothalamus (dorsal, medial prefrontal cortical fields, and medial hypothalamic regions). The dPAG does not project directly to the medulla, but can influence the rostral ventrolateral medulla via the cuneiform nucleus. Modified from Keay KA and Bandler R (2009) Emotional and behavioural significance of the pain signal and the role of the midbrain periaqueductal gray (PAG). In: Basbaum AI and Bushnell CM (eds.) *Science of Pain*, pp. 627–634. San Diego, CA: Academic Press.

a critical role in integrating active emotional coping responses in response to physical (rather than psychological) stimuli, for example, acute cutaneous pain. Once more, data in support of this idea are found in experiments using expression of the *c-fos* gene as a marker of neuronal activity, which have shown that brief applications of noxious

thermal stimuli: selectively increase *c-fos* expression in neurons of the IPAG; trigger increases in arterial pressure and heart rate and evoke active emotional coping responses (Figure 4). The active emotional coping responses evoked from the IPAG have directional qualities, which are related to the precise location of the stimulus, accentuating the

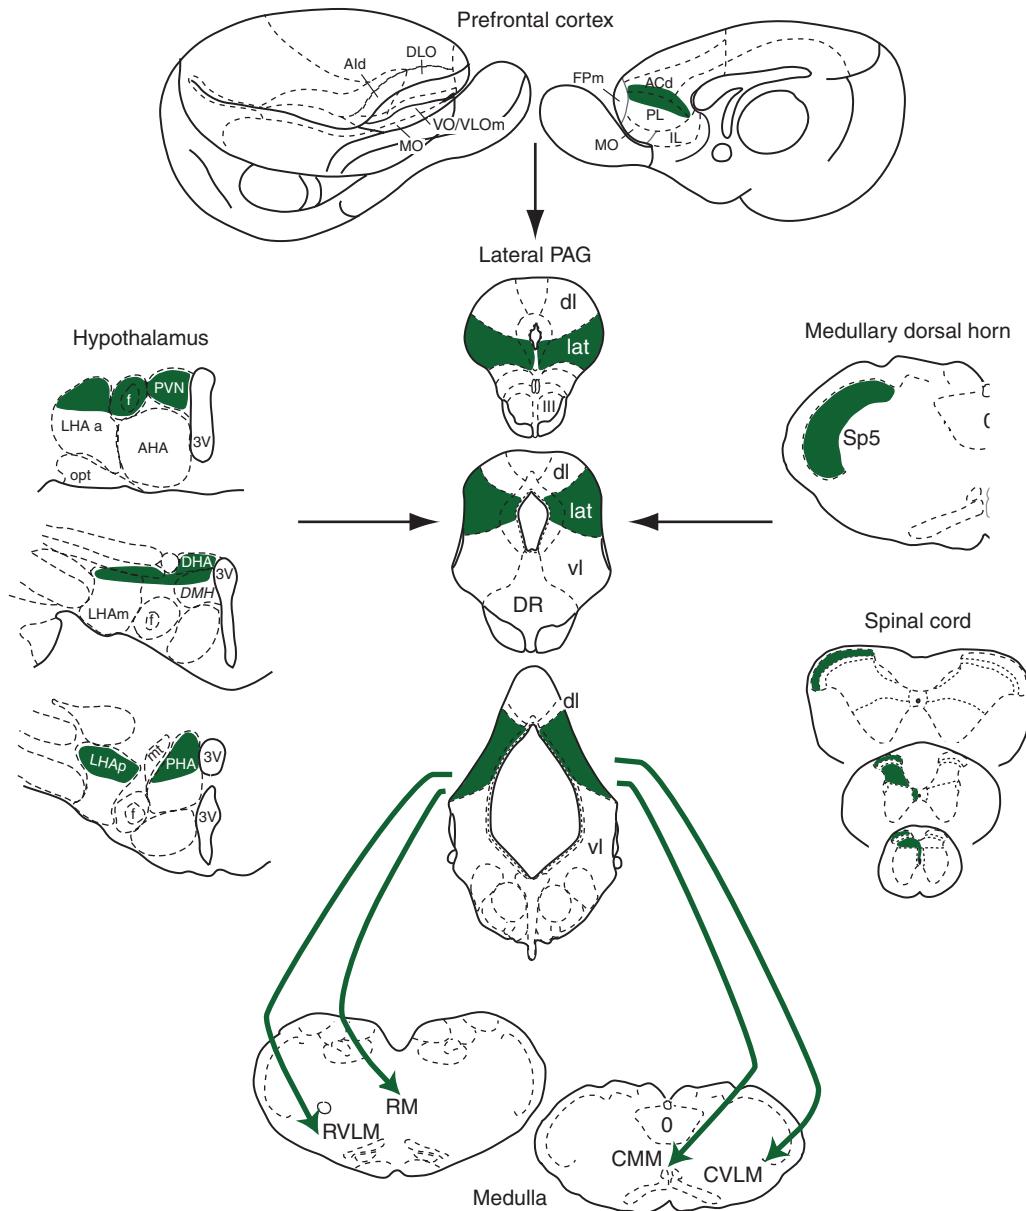

Figure 2 Schematic illustration of the inputs to lateral PAG. Major ascending inputs arise from spinal cord and the medullary dorsal horn (Sp5). In addition, restricted parts of medial prefrontal cortex and the dorsal subnuclei of the hypothalamus provide smaller inputs to this region. The IPAG projects directly to the rostral and caudal ventrolateral medulla (RVLM, CVLM) as well as the rostral and caudal ventromedial medulla (RM, CMM). Modified from Keay KA and Bandler R (2009) Emotional and behavioural significance of the pain signal and the role of the midbrain periaqueductal gray (PAG). In: Basbaum AI and Bushnell CM (eds.) *Science of Pain*, pp. 627–634. San Diego, CA: Academic Press.

likely functional significance of the somatotopically organized spinal and Sp5 projections defined in anatomical studies (Figure 2). On balance, therefore, it appears that neurons of the dorsal PAG trigger active emotional coping responses to psychological stimuli (dIPAG) and to physical stimuli (IPAG). The neural circuits within which each of these PAG columns (dl vs. IPAG) is embedded form discrete networks critical in integrating the affective/motivational/drive states, which characterize distinct classes of escapable pain.

In contrast to the dorsal PAG (dIPAG and IPAG), neurons within the vIPAG have been shown to mediate a coordinated response that resembles the conservation-withdrawal response defined in earlier literature investigating stress responses. The activation of vIPAG neurons triggers reduced responsiveness to external events, behavioral quiescence, falls in arterial pressure and heart rate, as well as an opioids-mediated analgesia. The behavioral reaction triggered by the vIPAG comprises the passive emotional coping response. In common with the IPAG,

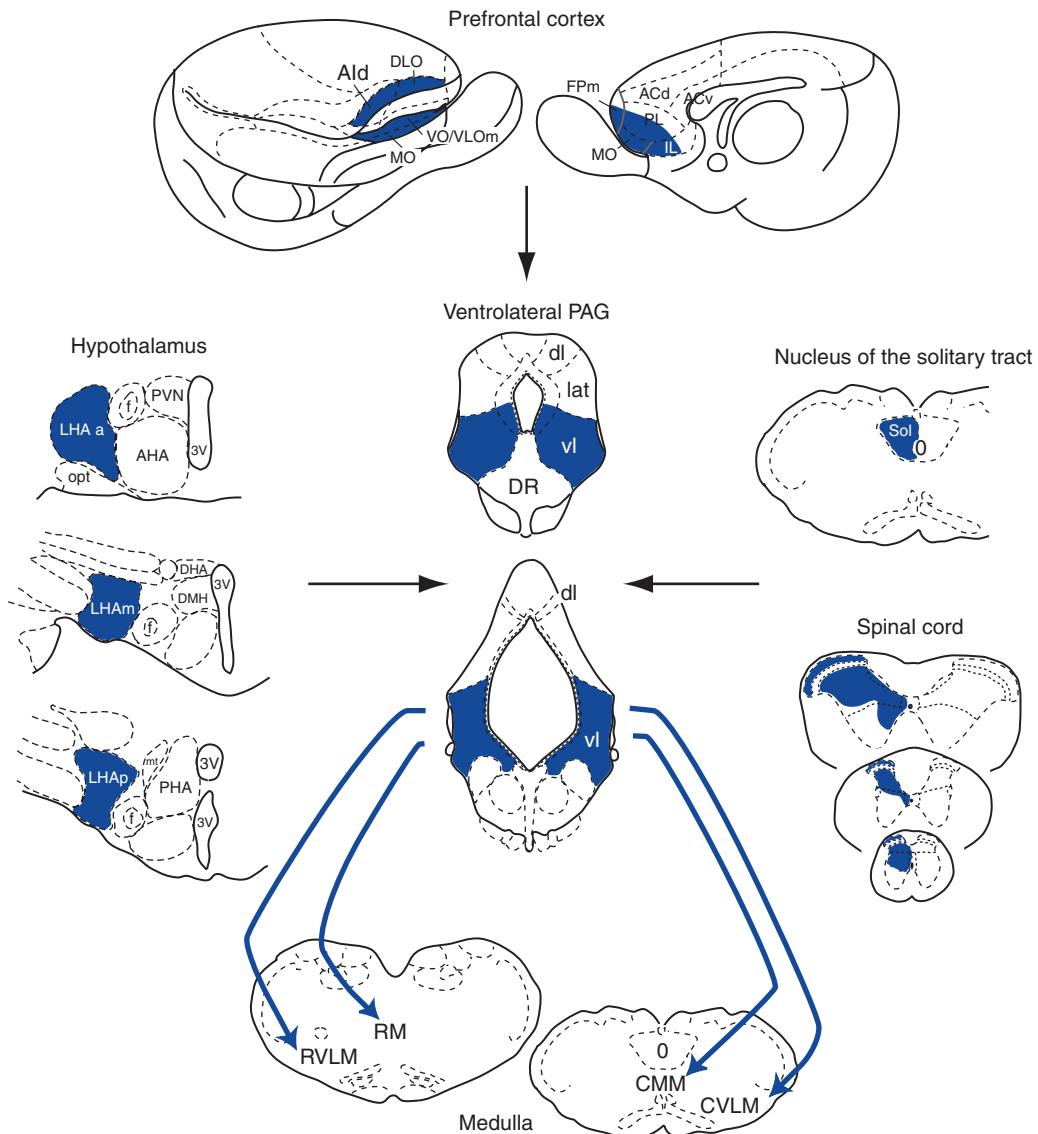

Figure 3 Major ascending projections to the vlPAG arise from the spinal cord and the nucleus of the solitary tract. Significant descending inputs arise from ventromedial prefrontal cortex, orbital/insular cortices, and the lateral hypothalamus. The vlPAG projects directly to the rostral and caudal ventrolateral medulla (RVLM, CVLM) as well as to the rostral and caudal ventromedial medulla (RM, CMM). Modified from Keay KA and Bandler R (2009) Emotional and behavioural significance of the pain signal and the role of the midbrain periaqueductal gray (PAG). In: Basbaum AI and Bushnell CM (eds.) *Science of Pain*, pp. 627–634. San Diego, CA: Academic Press.

the vlPAG receives substantial inputs from the spinal cord and SpV; these inputs arise from the same laminar divisions (Rexed's laminae I, II, IV, and V) (Figure 3); however, the projections to IPAG and vlPAG columns arise from different neuronal populations. That is to say, the IPAG and the vlPAG each receive unique signals from spinal cord and SpV regions. Furthermore, in contrast to the somatotopy seen in spino- and SpV projections to the IPAG, the projections to the vlPAG terminate throughout the neuronal cell column. In addition to its spinal/SpV input, the vlPAG also receives substantial inputs from nuclei of the solitary tract (NTS); these inputs again terminate throughout the cell

column showing little topographic specificity (Figure 3). Besides being the recipient of substantial ascending projections, the vlPAG also receives major descending inputs from cortical and hypothalamic nuclei. Specifically, the vlPAG receives input from orbital and insular cortical regions, and from the lateral hypothalamus. Thus, the vlPAG receives convergent forebrain, medullary, and spinal/SpV afferents, which led to the suggestion that passive coping, irrespective of being triggered by physical or psychological triggers, is mediated by the vlPAG. Strong support for this view has once again been derived from studies using c-fos as a marker of neuronal activation. It has been shown that when passive coping is

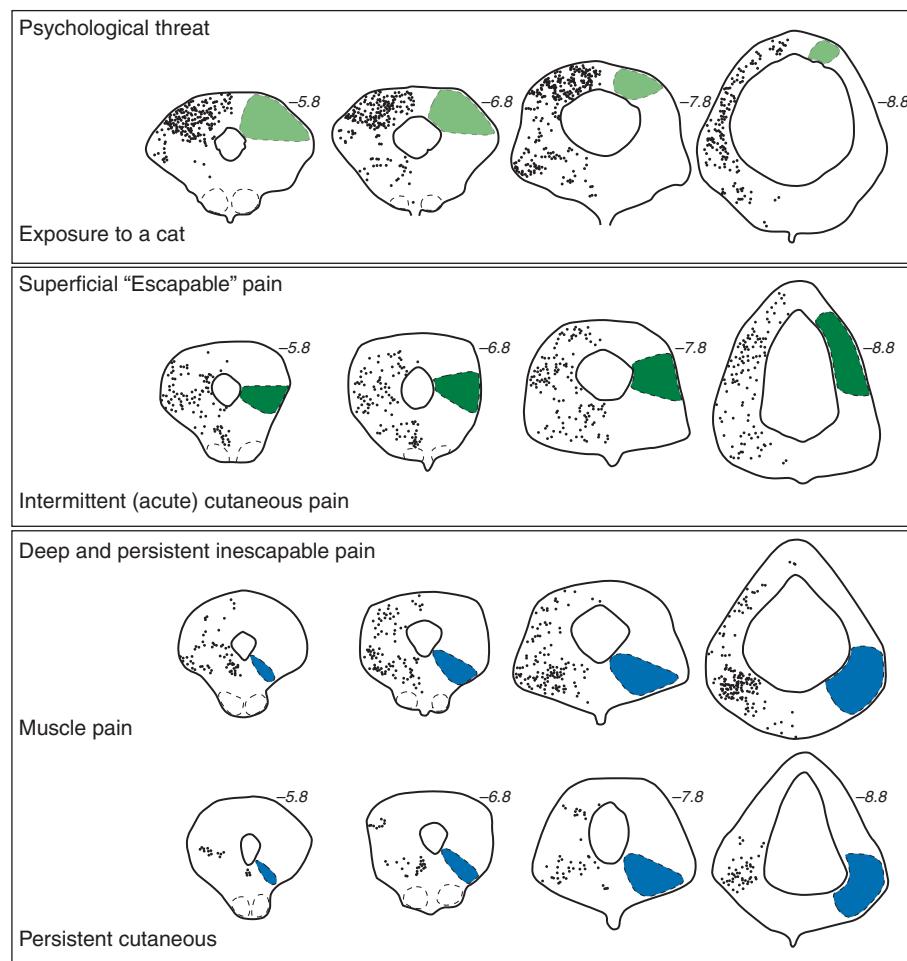

Figure 4 The upper panel illustrates the pattern of neural activation in the midbrain PAG of rats exposed to a psychological threat (exposure, without physical contact, of a rat to a cat), which evokes active emotional coping. The majority of active neurons are located within the dorsolateral PAG column, indicated by the shaded area. The center panel illustrates the location of activated neurons evoked by superficial escapable pain, evoked by intermittent (acute) cutaneous pain, which evokes active emotional coping. Majority of active neurons are located within the lateral PAG column, indicated by the shaded area. The lower panel shows patterns of neural activation evoked by deep and persistent inescapable pain. Muscle pain and persistent cutaneous pain, each of which evokes passive emotional coping, both activate neurons selectively in the ventrolateral PAG as indicated by the shaded area. Modified from Keay KA and Bandler R (2009) Emotional and behavioural significance of the pain signal and the role of the midbrain periaqueductal gray (PAG). In: Basbaum AI and Bushnell CM (eds.) *Science of Pain*, pp. 627–634. San Diego, CA: Academic Press.

triggered as the initial response to pain of deep origin, or when a painful state becomes persistent, or in order to promote recovery and healing as a delayed response to acute injury, vIPAG neurons demonstrate significantly increased c-fos expression (**Figure 4**).

Although the lateral and ventrolateral columns of the PAG mediate distinct and different emotional coping strategies, and receive inputs from distinct and different forebrain, medullary, and spinal/SpV inputs, their descending output projections appear identical. Neurons in the lateral and ventrolateral PAG project onto the same ventrolateral and ventromedial medullary regions (**Figures 2 and 3**). However, consistent with their opposing functional roles, these projections mediate different effects on their target sites; for example, the IPAG projection to the rostral ventrolateral medulla, which

contains neurons whose activity increases arterial pressure, is primarily excitatory, whereas consistent with the hypotensive actions of the vIPAG, projections from the vIPAG to the rostral ventrolateral medulla are primarily inhibitory. In contrast to common descending output targets, the lateral and vIPAG provide distinct ascending projections to different hypothalamic and midline and intralaminar thalamic nuclei. Although the dIPAG mediates active emotional coping responses, unlike the IPAG, it has few direct medullary outputs. Its ability to influence the ventrolateral medulla is due most likely to its projections to the region of the cuneiform nucleus, which has substantial inputs to this region (**Figure 1**). In common with both the IPAG and vIPAG, the dIPAG also projects to a distinct set of thalamic and hypothalamic subregions.

It is clear, therefore, that animals have the capacity to respond to escapable (acute/superficial) or inescapable (chronic/deep) pain with different emotional coping strategies, in ways similar to that described in the observations of Livingstone, Wall, and Lewis. The PAG region of the midbrain is divisible into distinct longitudinal neuronal columns, which mediate distinct coping strategies (dIPAG/EPAG: active emotional coping; vIPAG: passive emotional coping), again reflecting the response profiles described by Livingstone, Wall, and Lewis. Furthermore, each of the PAG columns comprises critical nodes within parallel and distinct circuits. These discrete neural circuits are defined by: inputs from specific cortical (i.e., prefrontal cortex and insular regions), hypothalamic, brainstem, and spinal cord regions; outputs, either direct or indirect, to ventrolateral and ventromedial medullary regions in which somatic and autonomic ‘premotor’ neurons, and neurons regulating sensory responsiveness are located.

An important question raised by the data derived from experimental observations in animals is whether, as predicted by Livingstone, Wall, and Lewis, pain of superficial or deep origin is represented by more than just coding of stimulus properties (i.e., the pain) in the brains of humans. The advent of brain functional imaging techniques has allowed us to begin to describe the forebrain and brainstem representations of both the sensory and emotional dimensions of pain of different origins.

Brain Representations of Active and Passive Emotional Coping Responses: Human Studies

Although human brain imaging, using functional magnetic resonance imaging (fMRI), has the potential to investigate the brain representations of a wide range of noxious events, both superficial and deep, and acute and chronic, the vast majority of studies have focused on acute noxious cutaneous (thermal) stimuli, because such stimuli are reliable, reproducible, and easily administered within the restricted experimental environment. Data from these investigations have shown that acute cutaneous pain triggers signal changes in a consistent set of neural structures including somatosensory, anterior cingulate, and insular cortices. Such findings revived the idea that pain activates an invariant set of neural structures, the so-called neuromatrix for pain. Despite compelling experimental, clinical, and anecdotal evidence that pain arising from different tissues evokes different sensory, emotional, and motivational qualities, surprisingly few human brain imaging studies that investigate acute pain processing have addressed the possibility that acute deep and superficial pain may be differentially represented.

The limited spatial resolution of human functional brain imaging techniques has not allowed the activation

patterns within small structures such as the PAG to be determined with any reliability; however, the cortical regions defined by their connectivity to the PAG in the animal studies discussed above have been specifically explored in human imaging studies. In particular, during the last few years, fMRI investigations have been used to explore the activation of these forebrain sites during acute superficial and deep noxious stimuli.

Consistent with the clinical observations of Lewis, human subjects subjected to experimentally induced superficial and deep pain in the leg report differences in the spread of pain and use distinct and different sensory descriptors to define the pain. Superficial pain evoked by subcutaneous injections of hypertonic saline evokes: sharp; hot; burning sensations restricted to the region immediately surrounding the injection site. Deep pain evoked by intramuscular injection of hypertonic saline evokes deep throbbing and cramping sensations that spread distally from the injection site to the dorsum of the ankle and foot. Although both superficial and deep noxious stimuli recruit signal changes in structures broadly within the pain neuromatrix, the striking finding is that the regional patterns of change often are different.

The largest difference in regional signal intensity change – a large decrease during deep pain and no change during superficial pain – occurs in the contralateral perigenual anterior cingulate cortex (**Figure 5**). The perigenual cingulate cortex constitutes a component of the affective subdivision of the cingulate cortex and lesions encompassing this region decrease social interactions in monkeys and trigger emotional lability in humans. Given that deep pain often evokes behavioral changes characterized by conservation withdrawal, social disengagement, and negative emotion (e.g., depression), there may be a causal link between the decrease in signal intensity in the perigenual cingulate and the negative emotional feelings commonly triggered by deep pain. Further, imaging studies of emotion have revealed that negative emotional states such as sustained sadness consistently evoke signal intensity changes in the perigenual cingulate region. In patients with chronic negative emotional states, such as unipolar depression, the perigenual cingulate cortex is one of few brain sites that display significant baseline hypoperfusion and hypometabolism.

A second cortical region, the anterior insula cortex, is also differentially activated with deep pain evoking a large signal increase, and in superficial pain no change in signal intensity. Detailed analyses of insula activation patterns during deep and superficial pain have revealed both a somatotopic organisation and a tissue-based segregation of activity. Thus, it appears that within this cortical region, multiple representations of body location and pain type exist. The insular cortex in the rat projects strongly to the vIPAG. If there is any commonality of organization within mammals, then it is possible that the insula may be

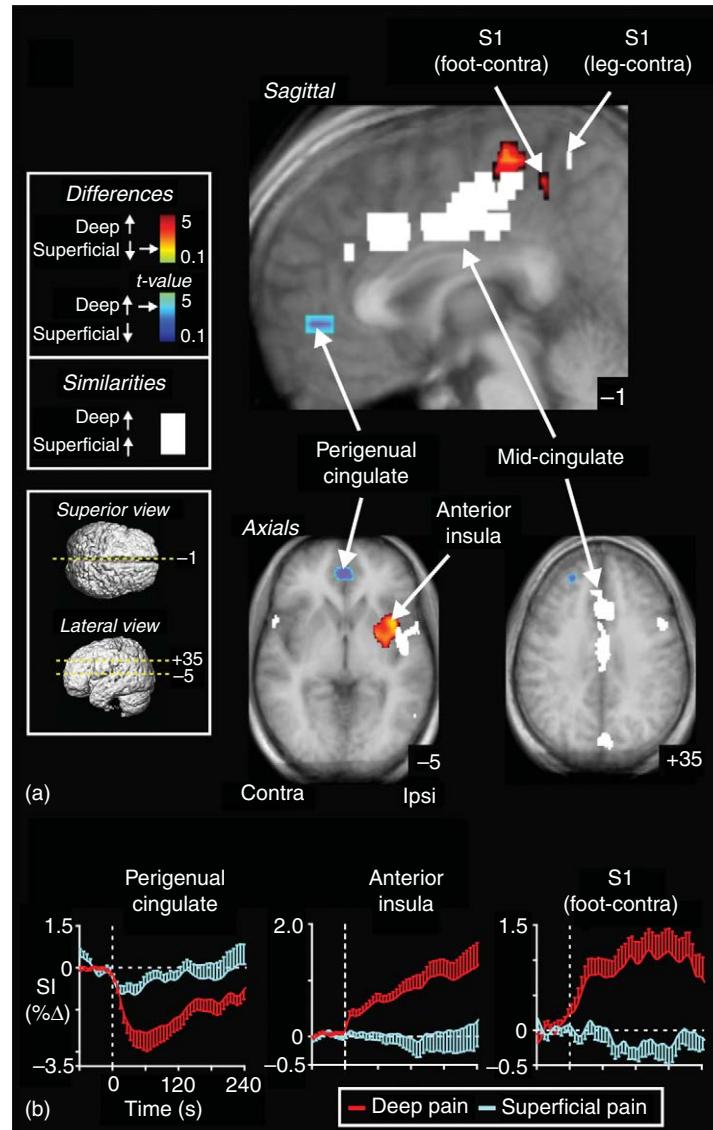

Figure 5 Brain activation patterns during acute cutaneous and muscle pain stimuli. (a) Significant fMRI signal intensity differences and similarities overlaid onto an average anatomical MRI scan. The hot color scale (coded for t-value) indicates regional signal increases during deep pain and either decreases or does not change during superficial pain. The cool color scale indicates regional signal decreases during deep pain and either increases or does not change during superficial pain. The white shading indicates regions in which signal increased during both pain stimuli. Slice positions are indicated in the right inset and by Montreal Neurological Institute coordinates at the bottom right of each image. (b) Percent changes in signal intensity. Modified from Henderson LA, Bandler R, Gandevia SC, and Macefield VG (2006) Distinct forebrain activity patterns during deep versus superficial pain. *Pain* 120: 286–296.

one cortical region from which signals relevant to deep pain and chronic cutaneous pain may arise to modulate the activity of vIPAG neurons. In humans, it has been shown that the anterior insula encodes not only the unpleasantness of painful stimuli, but also the unpleasantness evoked during challenges that trigger either olfactory or visual disgust. Further, different internally generated emotions activate different subregions of the right anterior insula. It is interesting to note that the region of the right anterior insula activated by deep pain is the same as the region activated by internally generated states of

sadness and anger. Thus, the role of the right anterior insula may be to monitor the internal state of the body, replicating the function and organization of the interoceptive cortex of the dorsal posterior insula. A pivotal role for the right insula cortex in the integration of the response and experience of both superficial and deep pain is well supported by brain imaging data. The importance of this role is confirmed further by clinical observations of individuals with lesions encompassing large areas of the insula. In humans, insula damage can result in asymbolia for pain – a condition in which

patients can distinguish between superficial and deep painful stimuli and describe their quality (sharp, dull, etc.) but fail to display appropriate emotional responses, including motor withdrawal, or usual facial signs (i.e., grimacing).

The somatic marker hypothesis suggests that the anterior insula integrates somatic and external cues of emotional relevance. The right anterior insula, thus, may integrate somatotopically organized information from nociceptors with the personal relevance of these emotionally charged stimuli helping to decide on an appropriate course of action. As is the case for the PAG, information regarding the stimulus location would be advantageous in deciding on the appropriate behavioral response to a noxious stimulus. In addition, given that the anterior insula is organized both somatotopically and, according to pain modality, it may also code the different sensory qualities associated with pain originating in different body tissues, that is, activation of the anterior insula may be necessary for both the location and quality of pain to be appreciated. Indeed, in animal studies, signals from noxious stimuli are known to be transmitted from the dorsal horn of the spinal cord to the posterior division of the ventral medial thalamic nucleus (VMpo). Although the existence of the VMpo in humans is still a matter for debate, it is proposed that somatotopically organized noxious information is transmitted from the VMpo to neurons in the ipsilateral anterior insular cortex via a relay in the contralateral posterior insula. The simultaneous activation of the primary somatosensory and insula cortices, by VMpo neurons, could then provide the brain with representations of both stimulus location and the sensory qualities associated with a painful stimulus. A further striking difference in the central representations of superficial and deep pain is their perceived spread. Whereas superficial pain is restricted to the region surrounding the injection site, deep pain almost always radiates distally to the ankle and foot. This pattern of perceived spread is highly correlated to the spread of fMRI signal intensity change within the primary somatosensory and insular cortices. That is, the greater the perceived spread of pain, the greater the extent of primary somatosensory and insular cortex activity, further supporting the notion that the primary somatosensory and insular cortices code the perceived stimulus location.

Evidence from human experimental studies support the notion that the opposing emotional state changes triggered by acute pain arising from different body tissues are underpinned by differential brain-activation patterns. Although pain originating in muscle and skin evoke similar activity changes in a number of brain regions, differential activation patterns are revealed in cortical regions that process perceptual and emotional state changes. As the spatial resolution of brain imaging techniques improves, it will

be possible to explore the activation patterns within brain-stem sites such as the midbrain PAG, to determine if the predictions of the animal studies are borne out in the human brain also.

Endnote

Although our understanding of the central representation of pain has in the past been constrained by the viewpoint of the sensory physiologist, the recognition that pain has both sensory and emotional qualities has triggered new approaches to the study of pain. Understanding that merely describing the anatomical pathways and physiological processing of the sensory dimensions of a noxious stimulus results in an incomplete picture of the neural representations of any pain state has resulted in the incorporation of neural circuits that mediate emotional behaviors into our neural representations of both superficial and deep, and acute and chronic pain states. To divide pain into physical and emotional defies our experience of any pain state: Pain is simultaneously a physical and emotional experience.

Glossary

Fear – A hypothetical brain state that results from the activation of brain structures, such as the amygdala, involved in processing aversive or threatening stimuli.

Negative reinforcement – The relationship between an instrumental response and an aversive stimulus arranged in a way that the response decreases the probability of the stimulus delivery.

Obsessive-compulsive disorder – A mental disorder characterized by repetitive thoughts or actions in an effort to reduce the level of fear and anxiety.

Phobia – Excessive fear of certain objects or situations, often expressed as extreme tendency to avoid the fear subject.

Punishment – The relationship between an instrumental response and an aversive stimulus arranged in a way that the response produces the stimulus.

Activation of the fear system initially triggers emotional reactions such as freezing behavior, autonomic nervous system activity, and hormonal release. It also mobilizes brain and body resources and prepares the organism to perform active responses that cope with the danger (i.e., flight). The former is usually referred to as fear, and the latter as escape or avoidance. Fear-elicited reactions prevent threat escalation and fear-motivated actions function to distance organisms from threat. Note that fear responses are adaptive in the sense that they protect individual organisms from life-threatening circumstances and, ultimately, improve evolutionary fitness. However, in the context of human pathology, fear responses can be maladaptive if their occurrence is inappropriate, excessive, or prolonged.

In the present article, we provide an overview of the psychological and neural mechanisms of active avoidance (AA) and escape ‘learning,’ rather than innately programmed responses. Note, however, that the responses themselves are usually not learned, but instead come under the control of previously innocuous stimuli through experience. Note also that although there are many procedural variations on avoidance conditioning, such as unsignaled (Sidman) and passive avoidance, for simplicity we focus on signaled AA. Finally, for our discussions of animal studies the term ‘fear’ refers to internal brain and body states that alter sensory processing and control specific defensive responses, not necessarily the subjective state of conscious fear experienced by the human.

Active avoidance and escape are forms of aversive, or defensive, instrumental learning. In a typical AA experiment, rats are placed in a chamber with two compartments separated by a small door. Training trials consist of presenting the rat with a conditioned stimulus (CS) that signals the upcoming delivery of an aversive event. Indeed, CSs in AA experiments are sometimes referred to as ‘warning signals.’ Brief visual or auditory stimuli usually

Overview of Avoidance and Escape Learning

Stimuli associated with predators or other dangers elicit defensive responses that function to keep organisms safe. Each species has certain stimuli that are innately wired to activate the fear system. Emotionally neutral stimuli – when associated with innate stimuli through experience – acquire the capacity to activate the system. By examining how the brain processes information concerning innate or learned fear stimuli, and how it generates specific defensive responses on the basis of this processing, the defense circuitry is being mapped. In this sense, emotion can be thought of as the process by which the brain computes the value of a stimulus for the purpose of responding adaptively.

serve as the CS, although stimuli of any sensory modality are effective. The aversive event, or unconditioned stimulus (US), is typically a mild electric footshock delivered through the grid floors in the chamber. Note that other aversive events such as very loud noises, hot/bright lights, and cold water can also be effective USs in AA experiments. Early in training, rats lack the knowledge that the CS predicts the US and make few, if any, avoidance responses. This results in CS-US pairings that rapidly create fear of the CS. As training progresses, rats learn that a shuttling response during the CS to the opposite chamber side terminates the CS presentation and prevents the delivery of the aversive US. Thus, AA learning is indicated by decreases in AA-response latencies during CS presentations, as well as increases the number of AA responses and the percentage of USs successfully avoided.

Escape learning is a component of most AA protocols but can also be studied independently. In the context of AA, escape learning typically precedes AA learning. On early trials, rats lack the knowledge that the CS predicts danger and thus fail to shuttle resulting in delivery of the aversive US. In most AA studies, the US persists until the rat emits the shuttling response and ‘escapes’ to the opposite chamber side. As training progresses, escape latencies become shorter and shorter until the rat ultimately begins shuttling before the US and actually avoids its delivery altogether. Although AA responses can be acquired if the escape and AA responses are different, AA learning progresses much more rapidly if they are the same. Note that animals will learn to escape most innately aversive stimuli but can also learn to escape fear-eliciting stimuli that are not inherently aversive.

AA and escape are forms of instrumental learning. In instrumental learning paradigms, responses under the animal’s control determine whether or not a US will be delivered. For instance, in an appetitive experiment a rat can press a lever to get food. Without pressing, no food is delivered. Thus, the rat’s response is ‘instrumental’ in the attainment of food. Similarly, in AA, the shuttling response is instrumental in preventing the delivery of footshock. This is in contrast to Pavlovian conditioning, where delivery of CSs and USs occurs irrespective of whether the rat makes or does not make any particular response.

Before moving on, it is important to point out two practical considerations related to designing successful AA experiments. The first is the choice of the AA response. AA learning is much slower than Pavlovian conditioning and typically requires multiple sessions consisting of many trials. However, some AA responses are learned more rapidly than others. Shuttling, for instance, is learned relatively rapidly, whereas lever pressing is learned extremely slowly. Robert Bolles and others suggest that AA responses compatible with an animal’s innate defensive responses (species-specific defense responses (SSDRs)) are much more likely to be acquired than

responses incompatible with innate defensive responses. Thus, shuttling is more easily acquired because it resembles the ‘flight’ SSDR. Lever pressing is difficult to train because rats rarely make such responses in dangerous situations (probably because they were unsuccessful in preventing danger throughout evolution).

A second factor important for AA experiments relates to ‘feedback stimuli.’ Although animals can learn AA without explicit feedback, training is usually faster if there is a brief stimulus marking the successful completion of the AA response (and prevention of the US). For instance, in an AA experiment where a tone predicts footshock, the experimenter may blink the houselight when the rat successfully shuttles and avoids the footshock. Feedback stimuli are especially useful when subtle response variations define the AA response, or when using unsignaled (Sidman) AA. Note that unintentional feedback stimuli are probably components of all AA protocols (i.e., proprioceptive sensation and CS termination), but salient intentional feedback signals enhance AA acquisition even further.

Psychological Mechanisms and Theoretical Considerations

Soon after Ivan Pavlov published his seminal work on associative conditioning, many researchers attempted to study conditioned fear, and its neural basis, with AA protocols. However, AA proved to be a difficult paradigm for the analysis and explanation of learning mechanisms. First, learning occurs on trials where the animal successfully avoids shock, and it was difficult to explain how the absence of a US could reinforce a response. Second, researchers realized that avoidance was actually a complex learning process where animals first learned that the tone predicted shock, and then learned to escape the tone and prevent shock delivery. Two-factor theory was initially proposed by O. H. Mowrer and N. E. Miller hypothesizing that avoidance conditioning involves both Pavlovian fear conditioning and instrumental response conditioning. In the almost 80 years since the emergence of two-factor theory, researchers have heatedly debated the contents (i.e., S-S, S-R, or R-S), conditions (Pavlovian operations, instrumental operations, or both) and mechanisms (drives, perceptions, etc.) of AA conditioning. However, one idea was proposed early and remains a viable possibility today: Escape from fear (EFF).

EFF learning was proposed to explain how Pavlovian conditioning and instrumental conditioning could interact to mediate AA. The basic idea is that Pavlovian conditioning first establishes fear of the CS. Then on later trials, active responding is reinforced by fear reduction associated with CS-termination. Another way to say this is that the response is instrumental in leading to the

reinforcement: fear reduction. Formally, this sort of learning is called conditioned negative reinforcement of a stimulus–response association. Importantly, expression of EFF/AA learning is also believed to be motivated by fear. As training progresses, escape responding is motivated by fear of the CS and reinforced by CS-termination.

Despite the promise and simplicity of EFF as a mechanism of AA, it has been the subject of considerable controversy over the years. A major reason is that some researchers have had trouble reliably reproducing EFF learning (independent of avoidance conditioning) in the laboratory. Many have reported successful EFF learning, but failures to obtain EFF learning are also common. In addition, some argue that EFF theory predicts that CSs eliciting greater fear should produce stronger instrumental learning, since the hypothetical reinforcement, fear reduction, should be greater when these CSs terminate. However, this relationship between the degree of CS fear and strength of instrumental response acquisition does not appear to be supported by the available data. These and other issues have hindered the widespread acceptance of EFF as an important mechanism of AA learning.

We recently conducted an extensive behavioral examination of EFF, using rearing as the escape response, in order to address reasons for the controversy and to suggest procedural improvements. For EFF training, rats were presented with fear-eliciting CSs in extinction (no footshocks). Rearing up on the hind legs during the CS caused its immediate termination. We found that EFF training led to a twofold increase in CS-evoked rearing relative to yoked control animals (**Figures 1(a)** and **1(b)**). This learning was long-lasting (24 h) and response specific (no increase in other nonreinforced behaviors). Interestingly, successful EFF learning also resulted in a transition from passive Pavlovian freezing reactions to active instrumental escaping; rats that learned the EFF response showed no spontaneous recovery of freezing following the extinguishing CS presentations used for EFF training (**Figure 1(c)** and **1(d)**). Importantly, expression of EFF learning was also motivated by fear of the CS; animals that went through EFF training did not rear differently than yoked controls until the CS was presented. Thus, our data suggest that instrumental escape responses can be reinforced by CS termination and be motivated by fear.

Although EFF learning likely contributes to AA acquisition in a significant way, it is also likely that other psychological factors play important roles. As mentioned earlier, feedback stimuli can play a powerful role in facilitating AA learning. Any stimulus that marks the successful completion of the AA response, and successful avoidance of the US, can serve as a feedback stimulus. Feedback can be an explicit stimulus delivered by the experimental protocol or can simply be proprioceptive or spatial stimuli associated with the response sequence.

Since feedback stimuli are negatively correlated with both the fear-eliciting CS and the painful US, they are likely to become conditioned inhibitors (safety signals) during AA conditioning. Thus, AA responses may also be approach responses to safety, where the AA response is reinforced by conditioned positive reinforcement (presentation of the feedback stimulus).

Others have also argued that the US-avoidance contingency plays an important role in AA acquisition; that is, independent of EFF or approach to safety, nondelivery of the shock US is registered by the animal and serves to reinforce AA responding. Although it is admittedly difficult to disentangle these separate influences on AA learning, it is important to point out that each may play a role in supporting AA learning and expression; the involvement of one of these mechanisms does not negate the involvement of another. However, the jury is still out on the relative importance of these psychological processes.

Brain Mechanisms

The neural circuits mediating AA learning and expression are far from understood. This is not surprising given the controversies over the psychological mechanisms involved, the variations in AA protocols studied and the different experimental tools employed. The following section summarizes the available data and suggests new directions for future research of AA neural mechanisms.

Pavlovian Conditioning

Pavlovian fear conditioning likely plays a fundamental role in AA learning and expression. The neural mechanisms of Pavlovian fear conditioning are covered in detail elsewhere in this encyclopedia, but we give a brief overview here given its importance. The amygdala – a temporal lobe structure comprised of a dozen or so distinct nuclei – is critical for the learning and expression of fear conditioning (**Figure 2**). The lateral amygdala (LA) is believed to receive sensory inputs relaying CS and US information. Prior to conditioning, CS inputs are not strong enough to drive LA activity and downstream regions controlling fear reactions. However, plasticity in LA CS pathways during conditioning strengthens these inputs so that subsequent CS presentations can drive LA activity. Direct and indirect connections then drive central amygdala (CE) activity. CE outputs to the hypothalamus and midbrain – regions mediating fear reactions – then drive defensive responding. LA is believed to be critical for the learning and storage of the Pavlovian CS–US memory, and CE for the generation of fear reactions. Another major output nucleus of LA, the

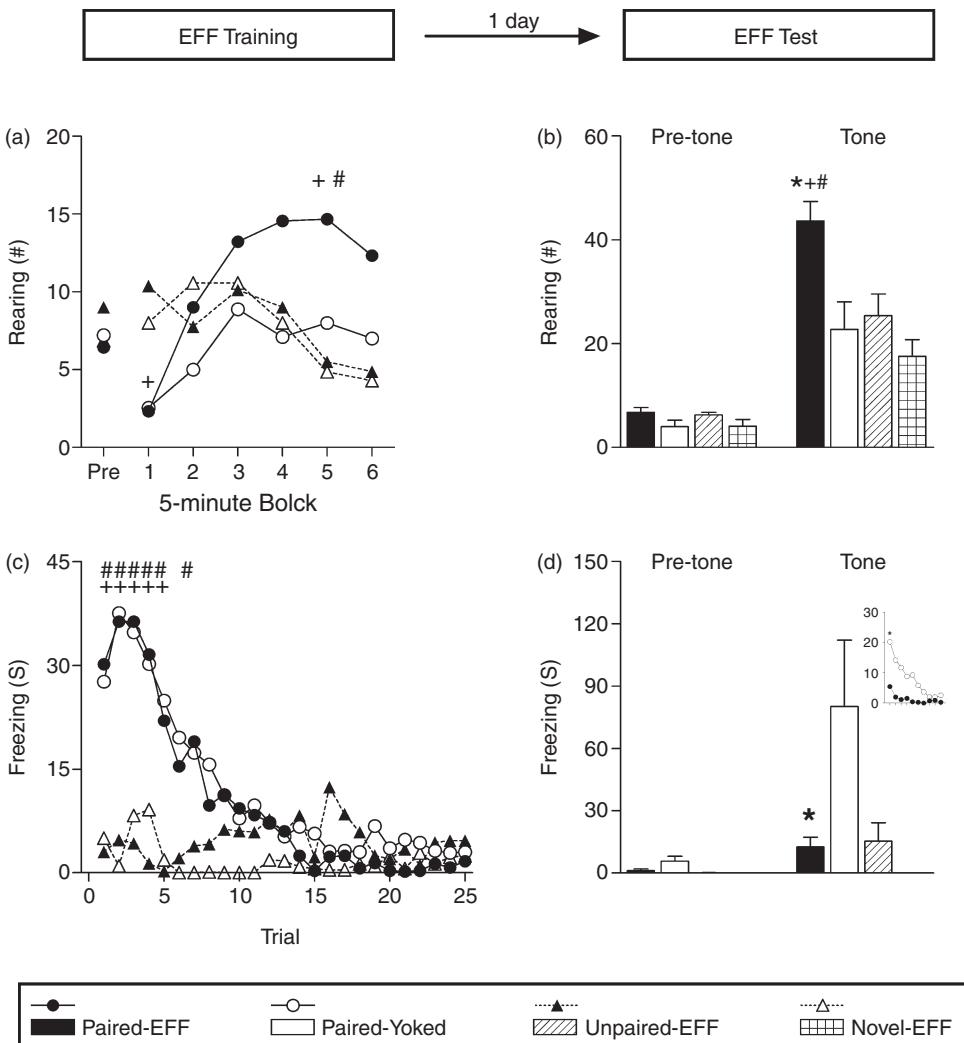

Figure 1 Escape from fear learning represents instrumental learning that is motivated by fear and reinforced by fear reduction. One day after Pavlovian tone–shock pairings, rats were presented with 25 tone-alone presentations in a novel context (EFF training, left). For Paired-EFF rats, rearing during a tone presentation led to its immediate termination (response-reinforcement pairing). Paired-Yoked rats received identical tone presentations independent of their behavior. One day after EFF training, rats were presented with a single, continuous 10-min tone presentation to assess long-term EFF memory (EFF test, right). Rearing and freezing were assessed during both phases. Paired-EFF rats showed a twofold increase in the EFF escape response (rearing) during the training and testing session compared to Paired-Yoked rats (a) and (b); note change in scales between training and testing). Unpaired-EFF rats had no fear of the CS and did not acquire the EFF response (enhanced rearing). Although freezing extinguished in both Paired-EFF and Paired-Yoked groups during EFF training (c), successful acquisition of the active escape response (Paired-EFF only) was associated with less spontaneous fear recovery (d). The inset in (d) shows minute-by-minute freezing during the final EFF tone test for Paired-EFF and Paired-Yoked groups. Further analysis demonstrated that EFF learning was response-specific and performance was motivated by fear (no difference in rearing in the absence of the CS; data not shown). Adapted from Cain CK and LeDoux JE (2007) Escape from fear: A detailed behavioral analysis of two atypical responses reinforced by CS-termination. *Journal of Experimental Psychology: Animal Behavior Processes* 33(4): 451–463.

basal amygdala (B), is not required for Pavlovian fear conditioning or expression.

Signaled Active Avoidance

Investigations into the brain mechanisms of signaled AA peaked midway through the last century and then tapered off. This may be partly due to the emergence of Pavlovian conditioning as an ideal model for relating behavioral

learning to brain activity and partly to the theoretical controversies with regard to instrumental conditioning. Many of these studies focused on the amygdala as a region important for AA. The techniques most commonly employed to investigate amygdalar involvement in avoidance were lesions, local drug infusions, and sub-seizure electrical stimulation. However, it is important to note that many, if not most, of these studies were conducted before researchers appreciated the importance of

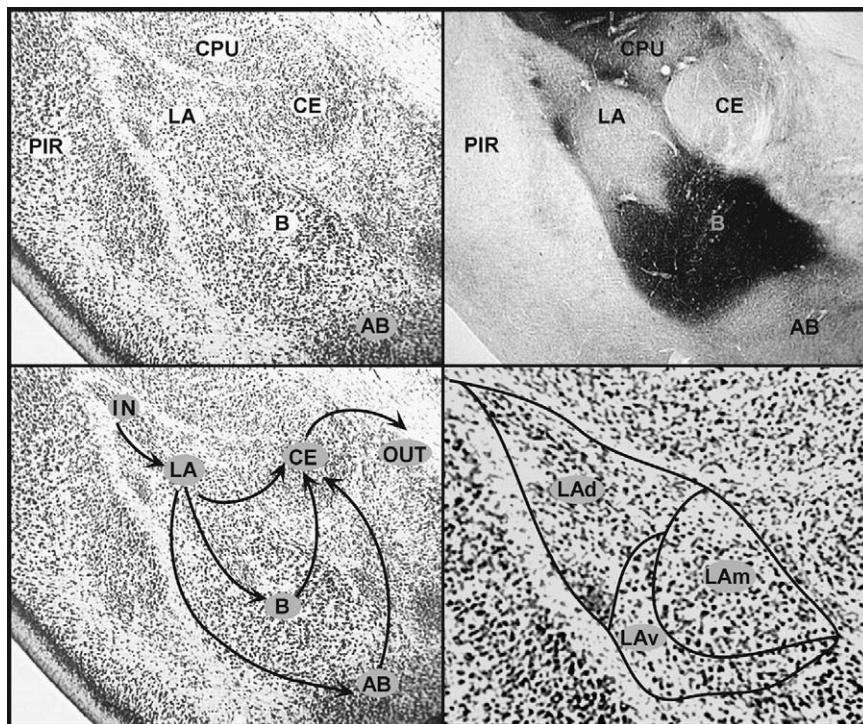

Figure 2 At least 12 nuclei comprise the mammalian amygdala. Particularly important for fear conditioning are the lateral nucleus (LA), the basal nucleus (B), and the central nucleus (CE). Top panels show coronal slices taken from rat brain (left: Nissl's stain, right: Acetylcholinesterase stain) including the LA, B, and CE. The basic amygdalar circuit mediating auditory fear conditioning is shown in the lower-left panel. Sensory inputs enter through the LA, and the LA connects to CE both directly and indirectly by way of the B. The CE is a major output nucleus mediating expression of Pavlovian conditioned reactions. Direct connections from the LA to the B appear to be critical for active avoidance and escape from fear learning. Bottom-right: higher magnification image of the LA demonstrating that amygdala nuclei can also be divided into functional subregions called subnuclei. Abbreviations: Pir = piriform cortex, AB = accessory basal nucleus, CPU = caudate putamen, LAd = dorsal subdivision of the LA, LAm = medial subdivision of the LA, LAv = ventral subdivision of the LA. Reprinted from LeDoux JE (2000) Emotion circuits in the brain. *Annual Reviews of Neuroscience* 23: 155–184.

investigating the function of amygdalar subnuclei separately, and thus the results are mixed and bit difficult to interpret. In addition, the majority of studies involved prelearning manipulations that can potentially affect acquisition, consolidation, and storage functions.

The most common finding from early studies was that impairing amygdalar function disrupts the acquisition and recall of AA. For instance, pretraining lesions that included the entire amygdala, or the basolateral complex alone, resulted in slower rates of within-session acquisition that persisted across days. However, a number of studies employing complete or partial amygdalar lesions resulted in no impairment of AA, or rather even facilitated AA conditioning.

Michael Gabriel and colleagues have identified a number of brain regions and neural mechanisms important for signaled AA. In their preparation, rabbits are trained to discriminate between a CS+ and CS- in an AA paradigm that requires the animals to walk on a rotating wheel to avoid shock delivery during CS+ presentations. Using an elegant combination of lesion, pharmacology, and multisite single-unit recording techniques, this group has implicated

the amygdala (LA, B, and CE), cingulate cortex (anterior and posterior), thalamus (medial geniculate and anterior nuclei), and auditory cortex in the acquisition and storage of signaled AA. The amygdala appears to be particularly important in this task and is required for behavioral learning and the development of training-induced neuronal activity changes in all of the other regions. These authors also demonstrate that discriminative changes in neuronal firing in the LA develop with the initial AA training session, consistent with previous reports in Pavlovian conditioning. The work from this laboratory emphasizes the interactivity of multiple brain regions in coordinating the learning and performance of complex AA.

Recent work in our own laboratory has focused on the dissecting the contributions of specific amygdala subnuclei to signaled AA learning (Figure 3). Rats were trained in a two-way AA paradigm where the animal was required to perform a shuttle response to the opposite side of the chamber in order to avoid shock delivery at the end of a tone CS presentation. Posttraining lesions of LA or B severely impaired performance of this task. CE lesions had no effect on performance in animals that

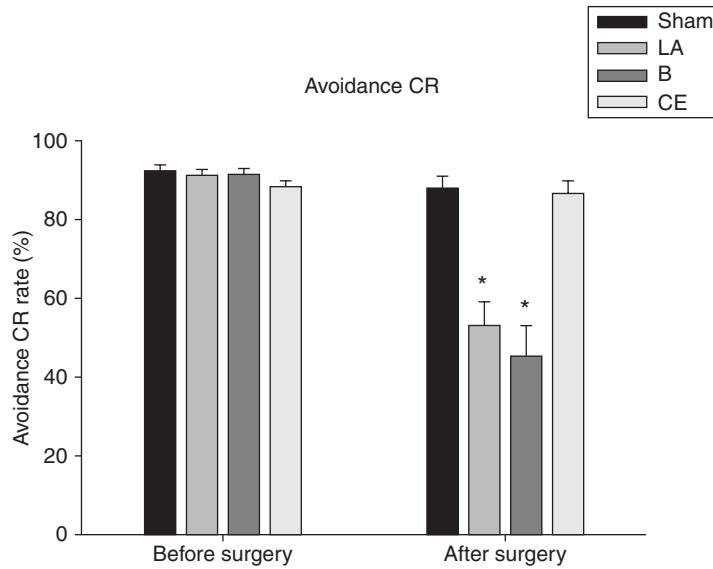

Figure 3 Posttraining lesions of the lateral or basal amygdala impair expression of signaled active avoidance. Rats were trained daily to criterion (>80% successful avoidance) on a two-way active avoidance task where tone presentations signaled footshock. After this moderate training protocol, rats received sham or bilateral electrolytic lesions of the lateral (LA), basal (B), or central (CE) amygdala. After recovery, all rats were given a single test session where the AA-conditioned response (CR) rate was assessed. Lesions of the LA or B severely impaired AA performance whereas CE lesions had no effect. Reprinted from *Learning and Memory* (Choi et al., (2010) The role of amygdala nuclei in the expression of auditory signaled two-way active avoidance in rats. *Learning and Memory* 17: 139–147).

showed high levels of initial AA conditioning. Interestingly, CE lesions rescued the ability to learn AA in poorly avoiding rats. Unoperated rats that failed to acquire the AA response with three training sessions (<20% avoidance) were subsequently given sham or CE lesions. Following recovery from surgery, poor learners in the sham group remained unable to acquire AA with five additional training sessions. CE-lesioned rats, on the other hand, were now able to acquire the response reaching an asymptote of 70% successful avoidance by the fifth post-lesion session (data not shown). These data are consistent with the notion that LA is important for the acquisition of CS-US associations important for both Pavlovian fear reactions and instrumental fear-action learning. B may be important for using this conditioned incentive information to guide goal-directed action learning and CE for mediating Pavlovian reactions. Given that the primary rodent fear reaction to a conditioned CS is freezing, it seems likely that some reciprocal inhibitory mechanism between B and CE outputs exists that determines the likelihood of reaction versus action responding, although it is currently unknown how this might occur. The present findings may also help explain apparent inconsistencies present in early studies of signaled-avoidance brain mechanisms, where some manipulations impaired avoidance and others facilitated avoidance. These contradictory effects may be due to the degree the manipulations affected LA/B versus CE.

Escape from Fear

Research on EFF learning has been sporadic over the last half-century and only one study to date has investigated brain mechanisms of EFF learning. Amorapanth et al., in 2000, created selective electrolytic lesions of amygdaloid subnuclei to investigate their potential involvement in EFF learning (Figure 4). Lesions of the LA, CE, or B were made prior to fear conditioning and EFF training, and both conditioned freezing and escape responding were measured. In this case, chamber crossing served as the escape response. LA lesions disrupted both conditioned freezing and EFF learning. CE lesions disrupted freezing, but not escape responding. In addition, B lesions disrupted escape responding but not conditioned freezing. Thus, consistent with the model proposed above, LA damage prevented the acquisition of CS-elicited fear, which is necessary both for fear reactions (freezing) and fear actions (escaping). The double dissociation between the CE and the B on freezing and EFF suggests that the CE mediates fear reactions and the B participates in the motivation/reinforcement of fear actions like instrumental escape learning. Interestingly, Simon Killcross and colleagues found a similar profile with conditioned positive reinforcement; lesions of LA + B, but not the CE, impaired conditioned punishment supporting the notion that the LA→B pathway may be critical for learning about aversive instrumental actions.

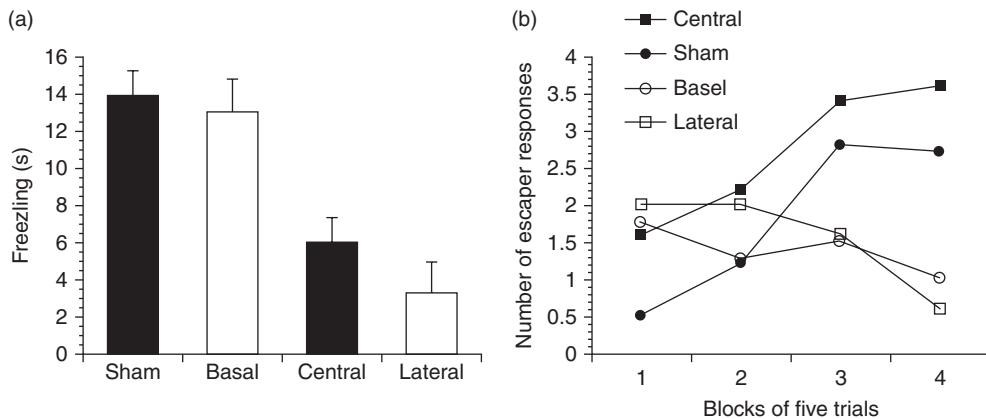

Figure 4 Escape from fear learning depends on the lateral and basal, but not the central, amygdala. Prior to behavioral training, rats received bilateral electrolytic lesions of the LA, CE, or B. Rats were first subjected to Pavlovian fear conditioning and then EFF training using chamber crossing as the escape response. LA and CE lesions disrupted performance of a passive fear reaction to the CS ((a) freezing). LA and B lesions disrupted performance of an active EFF response ((b) chamber crossing). These data suggest that the LA is necessary for establishing the CS as a conditioned incentive. This information is then relayed to the CE to initiate passive Pavlovian reactions and to the B for active escape responding. Reproduced from Amorapanth P, LeDoux JE, and Nader K (2000) Different lateral amygdala outputs mediate reactions and actions elicited by a fear-arousing stimulus. *Nature Neuroscience* 3: 74–79.

Approach to Safety

The learning of safety (conditioned inhibition (CI)), and subsequent learning of approach to safe feedback signals, likely contributes to AA acquisition and expression. The brain mechanisms of safety learning and approach are only beginning to be understood. An elegant recent study by M. T. Rogan and E. R. Kandel implicated both the LA and overlying caudal caudate putamen (CP) in safety learning. Physiological responses to a CI stimulus were recorded during safety training in these two regions and were found to decrease in the LA and increase in the CP. Since the LA is necessary for fear learning and expression, decreases in neuronal responses are consistent with fear reduction/suppression. The authors argue that the caudal region of the CP is involved in reward and euphoria, suggesting that safety signals trigger positive affect. Consistent with this idea, they also demonstrate that mice prefer to spend time in a chamber where the CI is present. Thus, safety signals appear to support approach learning possibly by increasing physiological responses in the caudal CP. This dorsal striatal region has not yet been evaluated in aversive AA but will be an important candidate region for future study.

Other Potentially Important Regions

The LA and B appear to be critical for AA acquisition and expression, but which downstream brain regions are potentially responsible for receiving information from the B and translating it into instrumental escape/avoidance responding? One possibility is the nucleus accumbens (NAcc) which contributes to appetitive motivated action, including action learning about conditioned

reinforcers. Anatomically, NAcc shares direct connections with the B and regions important for motor control. Thus, NAcc is positioned to receive information about aversive CSs and translate this into motivated action. NAcc activity has been shown to correlate with AA learning and NAcc manipulations affect unsignaled AA; however, the role of the NAcc in signaled AA has not been systematically explored.

Note that, earlier we described how animals initially react to AA CSs with Pavlovian fear reactions mediated by the CE. But as training progresses, CE-mediated responses appear to be suppressed allowing for information flow from the LA to the B and AA learning. Two candidate regions may be involved in this suppression of Pavlovian reactions and switch from passive to active coping strategies, although neither have been thoroughly investigated. The medial prefrontal cortex (mPFC) has been shown to be critical for the suppression of Pavlovian fear reactions in studies of extinction. Thus, the mPFC may play a role in suppressing Pavlovian reactions allowing for AA learning and expression. The orbitofrontal cortex (OFC) has been implicated in behaviors involving integration of incentive value with instrumental action, and in flexibly changing behavior as contingencies change. Thus, the OFC may play a role in the switch from passive Pavlovian to active instrumental responding in AA.

Finally, a large body of work in appetitive instrumental conditioning indicates that with continued training, instrumental responses progress from goal-directed (or outcome-dependent) to habitual responses. Thus, changing the value of the US alters responding after moderate training, but not after overtraining.

Interestingly, the neural circuit mediating instrumental responding changes as well. Bernard Balleine's group has shown that lesions of the dorsomedial striatum impair instrumental performance after moderate training, but not overtraining. Conversely, lesions of the dorsolateral striatum impair instrumental performance after overtraining but not moderate training.

An interesting parallel may be seen with aversive AA conditioning. Although changing the value of the US is difficult in aversive studies, the neural circuit important for AA expression does appear to change with overtraining. After moderate training, lesions of the LA or B severely impair AA performance. However, with overtraining, lesion or inactivations of the LA and B have no effect on AA performance. This begs the question of which brain region(s) mediate AA performance after overtraining? It will be interesting to see if the dorsomedial striatum is initially important, but then gives way to the dorsolateral striatum with overtraining. Future studies will be needed to investigate this possibility.

Summary of Brain Mechanisms

The brain mechanisms of AA learning and expression are poorly understood. However, guided by progress in Pavlovian fear-conditioning studies and appetitive instrumental studies, the complex neural circuit is beginning to be unraveled. Our current model is as follows (see **Figure 5**): Early in training, CS-US pairings produce Pavlovian fear conditioning via plasticity in the LA. This plasticity initially drives fear reactions via connections to the CE and downstream effector regions. As training progresses, the CE is suppressed, possibly by the mPFC or OFC, and information flow is diverted from the LA→CE pathway to the LA→B pathway. Initial conditioned negative reinforcement and conditioned motivation important for AA learning and expression may then depend on interactions between the B and striatum (NAcc and/or dorsomedial striatum). At this stage, safety-signal approach mediated partly by the caudal CP may contribute to instrumental response reinforcement. However, with overtraining, these regions become unnecessary and the dorsolateral striatum may then mediate a more reflexive S-R-avoidance habit.

Relation to Human Psychopathology and Treatment

National Institutes of Mental Health resources indicate that approximately 40 million American adults, or ~18% of the adult population in any given year, suffer from anxiety disorders such as panic disorder, obsessive-compulsive disorder, posttraumatic stress disorder, or phobias. A hallmark of most anxiety disorders is

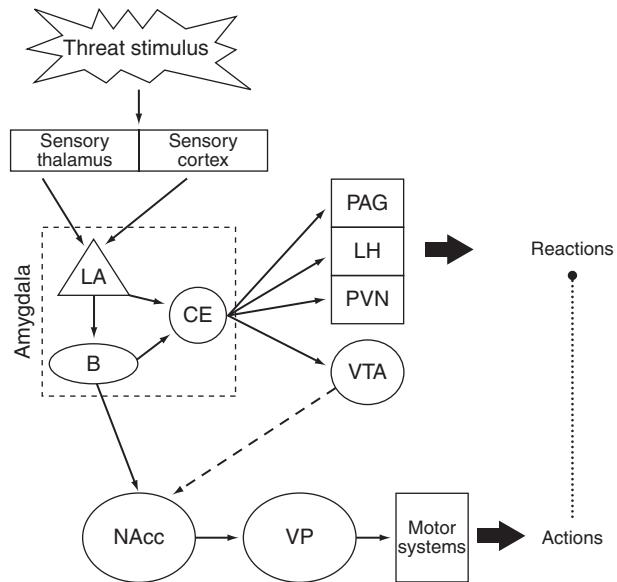

Figure 5 Schematic representation of a hypothetical brain motive circuit mediating active avoidance/EFF learning. Following Pavlovian fear conditioning (CS-US pairings), threatening stimuli – processed in the sensory thalamus and cortex – drive activity in the LA and CE leading to passive fear reactions (like freezing) and also activate arousal centers like the ventral tegmental area (VTA). Incentive information flows also from the LA to the B which projects to the nucleus accumbens (NAcc). The NAcc processing of incentive information invigorates and guides active behavior via projections to the ventral pallidum (VP) and downstream motor systems, with the aid of dopamine arriving from the VTA (dashed line). Note that early portions of this model are derived from work on amygdala-dependent fear conditioning and EFF learning while downstream portions of the model are borrowed from work in appetitive conditioning. Once avoidance or EFF is well-learned, there is a hypothetical inhibition of passive fear actions (dotted line). Additional abbreviations: PAG = periaqueductal gray, LH = lateral hypothalamus, PVN = paraventricular nucleus, LA = lateral amygdala, B = basal amygdala, CE = central amygdala.

pathological avoidance of fear-eliciting stimuli established through trauma. Avoidance is pathological when it interferes with normal day-to-day activities and causes personal distress. Although avoidance responses can take time to learn, once established, they are extremely difficult to extinguish or eliminate. Once the pattern of avoidance is established, the subject rarely withdraws the response to test whether or not the warning signal (CS) still accurately predicts danger. On the contrary, each fear-elicited avoidance response is reinforced when no aversive outcome is encountered. Treating pathological anxiety requires that new behavioral and/or pharmacological strategies be developed to break this vicious cycle. Elucidating the core neural circuits underlying AA behavior will be an essential first step.

One must keep in mind, however, that escape from fear (EFF) and avoidance are common precisely because they are such an effective means of coping with the fear. Prior

to learning an EFF or avoidance response, aversive stimuli trigger distressful physiological reactions and emotions. EFF and avoidance acquisition give the subject control over exposure to the fearful CS resulting in suppression of these reactions. Indeed, animals, including humans exhibiting avoidance responses often show now overt signs of fear other than the avoidance response itself. In addition, unlike passive treatments based on fear extinction (e.g., exposure therapy), return of overt fear is much less likely following avoidance learning. The recognition of this fact has led researchers and clinicians such as B. A. van der Kolk, J. E. LeDoux, and J. M. Gorman to suggest that active coping strategies should be pursued more regularly during treatment of anxiety. The key here is that the active (avoidance) response strategy not interfere with normal living and well-being. Thus, future research into the neural mechanisms of avoidance holds out the hope of not only breaking the vicious cycle of pathological avoidance, but also of improving treatment by harnessing the power of avoidance learning.

Behavioral Pathologies in Nonhuman Primates

J R Anderson, University of Stirling, Stirling, UK

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Affiliative behavior – Acts which promote friendly or peaceful interaction with another individual (e.g., grooming and huddling).

Agonistic behavior – Any act involving aggression (normally producing injury or flight by the target individual, e.g., threat and attack) or fearful behavior (normally reducing injury or aggression, e.g., submissive expression or posture, or flight).

Stereotypy – Behaviors performed excessively repeatedly and without obvious purpose, either involving the whole body (e.g., pacing or somersaulting) or individual body parts (e.g., mouthing or manipulating).

Introduction

Laboratory- and zoo-housed nonhuman primates (hereafter, ‘primates’) commonly display abnormal behaviors. The present review will not deal with unusual behaviors that are species-typical responses to variations in the animals’ habitual environment, such as drastic food shortages or inclement weather, or to changes in physical health, (e.g., disease or injury). Nor will behavioral pathologies induced by invasive treatments (e.g., involving drugs, pain, brain stimulation, or lesions) be addressed. Instead, the focus will be on aberrant behaviors that result from rearing or living in environments that provide the animal with insufficient stimulation. In one survey of over 360 rhesus macaques housed in individual cages in a North American primate research center, almost 90% were found to show at least one aberrant behavior, with individuals typically demonstrating more than one kind. Aberrant primate behaviors may include repetitive whole-body movements such as pacing, swaying, or somersaulting, or smaller-scale acts such as mouthing or manipulation, which may be externally directed (e.g., stereotyped cage manipulation) or self-directed (digit-sucking or hair-pulling). Such stereotypies and other abnormal behaviors may be physically harmless, but they are certainly esthetically undesirable, and, in extreme cases, they can lead to serious health issues (see below). They are almost always a sign of psychological maladjustment.

The Isolation Syndrome

Abnormal and Self-Directed Behaviors

Reports of abnormal behavior can be found in the early primatological literature; a case of self-directed aggression (biting of own hands and feet) by a young adult male rhesus macaque on dismounting a female following an incomplete copulation was described over 80 years ago. However, it was not until publication of studies by Harry Harlow and his colleagues in the late 1950s and the 1960s that primate behavioral abnormalities started to receive widespread attention. Neonatal rhesus monkeys were separated from their mothers and reared in individual cages that permitted only nontactile contact with neighbors (partial isolation), or in enclosed cages that offered no social experience of any kind (total isolation). Isolation-reared infants soon started to show a range of behaviors that are almost never seen in young monkeys reared in more natural social settings. The so-called ‘isolates’ directed toward their own bodies behaviors that would typically be directed toward other individuals (under normal circumstances for neonates this would primarily be the mother). The young isolates spent considerable amounts of time sucking their own digits or fur (‘auto-orality’) and hugging themselves (‘self-clasping’). They might also perform stereotypical movements, including body rocking. The predominance of self-directed acts is interpreted as the isolation-reared infant redirecting onto itself behaviors, probably innately programmed, that would normally function to maintain contact with the biological mother, including grasping (the mother’s fur) and sucking (mother’s nipple). Stereotyped body movements can also be viewed from this perspective as an attempt to replace the vestibular stimulation that would normally arise from being transported by the mother. Correspondingly, long periods of immobility accompanied by staring into space and softly caressing one’s own body might be viewed as an ‘imitation’ of the attitude of an individual receiving grooming.

Another aspect of what is generally called the ‘isolation syndrome’ consists of a range of bizarre postures, including the ‘floating limbs’ phenomenon. For example, one or both legs might be extended behind and above the head so that the feet remain suspended in the air, or an arm might start to rise up and appear to float in the air for no apparent reason. Some infants looked at and then attacked their floating limb, and isolates spent more time overall looking at their own body parts compared to socially

reared controls. Again, in the absence of conspecifics to look at, isolates redirected their visual attention onto their own bodies. The lack of sufficiently varied visual stimulation might be one reason for the development of another common abnormality, known as the ‘salute.’ Here, the monkey presses with its hand against its eyelid or pulls on the skin around the eye. This causes a deformation of the visual image experienced by the monkey, which it may find preferable to its normal, monotonous visual environment.

Social Deficits Following Early Social Deprivation

Affiliative and agonistic behavior

A range of other effects of inadequate early social experience were revealed, some of which clearly compromised isolates’ ability to adapt to environmental events and opportunities. Isolation-reared rhesus monkeys showed excessive fearfulness to unfamiliar objects and situations, abnormal information processing, and impaired learning abilities. However, it was especially in the social domain that the inadequacies of isolation-reared monkeys caught the attention of scientists, philosophers, and the lay public. After their period of isolation from birth onward (typically between 6 and 12 months), when placed with other monkeys, isolates were clearly inept in almost all aspects of social life, including affiliative and agonistic interactions, dominance hierarchy formation, alliance formation, and sexual behavior. They played much less than control monkeys that had extensive early social experience, neither soliciting play bouts nor responding appropriately to solicitations by others. They would often get involved in serious aggression with other individuals, both as perpetrators and recipients. Thus, instead of responding to threats from more powerful individuals by showing appeasement or submissive gestures that might prevent the episode escalating into a physical conflict, socially deprived monkeys might counter-threaten, a clearly inappropriate response that would elicit an attack.

Note that isolation-reared monkeys possess all of the facial expressions and vocalizations of their species. However, they appear to lack the ability of normal individuals to cope with potentially volatile situations through appropriate exchanges of signals. The early social environment is clearly important for learning this ability. For isolates, however, the combination of fearfulness, disorganized behavior, aggressiveness, and self-directed tendencies prevented their full integration within a group. Consequently, they were often rejected by socially competent individuals, kept on the periphery of the group – where they might associate to some extent with similarly reared deviants; experiments showed that isolates preferred to approach other isolates over normal individuals.

As already mentioned, one aspect of the impaired social abilities of isolates was their difficulty in forming alliances with other monkeys. In other words, they showed little reciprocal support to others in situations of contest or conflict. Their behavior was often at odds with respect to the dominance hierarchy, resulting in further intra-group hostility. One mechanism that appears to contribute to the higher levels of aggression in early socially deprived macaques is their compromised post-conflict reconciliatory tendencies. Clearly, if an isolate is less likely than another individual to come together with a previous opponent to make peace, then continued aggression appears more likely. There is evidence that reconciliatory tendencies may be learned especially during infancy and the juvenile period, but this requires social partners, which isolates did not have.

Sexual and maternal behavior

Sexual behavior was found to be seriously affected by early social deprivation. Excessive masturbation in the home-cage was recorded (so-called ‘auto-eroticism’), and attempts at copulation when isolates were eventually placed with other individuals typically failed. Infrequent reproduction by isolates was due to inappropriate attempts at copulation, rather than a lack of motivation. Males appeared generally more vulnerable to the disabling effects of early social deprivation. In the sexual domain, their attempts at mounting females were often disorganized, mistimed, and poorly oriented. Females also showed sexual inadequacies, such as failing to maintain the posture of lordosis required to accept the male’s copulatory mount, or a female might take fright and run away just before intromission was achieved.

Although the sexual behavior of males was more severely impaired than that of females, if the latter did eventually become pregnant (sometimes through artificial means) then another exclusively female aspect of reproductive behavior was found to be grossly inadequate: maternal behavior. Although normal primiparous macaques may be less accomplished than older and more experienced females at caring for their newborn, first-time mothers are generally able to clean, support, feed, and protect their newborn. However, this was not the case for females raised in isolation (‘motherless mothers’). The inadequacies of motherless mothers were expressed in a variety of ways, ranging from indifference (allowing the weakened offspring to fall from her body, and failing to retrieve it), to preventing access to the nipple (pushing the hungry baby away), to serious abuse (biting, or even killing the infant). In some cases, the only way to ensure the newborn’s survival was to remove it from the abusive mother and rear it by hand. Although this was effective, if hand-rearing again meant early and prolonged social deprivation, then the infant could be expected to develop abnormal behaviors. In spite of receiving continuous

maltreatment, however, some infants were able to survive being reared by an abusive, motherless mother. For those female infants that went on to have their own baby, an abusive style of mothering was also noted.

Early deprivation and the brain

Prolonged lack of appropriate social experiences (isolates were typically reared alone for 6–12 months) resulted in the emergence of behavioral pathologies that may always remain in the repertoire. Clearly, aberrant behaviors resulting from an inadequate rearing environment are the expression of central nervous system changes. Studies have examined the neural consequences of isolation rearing in monkeys using a range of techniques including electrophysiology (EEG), neuroanatomy, and neurochemistry. Several studies have reported reductions in stereotyped motor acts following treatment with drugs, such as fluoxetine, a serotonin reuptake inhibitor. There have even been attempts to improve the behavior of isolation-reared monkeys through electrical brain stimulation. However, the literature on the brain mechanisms underlying the isolation syndrome in primates is tiny compared to that on the effects of early environmental and social deprivation on the brain and behavior of rodents. It is sufficient to note that the developing brain is highly sensitive to environmental effects, and that arrested or corrupted cellular development due to early deprivation is likely to have lasting effects at the psychological and behavioral levels.

Self-Aggression and Self-Injury

With increasing locomotory competence and independence from the mother, normal infant monkeys soon start to play with each other, grappling and play-biting. In the absence of social partners, isolation-housed infants will start to play with their own bodies, rolling around and pulling and gently biting their own limbs while displaying the ‘play-face’ facial expression. At around the same time, the first occurrences of another early social-deprivation-induced behavioral pathology may be seen: self-aggression. Self-aggression progressively becomes more prominent in the repertoire. In some cases, self-aggression may result in self-mutilation serious enough to require acute veterinary intervention; self-castration has even been described in a self-aggressive macaque. However, in most cases habitual self-aggressors appear to control the intensity of their actions, so that either only superficial or no tissue damage results.

It is useful to distinguish self-aggression from self-injury that might arise as a consequence of repeated stereotyped motor acts such as cage-biting, or habitually gnawing one’s fingers or tail. What typifies self-aggression is the expression of truly aggressive motor patterns,

including postures, facial expressions, and, sometimes, vocal threats directed toward the individual’s own body. However, some authors do not make the distinction between general ‘self-biting’ and self-aggression; in any case, the greater the degree of early deprivation, the greater the incidence of these pathological behaviors. One study of singly housed, male, pigtailed macaques found that the amount of abnormal behavior shown in adults was related to the proportion of time they had been housed alone during the first 4 years of life. Although it is usually a sign of early inadequate social experience, self-aggression – like some other abnormal behaviors – may also occur in normal individuals as a response to extreme frustration or stress. One study found an increased occurrence of abnormal behaviors in socially housed female baboons after the birth of their infants. This was related to psychological stress, as measured by the incidence of self-directed scratching.

Self-aggression may be expressed idiosyncratically, but a typical bout in a habitual self-aggressor might start by the individual slowly reaching up and tugging at the hair on the top of its head. The ‘offending’ hand might then be brought down in front of the face and threatened, with the threat face appearing identical to one that would normally be directed toward a real victim (although no confirmatory analysis of facial action patterns has yet been done). The bout might end at that point, or the tug-threat sequence might be repeated, and/or the monkey might start to bite its hand. In some cases, when the foot is the target, then biting might be interspersed with the monkey kicking its own face repeatedly, in a sequence somewhat similar to repeatedly scratching the head with the foot, though more violent. Self-fighting monkeys might literally throw themselves around their cage or enclosure in a fit of rage (see **Figure 1**).

Once self-aggression becomes established in the repertoire, it may become the preferred, if not the exclusive, form of aggression, even for socially housed monkeys. This is probably because the self-aggressor learns that it is safer to target itself than to get into real fights; although self-mutilation may occur, in most cases, the intensity of self-biting is controlled, so that any injury sustained is minor. Experimental studies have shown that, much like normal aggression, self-aggression may be increased by factors such as alcohol ingestion and frustration. Individuals who injure themselves due to self-aggression clearly respond to frustrating situations differently to nonself-injurious counterparts, for example, showing extinction deficits following the acquisition of a learned response (lever-pressing) for continuous reinforcement. Self-aggression-induced injury is more often reported in males than in females, probably due to a combination of the formers’ greater strength and canine development.

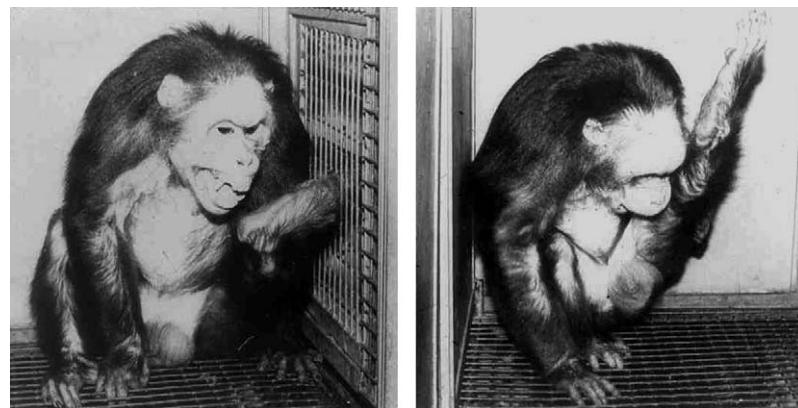

Figure 1 Self-aggression in an adult male stumptail macaque, showing self-directed threat (left), and self-biting (right). Photos by J. R. Anderson.

Some studies have looked at the underlying pathophysiology of self-aggression in monkeys. For example, a hypothesized possible link between propensity for self-injurious behavior and abnormalities in serotonergic function has been studied, although the results are not clear-cut. A reduced cortisol response to mild stressors indicates compromised hypothalamic–pituitary–adrenal axis function, in association with disturbances in central and peripheral opioid systems. Studies of self-aggressive macaques have found that self-injury and other abnormal acts were reduced by cyproterone acetate, which among other effects may decrease testosterone. The serotonin precursor, tryptophan, also reportedly decreased the incidence of self-wounding. Another study, using macaques and a baboon, reported positive effects of guanfacine, an α_{2A} -adrenergic receptor agonist; it was suggested that the treatment might have strengthened inhibitory processes in the prefrontal cortex.

Preventing Abnormal Behaviors in Socially Deprived Monkeys

The pathological behavioral consequences of early prolonged isolation have been shown to be preventable by early intervention, based around providing alternative social experiences. For example, as a result of daily sessions with younger, so-called ‘therapist’ infant, isolation-reared rhesus monkeys gradually showed a recovery in social abilities. Another alternative rearing system consisted of pairing infants with same-aged partners, in the absence of any adults. These so-called ‘together-together’ monkeys grew up to be well adjusted and relatively free of isolation-syndrome behaviors, although their tendency to cling to each other beyond the age at which mother-reared infants would start to show greater independence resulted in a delay of some behaviors, including play. One

conclusion that can be drawn from these studies is that, in captivity at least, access to the mother is not critical for an infant monkey to develop adequate social capabilities; rather it is adequate physical contact with individuals that both solicit and respond to different kinds of social interactions. Thus, younger ‘therapist’ monkeys, and peer-only groups, were able to promote good social adjustment. On the other hand, inanimate mother surrogates, even those that afforded clinging and provided ‘contact comfort’ to the infants, failed to prevent the development of behavioral abnormalities.

Enrichment of the Physical Environment

As indicated above, in the absence of effective therapeutic interventions early isolation-syndrome behaviors may become permanently established in the repertoire, being expressed even after many years of living as a member of a group. However, their incidence can be lowered by appropriate environmental-enrichment techniques, such as provision of increased foraging activities. There can be dramatic decreases in the incidence of stereotypies and self-aggression when appropriate environmental enrichment is provided.

Research into the effects of early social and environmental deprivation in primates has declined in the past few decades, but there are still plenty of primates displaying abnormal behaviors. It is not uncommon for normal (i.e., socially reared) laboratory-housed primates, especially those housed in single cages, to show a range of abnormal acts such as stereotyped pacing or somersaulting, manipulation or biting of cage mesh or other structures, and excessive self-grooming. They may also manipulate, smear, and even eat their feces; coprophagy (and regurgitation) is particularly reported for captive great apes, even some that have been socially reared and that live in groups.

The kinds of behaviors seen in these circumstances tend to be different from those of the isolation syndrome; for example, floating limbs and bizarre postures are rare, as is self-aggression. Moreover, unlike isolation-syndrome behaviors, the aberrant behaviors of normal, individually housed primates are reversible. Removal from individual cages and being housed instead with compatible social partners leads to a marked reduction in abnormal behaviors, as the primates invest time and energy in their social relationship (which allows social grooming, huddling, exchange of signals, etc.). In other words, if animals can be occupied by something that elicits desirable behaviors, they are less likely to engage in undesirable alternatives. Changing from single housing to compatible social housing is viewed as best practice as a means of reducing the incidence of abnormal behavior in captive primates.

In recent years, abnormal behaviors have been increasingly used as a measure of the psychological well-being of captive primates (and other animals) in laboratories and zoos. For example, in one study of Indian zoos, only macaques housed individually in barren cages were found to show behavioral abnormalities (especially stereotypic pacing, but including floating limb and self-aggression as well). In addition, macaques housed in cages or enclosures with a hard substrate (e.g., cement or concrete) were more prone to abnormal behaviors than those in enclosures with a soft substrate (e.g., grass or soil). Studies of several species of primates including marmosets, macaques, baboons, and great apes have shown dramatic reductions in abnormal behaviors following transfer from individual cages to more spacious enclosures, and as mentioned above, housing primates with others is seen as the most effective way of normalizing behaviors.

The studies mentioned above are examples of applied animal behavior science, which addresses problems in husbandry and housing aiming at behavioral enhancement through the provision of more naturalistic and stimulating environments. In some cases, the aim is a behavioral profile that resembles that seen in the wild, and in other cases intervention targets a specific pathology, such as self-aggression, or regurgitation of food. Providing simple toys, sticks, or other manipulable objects can often reduce the incidence of abnormal behavior, as the primates turn their attention toward exploring and manipulating the objects. Similarly, there are many reports of positive effects of environmental enrichment in the form of increasing foraging opportunities. This can involve simply providing a deep woodchip litter on the floor of the enclosure and scattering some small food items to encourage foraging, or presenting specialized devices such as foraging boards and puzzle feeders. Combinations of foraging-based enrichment interventions have been found to decrease behaviors such as coprophagy, feces smearing, and hair pulling in chimpanzees.

Species Differences

The outcomes of interventions aimed at normalizing the behavior of primates vary across studies. At least part of the variation is due to the diversity of species in this taxonomic group. There are around 250 species of primates, ranging from the so-called ‘primitive’ species among the prosimians, to our nearest evolutionary neighbors – the great apes. Given the sheer diversity of behaviors seen across the primate order, it should be expected that species differ in vulnerability to developing behavioral pathologies and in the form these pathologies take. For example, although prosimians may develop stereotyped motor acts, they do not appear to develop the full-blown isolation syndrome described in macaques. Even between closely related species there may be differences: pigtail macaques were found to show a much milder isolation syndrome than rhesus macaques, assessed both in the home-cage and other environments. Rhesus isolates might be more prone to stereotypies, whereas stump-tail macaques might show more self-aggression. These days few, if any, researchers deliberately deprive primates of sensory and social stimulation in order to induce abnormal behaviors. But as long as zoo and laboratory primates continue to exhibit behavioral pathologies, researchers will continue to study them both in order to try to resolve the problem, and also to better understand them.

Glossary

Basal ganglia – A group of subcortical gray nuclei located in the depth of the cerebral hemispheres, interconnected with the cerebral cortex, thalamus and brainstem, and associated with a variety of functions: motor control, cognition, emotions, and learning.

Limbic system – A set of phylogenetically primitive brain structures located on top of the brainstem and which comprises cortical areas as the cingulate gyrus, the medial orbitofrontal cortex, the olfactory cortex, and the hippocampus as well as subcortical gray nuclei as the amygdala, fornix, hypothalamus, and thalamus. This system is involved in many emotional and motivational aspects of behavior, particularly those that are related to survival.

Obsessive-compulsive disorder – Anxiety disorder characterized by recurrent, unwanted thoughts (obsessions), and/or repetitive behaviors (compulsions). Repetitive behaviors such as handwashing, counting, checking, or cleaning are often performed with the hope of preventing obsessive thoughts or making them go away. Performing these so-called rituals, however, provides only temporary relief and not performing them markedly increases anxiety.

Stereotaxis – Relating to or denoting techniques for surgical treatment or scientific investigation that uses medical imaging to precisely locate in three dimensions an anatomical site to which a surgical instrument or a beam of radiation is directed.

Tourette syndrome – Also called Tourette's syndrome, Tourette's disorder, Gilles de la Tourette syndrome, GTS, or, more commonly, simply Tourette's or TS, it is a neuropsychiatric disorder with onset in childhood, characterized by the presence of multiple physical (motor) tics and at least one vocal (phonic) tic, which characteristically wax and wane.

stimulation (DBS). The technique has been used as a tool for the functional exploration of the brain and as a therapeutic tool, while also being employed in a complementary fashion for lesion surgery. DBS has opened up new opportunities for empirical studies in humans, following up and developing old lines of investigation and initiating new ones.

Neurophysiological investigation by electrical stimulation was massively boosted by the work of the neurosurgeon Wilder Penfield in the early 1930s. With electrical stimulation, every neurosurgical case opened up the opportunity for functional exploration. During neurosurgical interventions for epilepsy, he systematically carried out cortical stimulation in the awake patient with a neurologist continuously noting clinical responses. This method of the experimental human investigation completely transforms the nature and temporality of the observations. Unlike an irreversible lesion, electrical stimulation enables repetitive stimulation of the same human or animal subject. It allows, above all, in the case of neurological disorders, one to observe the clinical signs, record the subjective experience of the patient, and locate the underlying pathological causes within a manageable and reproducible time frame. Penfield therefore succeeded in performing experimental and clinical work within the same individual and fruitfully combining functional neurology, experimentation, and patient therapy in the same operative procedure. He therefore laid the foundations of functional neurosurgery, systematized the methodology, and prepared the ground for DBS which, as a combined therapeutic and research tool, falls into the same category of complementary approaches and techniques (preclinical, clinical, neuropathological, and neurosurgical). It was in this framework of complementary clinical investigation and research, with an ultimate therapeutic goal, that DBS was born. The empirical discovery in the 1960s by several independent research groups that high-frequency electrical stimulation of the thalamus has the same effects on tremor as lesions found its therapeutic application in the 1980s with the invention of DBS by the French neurosurgeon Alim Louis Benabid. He would be the first, as a result of this observation, to propose a chronic electrical stimulation system implanted within brain structures of the patient. Stimulation therefore became chronic and deep and took over from lesion surgery for tremor.

Introduction

Electrical stimulation of the brain has a long history, starting with the classic nineteenth-century animal experiments and then its systematic use in functional neurosurgery by Penfield and now to deep brain

Principles and Uses of Deep Brain Stimulation

DBS consists of stereotactic implantation of electrodes in deep brain structures. The electrodes are connected by a subcutaneous cable to an implantable electric stimulator enabling the application of high-frequency (80–180 Hz) current to the target structure. The effect of the stimulation is reversible and the various stimulation parameters (frequency, pulse width, and voltage) are adjusted in order to obtain the best possible results in the absence of undesirable side effects and low morbidity. Furthermore, bilateral implantation of DBS electrodes is possible, which was up to now impossible with traditional lesioning techniques. For many years now, this surgical intervention has been proposed for several movement disorders, principally Parkinson's disease but also essential tremor with high-frequency stimulation of the ventromedial thalamic nucleus and dystonia with stimulation of the internal globus pallidus showing sometimes spectacular improvement of the disability. Finally, recent studies provide hope that DBS could be an effective treatment for patients suffering from abnormal movements secondary to prolonged treatment with neuroleptics.

Modulation of Associative and Limbic Circuits

The spectacular efficiency of DBS in the amelioration of Parkinsonian motor symptoms is considered to be the result of the modulation of the striato-pallido-subthalamo-thalamo-cortical neuronal loops implicated in motor behavior. Reports of emotional behaviors during subthalamic nucleus (STN) stimulation such as mirth and acute depressive symptoms or symptomatic improvement of such symptoms as depression, anxiety, OCD, and pathological gambling suggest that DBS can also modulate the nonmotor loops within these same pathways. Functional imaging studies, in agreement with these clinical observations, have demonstrated modulation of limbic circuits during DBS. The clearest demonstration of emotional behavior during DBS is seen during stimulation of the substantia nigra pars reticulata (SNr), which triggers extreme manifestations of depression, or mania with functional imaging revealing a concomitant activation of limbic regions. Stimulation of anteromedial STN induces a hypomanic state without any effect on motor activity. Functional imaging data indicate increased regional blood flow concomitant with the hypomanic state in the antero-ventral thalamic nucleus (implied in limbic circuitry) and a decrease in the right prefrontal anteromedial cingulate

gyrus – thereby replicating the map of cerebral activity modifications seen during mood swings. On the basis of our knowledge of STN organization, this observation demonstrates the way in which this nucleus, despite its small size ($10 \times 6 \times 3$ mm), can receive and process a variety of different information. Thus, neural information related to motor control (explaining its efficiency in treating the motor signs of Parkinson's disease), cognition (i.e., the social and intellectual content of our behavior), and the emotional information which necessarily more or less colors all our expressed behavior. The extremely small size of the STN and the minimal separation of the four electrode contacts used in DBS have enabled to demonstrate that this brain region brings together these three aspects of our behavior to generate an output perfectly adapted from the social, affective, and motor points of view (Figure 1). Therefore, when we stimulate the STN, the exact position of the electrode determines which of the cortical–subcortical loops is activated and hence which of the motor, social, or affective components of behavior are modified.

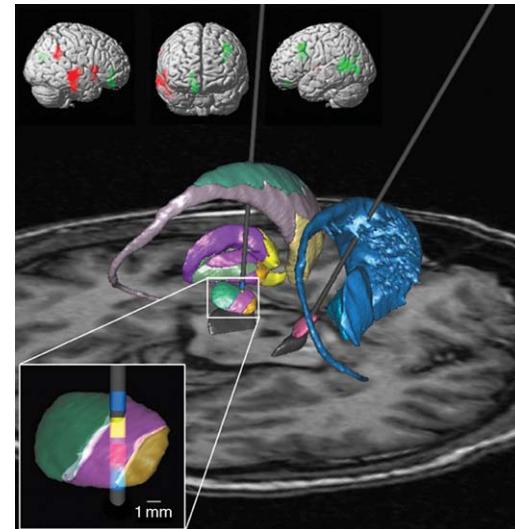

Figure 1 Upper part: Functional imaging of the cerebral regions activated (red) or deactivated (green) during stimulation inducing hypomanic symptoms. Lower part: electrodes implanted in subthalamic nuclei. Motor, associative, and limbic territories of basal ganglia are shown in green, violet, and yellow, respectively. Left inferior corner: subthalamic nucleus with the four contacts of the electrode. Stimulation through the red contact induces hypomanic symptoms. Stimulation through the yellow contact improves motor symptoms as well as the red one, without inducing behavioural changes. (2007) Stimulation of subterritories of the subthalamic nucleus reveals its role in the integration of the emotional and motor aspects of behavior. *Proceedings of the National Academy of Sciences of the United States of America* 104: 10661–10666.

The Basal Ganglia: The Integration Site for Cognitive, Motor, and Emotional Information

The basal ganglia consist of a series of nuclei found deep in the cerebral hemispheres: the striatum (caudate nucleus and putamen), the pallidum (internal and external), the substantia nigra (reticulata and compacta), and the subthalamic nucleus. Their principal source of information is the cerebral cortex, in other words, a copy of the motor plan constructed by the cortical motor areas but also a copy of all other events which may arise in other nonmotor cortical areas. Two opposing theories have been proposed concerning the organization and analysis of this mass of information. The first postulates the existence of three perfectly segregated parallel circuits within which the information is independently analyzed. The other, based on more recent anatomical data, suggests, on the contrary, that the different kinds of information are integrated within the basal ganglia to produce an output, which carefully balances these different sources of information. The basal ganglia circuitry is in the form of a loop originating over the whole of the cortical mantle and returning to the frontal cortex (Figure 2). It receives,

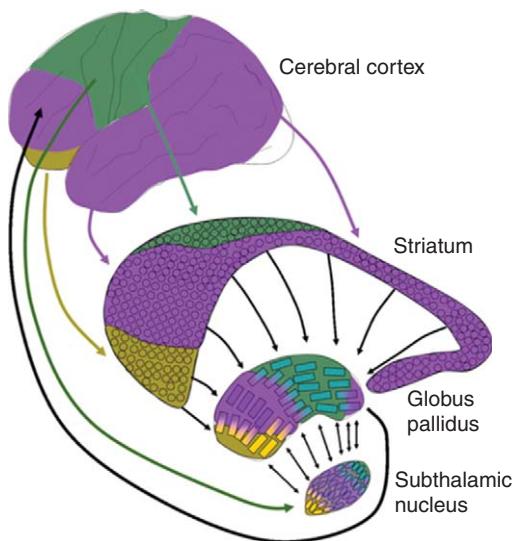

Figure 2 A diagrammatic representation of the basal ganglia organization. The basal ganglia receive information from three functional territories of the cerebral cortex, sensorimotor (green), associative (violet), limbic (yellow), that are transmitted to separate regions of the striatum. Information is received by spiny-striatal neurons, which have small spherical dendritic arborizations (spheres), which preserve functional specificity. In the globus pallidus, neurons are 100 times less numerous and have flattened and large dendritic arborizations (rectangles), which make transmission of striatal information onto pallidal neurons highly converging. In the subthalamic nucleus, information comes not only from the three functional territories of the globus pallidus, but also directly from motor cortices, which confers to this nucleus the role of a nexus in the circuit. From Yelnik J (2008) Modeling the organization of the basal ganglia. *Rev Neurol* 164: 969–976.

therefore, a copy of the motor plan originating in the motor cortical areas as well as the contextual cognitive and emotional information within which the plan is formulated. These sources of information are integrated within the system in order to produce the perfect balance of the three: motor, cognitive, and emotional components. In addition, a circuit exists that is more specifically devoted to the processing of emotional and motivational information and which involves the ventral part of the striatum (the so-called nucleus accumbens) and the ventral globus pallidus. This circuit is likely to be implicated in the pathophysiology of such psychiatric disorders as OCD or the Gilles de la Tourette syndrome. The internal organization of the basal ganglia also enables the learning of effective behavioral sequences arising from the dopaminergic reward signal present in the nigro-striatal pathway, although the reward-prediction error hypothesis can be discussed. The cortical inputs terminate on the heads of the striatal dendritic spines while the dopamine terminals are found at their necks, strategically positioned to enable the selection of the descending cortical information. The striatum is thus in a position to modulate (by excitation or inhibition) the cortical motor plan.

The Basal Ganglia as a Target for the Treatment of Psychiatric Disorders

In the context of therapeutic targeting, the basal ganglia offer the great advantage of a control center both receiving and sending information from and to the whole spectrum of cortical areas functionally subdivided into sensorimotor, oculomotor, associative, and limbic. Dysfunction of the associative loop with its cognitive functions and the limbic loop with its emotional function might therefore be expected to be involved in psychiatric disorders. This notion is in fact supported by neuroimaging data being collected for the development of DBS techniques in relation to both OCD and depression.

Certain advantages of DBS are also linked to the complexity of its action and require that we deepen our understanding of the neural mechanisms at play in target structures. Stimulation has its effect on cerebral function through several distinct but interrelated mechanisms, of which their respective roles are dependent on the stimulation site, the disorder being treated, its neuropathology, and the stimulation parameters employed. The exact mechanism, whether it be excitation or inhibition, and its effects on the chemistry of neurotransmission are all still unclear. Another important factor relates to the spatial features of the electrode/target arrangements and tissue conduction characteristics. Finally, the clinical effects of DBS reflect a complex combination of excitation and inhibition of cell bodies and axons dependent on the orientation of the electrodes. This range of factors

allows one to imagine the restoration of complex information processing such as emotional behavioral disorders by means of DBS and furthermore to extend its application to the field of psychopathology. DBS provides a range of possibilities for adjusting the anatomical specificity of the stimulation. Frequency, intensity, and pulse width are all programmable noninvasively after the implantation procedure in the awake patient. Furthermore, the stimulation can be unipolar or bipolar, redirected to any combination of the four electrode contacts, and can be continuous or intermittent. The patient, within limits determined by the doctor, can also be given the possibility of activating or deactivating the stimulator and even controlling his own stimulation parameters. This wide range of possibilities for parameter adjustment thus provides the opportunity for the optimization of the treatment and controlled therapeutic trials.

As far as the indications for DBS therapy are concerned, this remains reserved for the moment for the traditional cases appropriate for neurosurgery, in other words, disorders resistant to any alternative course of treatment. At the conceptual level, the neuropathological models for psychological disorders (basal ganglia dysfunction) are as yet still insufficiently detailed to propose DBS other than in the structured framework of multidisciplinary clinical research. Thus, even the simple clinical observations of emotional and abnormal behavioral reactions to DBS, carried out for the treatment of motor disorders, require extremely precise anatomical localization in order to establish reliable correlations with the clinical data. Below we have given some examples of the use of DBS in the treatment of psychological disorders: obsessive-compulsive disorder, Tourette syndrome, and depression in cases resistant to all available therapies.

DBS in Obsessive–Compulsive Disorder

OCD is a frequent illness in the general population with a whole life prevalence of between 2% and 3%. It is characterized by a chronic increase in severity and devastating disruption of social, professional, and family life. The classic treatment for OCD is by prescription of antidepressants of the class of selective serotonin uptake inhibitors, either alone or in conjunction with cognitive and behavior therapy. Nevertheless, these therapeutic strategies turn out to be inefficient in 25–30% of cases. Because of this, we can understand the drive to develop various types of psychosurgery based on various neurosurgical techniques, such as bilateral anterior capsulotomy, bilateral anterior cingulotomy, subcaudate tractotomy, and limbic leucotomy. These all had the objective of the destruction of the pathways linking prefrontal cortical areas with the subcortical limbic structures. When applied in the domain of psychiatric

disorders, these techniques were found to be efficient in 50–60% of cases, but they are rarely practiced today because of the irreversibility of the lesions and a number of undesirable cognitive and emotional side effects (euphoria, psychomotor agitation, affective blunting, and lack of motor spontaneity). As we have seen, the development of DBS therapy in the domain of psychological disorders is a new departure and poses the problem of the correct choice of a target whose neuropathology is incompletely understood. Functional imaging data suggest, however, that basal ganglia hyperactivity is affecting both the cingulate and the orbitofrontal cortex in these cases which raises the possibility of stimulating certain key nuclei within these loops.

The application of DBS for the treatment of OCD started in the late 1990s using as target the anterior limb of the internal capsule/nucleus accumbens, aiming initially to reproduce the results of lesioning neurosurgery. Other studies have since explored the effects of stimulation in the region of the ventral striatum with various specific anatomical targets. Certain more recent results point to the efficiency of more ventral and posterior regions than the initial internal capsule target, and would specifically identify the nucleus accumbens. The divergence of results sometimes found in these studies raises two questions: (1) the anatomical question which concerns the exact definition of the target and (2) the methodological question of the limited number of patients included in these studies and the lack of randomized designs; which, given the heterogeneous nature of the disease, would explain the variability of the results obtained.

Recently, STN stimulation (Figure 3), which has been previously shown to improve OCD symptoms in patients

Figure 3 The whole skull with the caudate nuclei and two electrodes implanted in the subthalamic nuclei. Credit: Image Luc Mallet/Jérôme Yelnik/Eric Bardinet (Inserm, CNRS-INRIA).

stimulated for disabling Parkinson's disease, was found to significantly improve OCD and global functioning. Nevertheless, these results necessitate some caveats. Prudence is required in their interpretation, given the behavioral effects induced by the stimulation, which, although reversible, demonstrates the narrow therapeutic margin inherent in the STN target, underlining the considerable functional convergence within this structure. Furthermore, this highlights the need for a high degree of technical expertise and coordination of the medical teams. Finally, regular psychiatric follow-up is indispensable both before and after the operation. The conclusions of this study open up great hope for these severely disabled patients but underline the need for great caution in the use of the technique. It would appear therefore crucial to apply these techniques only within a carefully controlled framework, taking into account the ethical issues and exploring in detail the risk/benefit ratio of potential DBS targets.

Modulation of Limbic Relays in Tourette Syndrome

Tourette syndrome (TS) arises from simultaneous dysfunction of both basal ganglia and limbic areas. The illness is characterized by both motor and vocal tics. The most frequently employed treatment for TS are dopamine antagonists and neuroleptics. These mainly improve motor tics but at the price of numerous side effects, in particular weight gain and tardive dyskinesias and other abnormal movements difficult to treat. Starting in 1960 ablative neurosurgery began to be practiced for severe forms of TS. The thalamus, zona incerta, anterior cingulate, the cerebellar dentate nucleus as well as frontal lobes were all chosen as targets for the treatment of tics and associated pathologies. Although the first case of DBS treatment for this disease was reported 9 years ago, the choice of target for optimal results remains a current issue. Stimulation of the centromedian–parafascicular complex (CM–Pf) of the thalamus, the internal part of the globus pallidus (GPi), and the anterior limb of the internal capsule, have been tested with a positive effect on tics. Bilateral stimulation of the CM–Pf and/or the ventrooralis nucleus of the thalamus has been applied to 18 TS patients with a 65% improvement in tics reported at various postoperative delays through an open follow-up. In line with pathophysiological hypotheses of a dysfunction in the associative-limbic component of the basal ganglia circuitry in TS, the efficacy of modulation of two associative-limbic relays (the CM–Pf of the thalamus and ventromedial part of the GPi) has been evaluated in a double-blind-randomized-cross-over design control study which demonstrated the importance of targeting the limbic networks. The best results were obtained by

stimulation of the anterior GPi, with an improvement of the order of 70% of the symptoms. The long-term follow-up of the patients (7 years of data for the first patient operated upon) demonstrates the maintenance of the effect over time and allowing a return to both professional activity and a normal social life.

The Neurosurgical Approach to Depression

Depression is a frequent, disabling, and recurring illness present in 6% of the general population. Depressive symptoms persist for at least 2 years in 10–20% of cases. Within the patient group showing a chronic worsening of symptoms, 20–30% are resistant to drug therapy and, of these, 50% are resistant to electroconvulsive therapy (ECT). For these patients again, neurosurgery was proposed in the past. Three approaches have been attempted: bilateral anterior cingulotomy, subcaudate tractotomy (destruction of the pathways descending from the orbitofrontal cortex to the ventral striatum), and limbic leucotomy which combines subcaudate tractotomy and anterior cingulotomy. These lesioning psychosurgical interventions, while improving certain depressive symptoms, showed their limitations in relation to poor patient selection, simultaneous presence of other psychological disorders, wide variability in surgical techniques and undesirable side effects. Furthermore, these studies were characterized by the lack of a multidisciplinary approach (grouping psychiatrists, neurologists, and neurosurgeons) and suffered from the irreversibility of the lesions produced.

The DBS approach when applied to depression is founded on neuropathological and functional imaging data, both of which demonstrate a dysfunction with basal ganglia-cortical loops originating within the orbitofrontal, dorsolateral prefrontal, and anterior cingulate cortices. Specifically, the ventral subgenual anterior cingulate cortex (sgCCA) would appear to be a seat of hyperactivity in the depressive state, and is correlated with the severity of the episode as well as its level of resistance. In an attempt to modulate the activity of these regions to reverse the depressive state, DBS of the white matter adjacent to the genu of the cingulate gyrus was applied in six patients suffering from severe drug- and ECT-resistant depression. Chronic stimulation of this area produced a state of remission in four out of the six patients implanted. More recently, another therapeutic option would appear to be the ventral striatum, since analysis of the early lesioning neurosurgical approaches showed that the greatest number of operations leading to remission involved interventions including the region below the head of the caudate nucleus. This was the case for both the subcaudate tractotomies and the limbic leucotomies. In these techniques, the lesions included the

entire ventral striatum, simultaneously touching the nucleus accumbens and the head of the caudate. Now, DBS of the ventral striatum in the region adjacent to the anterior arm of the internal capsule has been shown to improve depressive symptoms. Furthermore, stimulation of the nucleus accumbens in three depressed patients produced an immediate effect on the anhedonia, as has stimulation of the caudate nucleus targeted for treatment of severe OCD.

In summary, OCD and depression represent fairly different pathologies of the psychiatric domain which require different therapeutic approaches. In the domain of deep brain stimulation, two completely different targets have been proposed: the cortical Brodmann area 25 on the basis of functional imagery data and the subthalamic nucleus based on direct fortuitous observations in Parkinsonian patients. Experimental data in the nonhuman primate have revealed the role that the ventral caudate nucleus plays in the development of repetitive behaviors, and application of DBS in this nucleus for OCD patients has shown that both OCD and depressive symptoms were improved. This could suggest that both pathologies have common physiopathological processes. Nevertheless, the caudate nucleus is a very large structure and further work is needed to determine whether both pathologies respond to stimulation of exactly the same territory.

Conclusion

The DBS paradigm for the treatment of psychological disorders enables us to deepen our understanding of these afflictions on the basis of models founded on our improved knowledge of their underlying neuropathology. By specifying the neural bases of emotional behavioral disorders, in particular in relation to the basal ganglia, we have seen substantial improvement in the therapies available. Not only are we able to define the targets for neurosurgery more accurately but we are also able to systematically correlate the DBS results with the clinical observations. Finally, the application of DBS in the field of psychopathology has been a powerful stimulus allowing the integration of experimental scientific results, obtained in carefully controlled studies, with a greatly improved service to patients.

Human Fear and Anxiety

F G Graeff, University of São Paulo, Ribeirão Preto, São Paulo, Brazil

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Amygdala – Almond-shaped subcortical brain structure located in the medial temporal lobe. It belongs to the limbic system and has been involved in fear learning and expression.

Antidepressants – Drugs that are used to treat several depressive and anxiety disorders. They are effective only after several weeks of daily administration and do not induce a drug dependence.

Anxiolytics – This term refers mainly to benzodiazepine agents that reduce anxiety after a single administration. They are used to treat generalized anxiety disorder for a few weeks, since prolonged use can result in psychological and physiological dependence.

Cognitive behavior therapy (CBT) – A modality of psychotherapy based on learning principles. Its main goal is to promote the extinction or unlearning of fear-inducing associations by gradual exposure to the fear stimulus or context.

Ethoexperimental analysis of behavior – Study of animal behavior with a combination of systematic observation and experimental control of intervening variables.

Ethology – Systematic and comparative study of animal behavior from a biological and evolutionary perspective.

Generalized anxiety disorder (GAD) – Chronic, free-floating anxiety for at least six months, characterized by excessive worry about everyday events, with mild autonomic symptoms.

Hippocampus – Subcortical brain structure shaped like a seahorse and located in the medial temporal lobe that belongs to the limbic system. It has been involved in many functions, such as memory, spatial navigation, and anxiety.

Nuclear magnetic resonance imaging (MRI) – Imaging technique used to visualize the structure and function of bodily organs. It uses a powerful magnetic field to align the nuclear magnetization of atoms in water and provides detailed images in any plane.

Obsessive-compulsive disorder (OCD) – Disorder characterized by recurrent, unwanted thoughts (obsessions) and/or repetitive behaviors (compulsions) that is often accompanied by intense anxiety.

Panic attack – Sudden surge of intense fear, lasting for nearly ten minutes, and accompanied by marked autonomic changes, like sweating, shortness of breath, hyperventilation, choking, palpitation,

dizziness, nausea, stomach ache, trembling or shaking.

Panic disorder (PD) – Anxiety disorder characterized by a recurrence of panic attacks. With time, anticipatory anxiety about having another attack and avoidance of places where having an attack is embarrassing, develop.

Panicogenic agents – Chemical agents used to experimentally induce panic attacks. Examples are lactate and cholecystokinin injected intravenously, and carbon dioxide (CO_2) inhaled at concentrations higher than that in the atmosphere.

Periaqueductal gray matter (PAG) – Gray-matter layer that surrounds the midbrain aqueduct. It has been involved in the control of proximal defense (freezing/fight/flight) and of panic attacks.

Posttraumatic stress disorder (PTSD) – Anxiety disorder that can develop after exposure to terrifying events of physical or psychological nature. Soon, or even a long time after the traumatic event, patients undergo distressful experiences, such as reliving the traumatic event, tend to avoid situations reminding the trauma, as well as show emotional numbing and hyperarousal.

Receptor – Set of protein molecules localized in cell membranes, having sites where an endogenous substance, such as a neurotransmitter, binds with high affinity and selectivity to cause physiological changes.

Selective serotonin reuptake inhibitor (SSRI) – Second-generation antidepressant agent that inhibits 5-HT reuptake carried out by a transporter molecule at the neuronal membrane, with little or no action on the reuptake of other biogenic amines, such as noradrenaline or dopamine. As a result, 5-HT concentration in the synaptic cleft is increased.

Serotonin (5-HT) – Biogenic amine neurotransmitter chemically named 5-hydroxytryptamine.

Social anxiety disorder (SAD) – Intense, persistent fear of being watched and judged by others, what interferes with ordinary activities. Physical symptoms that often accompany the anxiety include blushing, sweating, trembling, nausea, and talking difficulty.

Specific phobia – Abnormally intense, persistent fear of certain objects, animals, activities, or situations.

Tricyclic antidepressant – First-generation antidepressant agent that nonselectively inhibits biogenic amine reuptake.

Anxiety, fear, and panic: do these emotions belong to a continuum of increasing intensity or differ qualitatively from each other? These opposed views have been sustained by respected scholars, but it is unlikely that the dispute will be settled on phenomenological grounds alone. Other levels of analysis are clearly necessary and, in this regard, the evolutionary approach, taken from biology, provides important material for this discussion.

From a biological perspective, it is important to remark that these three emotions are triggered by the perception of threat and mobilize defensive reactions to cope with the perceived challenge. Therefore, a way of understanding their function and neural substrate is to study the expression of defensive reactions in animals, especially in those phylogenetically related to our own species. This approach has been introduced by Charles Darwin, who first organized his observations and theoretical views in the book *The Expression of Emotions in Man and Animals* published in 1872. Basically, Darwin extended to the basic emotions, the notion of natural selection, through which certain characteristics of living organisms are selected and preserved along generations because of adaptive advantage, essentially the ability to breed more offspring capable of reaching reproductive age. In this way, the evolutionary perspective was introduced into psychology and, later on, in psychiatry. Along the twentieth century, this approach was systematically developed by ethology. At first, this discipline has studied the behavior of animals in their natural environment, without any interference from the observer, but later on experimental interventions have been added, giving rise to the field of ethoexperimental analysis of behavior.

Defense Strategies and Emotions

The ethoexperimental analysis of antipredator defense conducted by Robert and Caroline Blanchard has established that the type of defense strategy a given animal displays is mainly determined by the presence or absence of the predator, by the distance between the latter and the prey, and by the availability of an escape route.

The first pattern of defense occurs when the predator is absent, but had been met in the past by the prey in the same environment; or, alternatively, the situation met is novel, bearing both potential rewards and hazards. In both cases, there is conflict between the opposed tendencies toward approach and withdrawal. The resulting defense strategy consists of cautious exploration aimed at risk assessment. The second defense pattern, named distal threat, occurs when the predator is present, but placed at a safe distance from the prey. If there is an exit, the animal quickly escapes, but if there is no such outlet, the

animal becomes motionless, to impair detection by the predator and tenses its muscles in preparation for further active responses, such as fight or flight. This posture is often named 'freezing.' Finally, when the predator is in close proximity or makes actual contact with the prey, either energetic flight or defensive fight takes place, if there is no exit.

Although the topography of the defensive responses varies widely (e.g., pigeons fly, while rabbits run away from danger), in virtually all species, antipredator defense is functionally organized from risk assessment to tense immobility, escape, defensive threat and, finally, defensive attack. The same defensive strategies are used when the threatening animal belongs to the same species, but in conspecific interactions a further strategy comes into play, namely, submission, which is important to establish social rank and, thus, minimize injury and death.

The levels of antipredator defense described above have been related to the three emotions in consideration: potential threat with anxiety, distal threat with fear, and proximal threat with panic. In addition, submission relates to shyness.

Neural Substrate of Anxiety, Fear, and Panic

The risk-assessment construct elaborated by Robert and Caroline Blanchard overlaps, to a large extent, with the concept of the 'behavioral inhibition system' (BIS) proposed by Jeffrey Gray. In its last account, published in Gray and McNaughton's (2000) *Neuropsychology of Anxiety*, the septo-hippocampal system, which also includes the dentate gyrus, the entorhinal cortex, the subiculum area, and the posterior cingulated cortex, is supposed to play the central role of detecting conflict between opposed behavioral tendencies (approach vs. withdrawal), what generates anxiety. The septo-hippocampal system is seen as responding to threat – conveyed by either learned or innate danger cues, or novelty – by interrupting ongoing behavior and increasing the level of arousal and attention for better information gathering. In human anxiety, the septo-hippocampal system would be responsible for the cognitive manifestations of anxiety, like worrying about future adversity, whereas the affective or arousal component would be mediated by the amygdala. The latter has been involved in fear learning and expression, as well as in the acquisition and recall of emotional memories, mainly by the work of Michael Fanselow, Michael Davis, James McGaugh, and Joseph LeDoux.

Following the same line of thought, when there is no tendency to approach the source of danger, the experienced emotion is not anxiety, but fear. The structures of the central nervous system (CNS) likely to be involved constitute the so-called 'brain defense system,' comprising

the amygdala, medial hypothalamus, and midbrain periaqueductal gray matter (PAG). Summing up their interplay, Michael Fanselow has suggested that the amygdala evaluates the type and magnitude of danger, the results of this evaluation being conveyed to the hypothalamus and PAG, which are in charge of organizing and executing adaptive defense reactions. More recently, this defense system, together with connected cortical areas, has been named by McNaughton and Corr as the 'avoidance defense system' considered as the neural substrate of fear and panic; in contrast, a parallel set of structures suggested to deal with anxiety, including the septum–hippocampus was named the 'approach defense system.'

The main substrate of the third level of defense, proximal defense, is likely to be the dorsolateral column of the PAG, as determined by Richard Bandler and co-workers by injecting excitatory amino acids into different regions of the PAG. Either electrical or chemical stimulation of the dorsolateral column of the PAG causes a flight reaction and activation of the autonomic sympathetic system in laboratory animals. In patients undergoing neurosurgery, electrical stimulation applied in or near the lateral PAG induces feelings of terror or impending death, accompanied by respiratory and cardiovascular changes similar to those of a panic attack. In the proposal by MacNaughton and Corr, the distinction between fear and panic is made within the avoidance defense system, as a function of the defensive distance. Distal threat (fear) would activate forebrain structures, such as the frontal cortex and amygdala, whereas proximal threat (panic) would activate the PAG. The forebrain structures are necessary for careful environmental analysis and threat evaluation, as well as planning of purposeful escape strategies based on previous learning; in contrast, the PAG would elicit vigorous, but poorly directed flight responses, required in situations of extreme danger. This proposal has received strong support from the results of a functional magnetic resonance imaging (MRI) study performed by Mobbs and coworkers in 2007, showing that brain activity shifted from the prefrontal cortex (PFC) to the midbrain PAG, as a virtual predator capable of inflicting pain to the participant grew nearer to a virtual prey, controlled by the participant. In addition, the PAG activity correlated with reported subjective degree of dread and decreased confidence of escape.

Within a broader perspective, the last results imply that human beings share, with nonhuman mammals, approximately the same defense strategies and underlying neural circuitry. Nevertheless, there is at least one peculiarity in the human brain that deserves special comment: the remarkable development of the PFC. Even in laboratory animals, several findings indicate that the medial PFC is involved in the coordination of defense reactions. Supporting these findings, it has been shown that the medial PFC has direct connections with subcortical,

diencephalic, and brainstem structures related to defense, such as the amygdala, hypothalamus, PAG, and dorsal raphe nucleus, the latter containing serotonergic neurons. In rodents, the medial PFC has been particularly related to extinction, characterized by a decrease in a conditioned response to a stimulus, when the previously associated unconditioned aversive stimulus is omitted. The medial PFC is proposed to have a dual role in fear extinction, retaining information that aversive cues are no longer fearful, and acting on visceral structures to reduce autonomic changes. The interference in extinction seems to involve projections from the ventromedial PFC to the amygdala; in addition, the ventromedial PFC can influence autonomic responses associated with defensive responses by means of its extensive connections with hypothalamic areas. The medial PFC can also modulate the activity of the hypothalamic–pituitary–adrenal (HPA) axis through its direct connections to the bed nucleus of the stria terminalis or to the periventricular nucleus of the hypothalamus and, indirectly, through its connections to the amygdala, which projects to the periventricular nucleus through the bed nucleus. Finally, the medial PFC projects directly to the PAG.

In the human species, the role of the PFC in anxiety disorders has recently been highlighted by Rachel Berkowitz and co-workers (2007), who remarked the structural and functional peculiarities of the human PFC. This brain region is responsible for the remarkable cognitive abilities that are characteristic of the human species. In particular, the capacity to foresee future events and the consequences of one's actions would cause concern, the major symptom of generalized anxiety disorder (GAD). On the other hand, this development of the PFC allows for enhanced cognitive control of emotions, as testified by several functional neuroimaging studies, showing that cortical forebrain regions are able to attenuate emotional responses at subcortical levels, suggesting a neural basis for modulating emotional experience through interpretation and labeling. These findings may help to understand how psychotherapy works.

Pharmacological Analysis

The distinction between GAD and panic disorder (PD), presently established in psychiatric classification manuals, was first made on a pharmacological basis. In the early 1960s, Donald Klein originally reported that panic patients were improved by long-term (3–4 weeks) administration of imipramine, an antidepressant agent. In contrast, benzodiazepine anxiolytics were known to be ineffective. Nevertheless, further clinical trials have shown that GAD can also be ameliorated by chronic administration of antidepressants, and PD responds to some potent benzodiazepines, like alprazolam, when

given chronically. Nevertheless, the fact that PD is resistant to low doses of benzodiazepines that are effective on GAD remains true. Moreover, biological markers of PD have been found, the most well known being that nearly two-thirds of panic patients experience a panic attack following a lactate injection, in contrast to very few healthy people or patients with other diagnoses.

Other anxiety disorders, such as social anxiety disorder (SAD) and posttraumatic stress disorder (PTSD) can also be improved by long-term antidepressant administration. Furthermore, selective inhibitors of serotonin (5-HT) reuptake inhibitors (SSRIs), administered for over 6 weeks, have been shown to improve obsessive-compulsive disorder (OCD), a clinical condition that is considered, although not unanimously, as a primary anxiety disorder. Controlled clinical trials by David Nutt and co-workers using tryptophan depletion to decrease brain 5-HT level, have shown that the therapeutic effect of SSRIs is reversed by 5-HT depletion in PD, SAD, and PTSD, suggesting that 5-HT mediates the clinical action of these drugs. Interestingly, OCD is not affected, indicating that SSRI treatment of this condition is less dependent on 5-HT availability.

Preclinical and clinical investigation of the role of 5-HT in anxiety has contributed to the view that GAD and PD are neurobiologically different. In animal models of anxiety that generate behavioral inhibition due to conflict between approach and avoidance tendencies, and are predictive of drug response for GAD, for example, punishment or conflict tests, it has been observed that drugs that decrease 5-HT neurotransmission have anxiolytic-like effects, whereas those that increase 5-HT are anxiogenic. In contrast, escape tasks that are predictive for PD, such as switching off electrical stimulation of the PAG, are impaired by the drug treatments that enhance 5-HT. This has led to the suggestion that 5-HT facilitates anxiety, but inhibits panic (**Figure 1**). The latter action is likely to be localized in the PAG, since recent results obtained by Hélio Zangrossi Jr. and co-workers in the rat have shown that chronic, but not acute, administration of drugs that improve PD, including several antidepressants and the antipanic benzodiazepine alprazolam, sensitizes 5-HT receptors in the PAG, the stimulation of which inhibits escape responses. This action may underlie the property shared by these drugs of reducing the number of panic attacks in PD patients.

Data obtained with two procedures of inducing experimental anxiety in human beings further support the view that anxiety and fear have a different neural basis. For instance, drugs that presumably enhance the functioning of 5-HT neurotransmission have been shown to facilitate conditioning of skin conductance responses to a loud noise, associated with anticipatory anxiety, but decrease the fear of speaking in front of a videocamera; the opposite effects on both tests have been determined by drugs

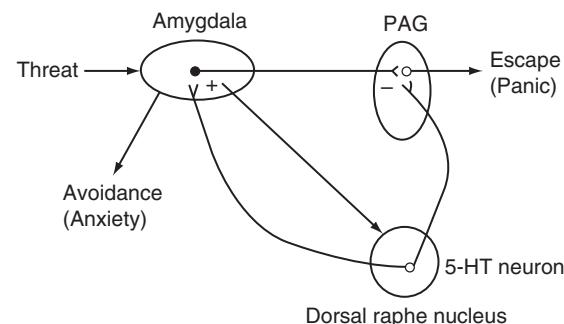

Figure 1 Dual action of serotonin (5-HT) in defense. Serotonergic neurons localized in the dorsal raphe nucleus project to both the amygdala and the periaqueductal gray matter (PAG). In the former structure, 5-HT is supposed to facilitate defense reactions to potential threat, related to anxiety, whereas in the PAG, 5-HT would inhibit proximal defense (freezing/fight/flight) related to panic attacks.

that impair 5-HT neurotransmission. The aversive conditioning test has been shown to have a pharmacological profile akin to GAD, whereas that of simulated public speaking resembles the drug response of PD, SAD, and PTSD.

Another important difference between anxiety and panic is in the activation of the HPA hormonal axis. Although situations that generate anticipatory anxiety release corticoids in the blood stream, panic attacks induced by selective panicogenic agents, such as lactate injection or CO₂ inhalation, or even natural panic, fail to activate the HPA axis. Interestingly, it has been reported that simulated public speaking does not seem to stimulate the HPA axis either.

Thus far, only one class of anxiety disorders has proved resistant to drug treatment, being otherwise responsive only to cognitive behavior therapy (CBT), namely specific phobias, such as claustrophobia (fear of closed environments), acrophobia (fear of heights), or arachnophobia (fear of spiders). These may be considered as pathologies of fear, partly due to overreaction to species-typical fear stimuli, as, for instance, closed spaces, spiders, and heights are for humans, and partly to associative learning or fear conditioning.

Overall, pharmacological analysis suggests the existence of three different neurobiological substrates for the defense-related emotions: one underlying anticipatory anxiety and GAD, which is sensitive to acute treatment with benzodiazepines as well as to chronic administration of antidepressants; another involved in PD, SAD, and PTSD, which is resistant to acute benzodiazepines, but responds to a chronic antidepressant regimen; and a third one that is drug resistant and underlies specific phobias. Therefore, such disorders may be viewed as dysfunctions of the anxiety, panic, and fear neural systems, respectively.

Neuroimaging Data

As already exemplified by the Mobbs *et al.* experiment described above, brain neuroimaging gives an important contribution to clarify the neural substrate of defense-related emotions by showing that anxiety involves the activation of forebrain structures, whereas panic engages the midbrain PAG. In the same vein, Rachel Berkowitz and co-workers have concluded from a thorough review of neuroimaging data that anxiety disorders that involve intense fear and panic, such as PD, SAD, and PTSD, seem to be characterized by PFC underactivity, thus disinhibiting the amygdala; in contrast, GAD and OCD, which involve worry and rumination, seem to be characterized by PFC overactivity. In agreement, a recent study aimed at assessing the effect of CBT in panic patients, using positron emission tomography (PET), carried out by Sakai and co-workers, has shown positive correlation between decreased activity in the left medial PFC and clinical improvement of anxiety and agoraphobia, as well as between decreased activity in the midbrain and reduction in the number of panic attacks during the 4 weeks separating the first scan, made before treatment and the second, made after CBT.

The latter study also testifies to another important contribution of neuroimaging, which is the demonstration that psychotherapy can change brain functioning in the same way as medication. This line of research started with the now-classical PET study by Lewis R. Baxter and co-workers in 1992 showing that treatment with either CBT or an SSRI could reduce activity in the caudate nucleus in correlation with improvement of compulsive symptoms.

Consonant with animal data indicating a pivotal role of the amygdala in defense-related emotions, several neuroimaging studies have shown amygdala activation by conditioned aversive stimuli, innate fear stimuli, and human faces expressing emotion, in particular fearful faces.

In many studies, anxiety-disorder patients have shown amygdala overactivation as compared to healthy individuals, and chronic administration of antidepressants has been shown to reduce amygdala activation by aversive stimuli. Nevertheless, increased activity of the amygdala may be present only at the onset of an experimentally induced state of conscious fear, with other regions such as the insula, thalamus, and brain stem-sustaining activity. As a result, Tracy Butler and co-workers (2007) have recently proposed that the amygdala works as a threat and novelty detector, whose initial, brief activity is accompanied by sustained tonic activity of other brain regions, which are responsible for maintaining the behavioral, autonomic, and metabolic responses to danger stimuli.

Further evidence has highlighted the role of the insula in anxiety disorders. In PD patients, functional studies have shown hyperactivity of the insula during experimentally induced panic attacks, and structural MRI investigations using an automated procedure of assessing volume (voxel-based morphometry) have shown an increase in gray matter volume of the insula in PD patients at rest. Since the insula has been involved in the process that ascribes negative emotional meaning to potentially distressing interoceptive stimuli, the reported alterations in the insula may be related to the abnormal evaluation of bodily signals shown by panic patients. One of the main goals of CBT is to reverse such overreactivity to interoceptive stimuli.

Conclusions

A synthesis of the above discussion is presented in **Table 1**.

It is suggested that anxiety disorders are dysfunctions of brain neural networks that control defensive strategies to different levels of threat, which evoke particular emotional states.

Table 1 Antipredator defense, related emotions, and anxiety disorders

Threat	Defense reaction	Critical brain structure	Emotion	Disorder	Drug treatment
Uncertain	Risk assessment	PFC Septum-hippocampus	Anxiety	GAD	Anxiolytics
Conflict	Behavioral inhibition	Amygdala			Antidepressants
Anticipated (CS)	Freezing (No exit)	Amygdala VPAG	Anxiety	Anticipatory anxiety	
	Avoidance	Amygdala	Conditioned fear	Specific phobias	None
Distal (US)	Escape	Medial hypothalamus	Unconditioned fear	Specific phobias	None
Proximal (US)	Flight or Immobility	DPAG	Panic	PD SAD PTSD	Antidepressants

CS = conditioned stimulus, US = unconditioned stimulus, PFC = prefrontal cortex, VAPG = ventral periaqueductal gray, DPAG = dorsal periaqueductal gray, GAD = generalized anxiety disorder, PD = panic disorder, SAD = social anxiety disorder, PTSD = posttraumatic stress disorder.

Returning to the opening question, the biological evolutionary approach illustrated in the preceding sections indicates that anxiety, fear, and panic are qualitatively different emotions.

Glossary

Generalized anxiety disorder – The disorder is characterized by various repetitive, uncontrollable, and distressing worries, accompanied by a range of physical symptoms. The definition of the syndrome has been recurrently modified through time, the disorder being still challenged as specific.

Obsessive-compulsive disorder – Recurrent intrusive and distressing thoughts (obsessions) and repetitive ritualistic behaviors (compulsions) characterize this disorder. Main theoretical cognitive models involve inflated responsibility and thought-action fusion as major features of the syndrome.

Panic disorder – The disorder is characterized by repetitive and sudden attacks of terror, accompanied by impairing physical symptoms, such as palpitations, sweatiness, faintness, or dizziness. Between episodes subjects feared the next attack; the state coined by the expression fear of fear.

Posttraumatic stress disorder – The hallmark characteristics of this disorder are distressing intrusive thoughts, nightmares, and vivid memories of the trauma associated with psychophysiological arousal. Other central features are avoidance of the stimuli related to the trauma and/or emotional numbing.

Social anxiety disorder – Individuals suffering from social anxiety disorder experience an intense, persistent, and chronic fear of being exposed in social situations. Distress is associated with anticipatory anxiety and *post hoc* rumination concerning social performance.

Specific phobia – Patients with specific phobia experience intense fear when they are confronted with the object of their phobia of which they develop an active avoidance. Numerous subtypes of phobia exist (e.g., spider and blood) which are associated with specific activations of the autonomic nervous system.

context. Different terms characterize the anxious spectrum as fear, concern, worries, apprehension, angst, terror, and anxiety. Taking into account the fact that anxiety is an emotion experienced by all human beings, the point is to distinguish normal anxiety from pathological anxiety. There is general agreement that the main attributes of pathological anxiety are to appear out of a relevant context, to be inappropriately intense or particularly chronic, to be associated with paroxysmal or chronic somatic symptoms and leading to incongruent behavior, and psychological, physical, or social impairment. Pathological anxiety, although a symptom belonging to a wide range of psychiatric disorders, is considered to be the central feature of only a few disorders. Therefore, the formal nomenclature of the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) includes 13 categories of anxiety disorders of which the main ones are obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), panic disorder (PD) with and without agoraphobia, social anxiety disorder (SAD), specific phobia (SP), and generalized anxiety disorder (GAD). A common feature of most anxiety disorders is the existence of acute episodes of heightened anxiety triggered by specific (SP, SAD, PTSD, OCD) or nonspecific (PD, GAD) threatening stimuli. The intensity of the acute episode may vary along with the nature of the disorder, the stimulus, and the individual. Specific and nonspecific cognitive strategies are employed to avoid or reduce both the occurrence and the level of the paroxysmal anxiety. For example, phobic patients actively avoid known threatening stimuli, although patients experiencing PD cannot employ such a strategy. The diagnostic reliability (inter-reliability and test-retest) of some anxiety disorders has been found to be low (e.g., for GAD) or moderate (SP and PTSD) even with the use of standardized interviews. Another problem is the high rate of comorbidity, principally with other anxiety disorders and with depression. Some epidemiologic studies have shown that more than half of the individuals with anxiety disorders present another psychiatric disorder at the time of assessment; more than 75% in the case of GAD which has been challenged as a distinct syndrome. Studies have reported several patterns of cognitive functioning among patients reporting high levels of state or trait anxiety. Their conclusions must be cautiously examined as they may not be extended to specific anxiety disorders without

Ordinary Fear and Pathological Anxiety

Fear is an archaic emotion common to numerous species. It plays a major role in adaptation to the environment. In humans, this includes physical, sociological, and cultural

evidence. The model proposed by Eysenck to explain some cognitive impairment among highly anxious subjects remains one of the most consensual. Eysenck put forward cognitive preoccupations with emotionally negative concerns in which preferential attention is given to the negative aspects of highly anxious subject's environment. This hypothesis is also known as the 'hypervigilance hypothesis' and is well supported by authors such as Beck and Bower. Moreover, some resources that are permanently allocated to tasks associated with these negative concerns may lead to impairment in executive function. In addition, some authors have suggested that individuals with anxiety disorders also tend, at various extents, to avoid or to inhibit deep processing of threatening information. This hypothesis, put forward in particular by Foa and Kozak, has been recently completed by the assumption that information processing among anxious individuals may be organized in two stages, with a tendency to increase attention to threatening information and then to avoid attention or to inhibit deep processing of the initially discriminated threatening information (hypervigilance-avoidance hypothesis).

Subjects with anxiety disorders display specific concerns and beliefs which in turn interfere with cognitive functioning. Morphologic and, moreover, functional neuroimaging can specify the cerebral structures involved in these processes. Executive functions, including inhibition, flexibility and planning, attention, judgment processes, and memory, have begun to be systematically studied for each anxiety disorder. In our presentation, we separate general cognitive impairments and specific cognitive biases for threatening stimuli. We also complete this presentation by giving an account on neuroimaging data.

From Psychiatric Categories to Cognitive Processing

All anxiety disorders present somewhat common clinical features: heightened sensibility to specific or general threatened stimuli, peaks of anxiety triggered by these stimuli, and cognitive or behavioral strategies of variable efficiency whose supposed aim is to cope with and/or to avoid the threatened stimuli. Beyond these general features, each anxiety disorder shows its own clinical specificities, OCD and PTSD displaying the more complex patterns.

Obsessive-Compulsive Disorders

The estimated lifetime prevalence of OCD in general population studies is 2.5–4%. Nevertheless, a large study using strict criteria and psychiatric interviews found lifetime prevalence lower than 1%. OCD is characterized by recurrent intrusive thoughts (obsessions)

and repetitive motor or cognitive ritualistic behaviors (compulsions). The main core of the ritualistic behaviors is to reduce the undue anxiety that obsessions generate, but they themselves may provoke anxiety and impairment. Fear of contamination/washing (washers) and pathological doubt/checking (checkers) are the most common combinations of symptoms. Complex cognitive models have been elaborated for OCD. The main theoretical models focus on the cognitive factors of inflated responsibility, thought-action fusion, and meta-cognitive beliefs.

Posttraumatic Stress Disorder

PTSD is triggered by a so-called traumatic event, which leaves the individual in an internal feeling of terror and of a total lack of control. Most individuals may experience a putative traumatic event in their lifetime, but according to the nature of the event and of the personal and social resources of the individuals, only a fraction of subjects will subsequently develop a PTSD. The hallmark characteristics of PTSD are the painful and distressing intrusive thoughts, nightmares, and vivid memories of the traumatic event associated with psychophysiological arousal. Intrusive memories, including flashbacks, contain contextual or core details of the traumatic event loaded with massive sensory inputs. A disorganized narrative memory of the trauma, but not of control events, characterizes a large part of PTSD patients. Brewin has hypothesized that memories associated with the trauma are encoded in a two-representation system – one verbal and the other contextual. According to the author, the former is voluntarily accessible and responsible for narrative memory; the latter responds automatically to sensory cues of the trauma and leads to sensory relivings. Other central features of the diagnosis are active avoidance of the stimuli related to the trauma and/or emotional numbing (e.g., feelings of detachment, disinterest, and restricted range of affect).

It has been suggested that PTSD symptoms result from both classical conditioning of emotional responses to extreme traumatic stimuli and operant conditioning of avoidance of traumatic stimuli. The traumatic experience overwhelms the emotional and cognitive system, promotes an excessive sensitivity to threatening stimuli, and then impairs fear-extinction processes. The threshold for stress is lowered and a large amount of stimuli may activate autonomous responses which in turn reactivate feelings and memories relative to the trauma.

General Anxiety Disorder

Lifetime prevalence of GAD has been estimated to 12%. The disorder is characterized by various repetitive, uncontrollable, and distressing worries, accompanied by

a range of physical symptoms. Individuals with GAD anticipate disaster, show intolerance for uncertainty, and they are especially disturbed by not being able to control the present or to predict the future. However GAD, as aforementioned, is discussed as a specific anxiety disorder and may be grossly described as a quite-durable (at least 6 months) high-anxiety state.

Panic Disorder

PD has a lifetime prevalence of 2–4%. It is characterized by repetitive and sudden attacks of terror, whose peak usually lasts around 10 min. It is accompanied by physical symptoms such as palpitations, sweatiness, shortness of breath, faintness, or dizziness. Between episodes, subjects worry intensely and dread the next attack; the state coined by the expression fear of fear. Repeated panic attacks may lead to social impairment, with a restriction of activities and agoraphobia. Central to the cognitive model of the disorder, it has been hypothesized that individuals developed an attentional bias toward cues associated with panic, with a special emphasis on bodily sensations. Agoraphobia in PD is generally understood as a consequence of panic attacks. Patients avoiding situations, in which help may not be readily available, present a quasi-similar pattern to phobics. The appraisal by the subject of its own coping abilities has also been put forward in the triggering of a panic attack. This hypothesis is known as the “theory of self efficacy.”

Social Anxiety Disorder

SAD is considered to be the most common anxiety disorder with a lifetime prevalence of 12–16%. Individuals with social phobia have an intense, persistent, and chronic fear of being exposed in social situations, in which they may be watched or judged by unfamiliar people. Physical symptoms of anxiety often accompany social phobia as other anxiety disorders. Distress in social phobia is associated with anticipatory anxiety and *post hoc* rumination concerning social performance. Self-focused attention leads to recollection of negative experiences, heightened attention to signs of threat, and misinterpretations of other's behaviors which in turn help to maintain social phobia.

Specific Phobia

SP has an estimated lifetime prevalence of about 12%. Individuals with SP experience intense fear when they are confronted with the object of their phobia and at the same time develop avoidance behaviors of contexts related to the phobic object. There are many subtypes of SP.

General Cognitive Impairments: Results from Experimental Studies

Cognitive impairments have been quite reliably found in individuals with OCD, particularly for executive functions and visual memory, and to a lesser extent with PTSD for attention and both verbal and visual memory. These impairments are generally understood as the result of a neural circuit dysfunction involving an orbitofrontal–subcortical network for the former and a brainstem and prefrontal network for the latter. They are detailed below. Fewer studies have addressed neuropsychological functioning in other anxiety disorders. Inconsistent results characterize PD and social phobia. Patients with SP and GAD generally show no deficit in general cognitive tasks.

Executive Functions

Executive functions refer to the ability to plan and carry out complex goal-directed behaviors. According to Miyake, shifting between tasks or mental sets, updating and monitoring of working-memory representations, and inhibition represent three latent variables which may potentially describe most of the executive functions. OCD patients show impairment in set shifting, set maintenance, and demonstrate lower abilities to learn from the changing responses brought by the environment. Such a deficit has been hypothesized to involve impairment in selective attention and obsessive checking, leading to an overloading of working memory. Deficits in neuropsychological tests measuring inhibition have also been quite regularly reported in OCD patients. Motor inhibitory processes have been explored with tasks such as ‘go/no go’ or “stop signal reaction time” and cognitive inhibition by tasks such as the “Stroop color-naming paradigm.” Inconsistent findings have been observed for planning and decision making in OCD patients although they tend to perform slower and to exhibit more perseverative errors than controls. Slowness and perseveration may be related to a lack of mental flexibility impairing organizational strategies. Deficit in shifting and inhibition have been considered as the hallmark of an orbitofrontal dysfunction.

No deficits in executive functioning have been consistently reported in other anxiety disorders except for PTSD, in which working memory has been quite reliably shown impaired, particularly when strategic cognition was also involved. Hence, in a plain task, such as “digit span forward” which focuses on passive storage of digits, patients generally exhibit no deficit contrary to the “digit span backward” that is more executive. In verbal or visuospatial tasks, which require maintenance and manipulation of short-term information, some deficits have been found although inconsistently. Individuals with PTSD generally failed to show impairments in set shifting.

Attention

No consistent deficits have been found in patients with OCD although they often exhibit a lack of confidence in keeping attentional focus. In contrast, an attention deficit has been quite reliably established for PTSD patients, particularly on measures of sustained attention and encoding, but not on measures of focused attention or attentional shifting. These deficits may reflect the frequent lack of concentration alleged by patients with PTSD.

Explicit and Implicit Memory

The terms, 'explicit memory' and 'implicit memory,' here refer to the recall or recognition of data that are expressed, respectively, with and without awareness of encoding. The exploration of explicit memory includes cued recall, free recall, and recognition of data. Many studies have established that OCD patients, particularly those with prominent checking symptoms (checkers), exhibit impairment for visuospatial memory. This memory impairment may result from an irrelevant organizational strategy involving lack of flexibility, perseveration, and checking. When reproducing a complex figure (Rey-Osterrieth complex figure test) to assess visual memory, OCD individuals tend to focus on irrelevant details during the initial copy of the figure which may explain their low scores. Concerning verbal memory in most studies, OCD patients perform as well as controls. Moreover, a study has shown that subclinical checkers exhibit better recognition for words than controls. Nevertheless, when memory tasks involve semantic strategies, especially if encoding is time limited, performances of OCD patients tend to decrease in immediate recall and recognition.

Regarding individuals with PTSD, many studies have identified decreased performance in verbal memory and learning. Although the deficits are commonly mild, delayed free recall has been found more frequently impaired than cued recall and recognition, which require less data manipulation. Initial acquisition in recall tasks has been shown impaired quite regularly when the memory task bears on semantically unrelated words (Rey auditory verbal learning test (RAVLT)) but not for words semantically linked (California verbal learning test (CVLT)). These conditions suggest that, similar to OCD, memory is more often impaired when searching and retrieving relevant information requiring more organization and manipulation of the data. Few studies have explored memory in other anxiety disorders and the results lack consistency. A small number of studies have found that PD patients exhibit performance impairments for recall of visual and verbal information and that SP patients exhibit recall deficits for verbal information.

Autobiographical Memory

Some studies have focused on 'autobiographical memory,' defined as recollections of one's own personal experiences that can be placed in a specific time and location. Autobiographical memory is narrowly attached to the construction (or the maintenance) of the self and is linked to the regulation of emotions and beliefs. Anxious participants asked to retrieve specific personal memories in response to neutral- or positive-trait cue words tend to respond slower and/or to be less specific than controls. Several studies have found evidence of overgeneral autobiographical memory for PTSD, OCD, and in a lesser extent for SAD. In case of overgeneral memories, answers usually did not refer to a specific episode, precisely localized in time and space. On the contrary, they either referred to an extended or a vaguely defined period or described habits or categories of events with quite wide-ranging descriptions. It has been hypothesized that overgeneral memories protect the patient from the unpleasant recall of painful or even traumatic events. However, when depressive symptoms were controlled for, fewer or no significant results emerged, emphasizing the importance of controlling for depression within the research field of anxiety disorders. A study showed that OCD checkers used less visual imagery to recall biographical information than controls which may contribute to explain the trend to overgeneral memory. However, for all individuals, difficulty in remembering the past may render it difficult to picture the future. There are no clear results regarding specificity of autobiographical memory in SAD. Most studies exploring autobiographical memory have failed to establish consistently a memory bias toward social threats in comparison to positive and neutral cues. Moreover, when cued with social threat stimuli, SAD patients take more time to recall a memory which tends to be more general than controls. In PD and SP, no impairment in autobiographical memory has been established. To the opposite, some studies show a better recall of vivid memories in response to threatening cues.

Reality Monitoring

OCD patients often express doubt concerning the reality of what they recall, uncertain if they have performed an action or merely imagine it. Nevertheless, studies of reality monitoring in OCD patients, checkers and noncheckers, have not reliably shown a real impairment but instead, a lack of self-confidence and an intolerance of uncertainty. The lack of confidence in reality monitoring has been significantly correlated with dissociative state in a recognition task study.

Cognitive Bias Relative to Threatening Stimuli: Results from Experimental Studies

Attention Biases

Most of the studies using experimental approaches to explore attentional processes in anxiety disorders have employed either facilitation or interference paradigms. Emotional analogs of the Stroop color-naming paradigm task and the dot-probe paradigm have by far been the two most employed. The classic Stroop task has been modified to test patients with an anxious disorder by examining the response time of the participant to name colors of neutral or negative emotional words. These negative words may refer either to general threatening contents (e.g. 'danger') or more specifically to the core of their anxious preoccupations (e.g. 'dust' in case of OCD Washers). Individuals with anxiety disorders often exhibit delayed color naming for emotionally threatening words compared to controls. The dot-probe paradigm measures the distribution of visual attention. Typically, subjects are instructed to press on a button as soon as they have detected in what part of a screen a dot appears. Dots are presented on a split screen just after the disappearance of a threatening or a nonthreatening (neutral) stimulus, usually a word. Generally, anxious patients answer faster when the dot is situated in the part of the screen where the threatening stimulus stood. In nonclinical population, the opposite result tends to be found. Emotional Stroop tasks demonstrate quite consistently attention biases for social phobia (with social threatening stimuli), OCD (with words specifically linked to their concern as dirt for washers, but not for general threatening or positive words), PTSD (specific and general threat words), PD (for general threat words, but not for panic-related words as those pointing the attack itself, the bodily sensations, or their feared consequences). Such facilitated attention to threat stimuli (e.g., faces) has also been reliably found with dot-probe paradigm and other tasks exploring attention biases in GAD, some subtypes of SP, SAD, and PTSD.

Stroop task and the dot-probe paradigm fail to differentiate between enhanced detection of threatening stimuli (attentional facilitation) and difficulties in disengagement from such stimuli (attentional interference). Various tasks such as the dot-probe detection task and the visual search task have been adapted in order to disentangle the two main mechanisms that may be involved in attentional bias for threat. They quite reliably found a reliable emotion-congruent attentional interference, but inconsistent results for emotion-congruent attentional facilitation to threat stimuli.

Judgment Bias

Anxious subjects tend to overestimate the threatening character of their environment. Some anxious individuals tend to increase the probabilities of the outcome of an adverse event even in neutral or positive circumstances, others disproportionately exaggerate its cost estimation, and others misinterpret stimuli or situations as a potential threat. A threatening appraisal of a situation may subsequently transform the attentional processes and lead the subject to focus on potential threats. This selective attention to putative threatening stimuli leads to an increased probability of misinterpretations of the environment. Biased judgment may play a role both in the etiology and the maintenance of anxiety disorders. Numerous experiments, most relying on the interpretation of ambiguous stimuli or situations, consistently evidence that anxious patients tend to report more aversive interpretations than controls. Priming has also been used to demonstrate the consequence of the tendency to misinterpret adverse stimuli or events. After an initial presentation of ambiguous sentences, words, or scenarios, patients tend to consistently choose a subsequent lexical task, target words related to the negative meanings of the previous ambiguous primes. Authors, such as Foa, consider that alternative meanings of an ambiguous event are activated automatically, regardless of the meaning coming to awareness depending on a system of mutual inhibition. They also postulate that, in that competition, an automatic preference to pejorative meanings may result from the repetition in the past of such a choice. Questionnaires exploring judgment processes have shown that social phobics and socially anxious individuals were more likely to interpret social scenarios as negative when the situations were rated as self-referent but not when the situation was quoted from the point of view of other's mind.

Memory Bias

An anxiety-linked advantage for memory of threatening information among anxious patients has frequently been speculated. This hypothesis is coherent with the frequent uncontrollable rumination or worrying that anxious patients present with regard to some specific situations or stimuli. Hence, individuals with social phobia could be overwhelmed with vivid recall of social humiliation, while patients with PTSD face intrusive and repetitive memory of a traumatic event through flashbacks and nightmares. Actually, results are more contrasted. With the exception of PTSD and to a lesser extent in PD, no memory bias has been evidenced for threatening stimuli that are not of central concern to their clinical condition. In PTSD, standardized episodic memory tasks have quite

reliably shown that patients retrieve less neutral and positive words than controls and, within PTSD group, more negative words even of nonspecific content were retrieved compared to positive and neutral words. Recognition tests appear less sensitive to these effects. In PD, a quite similar pattern has been established particularly when memory tasks involve deep encoding. In several studies using directed forgetting procedures, PTSD patients have not exhibited heightened forgetting of trauma words, but to the opposite, they have shown impairment in explicit memory for positive and neutral words. However, a bias for threatening stimuli may be evidenced in most anxiety disorders when the protocol engage the patient to self-reference, either by an experimental setting increasing his specific anxiety or with the use of a threatening material narrowly linked to his preoccupations. In OCD, a positive memory bias for threatening stimuli has been demonstrated with checkers if the patient perceived responsibility for the outcome of a particular check and with washers for objects which have been contaminated by the experimenter. In studies of PD patients in which encoding was self-referred, individuals exhibit a bias for threatening material. This effect has been interpreted in reference to the theory of self-efficacy. In social phobia, advantage for memory of threatening stimuli has been evidenced in experiments in which the level of social anxiety has been artificially heightened. Inducing the individuals to focus on themselves and their own competence in social performance involves self-reference and hence increases the probability of an interpretation bias which itself interferes in memory tasks. The importance of self-reference in all anxiety disorders is progressively taken into account. Moreover, some studies show that patients with GAD tend to demonstrate impairment in the retrieval of negative words of general content, but not if they are specific to their individual worries. This result may be understood with respect to the hypervigilance-avoidance hypothesis previously described.

An implicit memory bias for threatening stimuli has been displayed in some anxiety disorders (social phobia, PTSD, PD, and OCD), but some well-designed studies have also failed to replicate this result. Among the more frequent study protocols, we may cite the white noise paradigm relying principally on automatic processes and the word-stem completion, a less purely implicit task which may include some explicit resources.

Functional Neuroimaging

The study of human anxiety disorders has benefited from functional neuroimaging approaches with methods such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI). They allow to measure across time the relative variation of metabolic activity, such

as indexed by glucose metabolic rate (PET) or regional cerebral blood flow (fMRI and PET). These indexes indirectly reflect regional neural activity. Provocation studies, resting state studies, and cognitive activation studies have been used to explore regional brain activity and, additionally, longitudinal studies comparing functional brain activity before and after treatment. These studies, in conjunction with other sources of knowledge, have brought some evidence that some network of structures play a critical role in anxiety disorders, namely an amygdala-centered network, a network involving the anterior cingulate cortex (ACC) and the medial prefrontal cortex (PFC), and a prefronto-striatum circuitry.

A general pattern of facilitated and heightened activation of the amygdala for threat-related stimuli has been established in PTSD, SAD, SP, and GAD, but not in PD and inconsistently in OCD. In PTSD, hyperresponsivity to threat-related stimuli, within the amygdala, may result from a defective top-down inhibition of the ventromedial PFC, but as suggested by studies of masked fear faces, the hyperresponsivity of the amygdala could be also automatically engaged. Most correlation studies using provocation paradigms have shown that activities of the amygdala and medial PFC are negatively correlated. Functional studies have also shown a diminished activation of the hippocampus during tasks involving both explicit encoding and retrieval tasks. In addition to these functional specificities, a reduction of hippocampal volume has been quite reliably found in adult PTSD patients. Animal studies suggest that the decreased volume results from cortisol-induced and glutamate-mediated neurotoxicity. However, a study involving twins suggests that hippocampal volume reduction is a predisposing factor. In resting state studies and in provocation studies, compared to controls, OCD patients reliably show increased activity in the orbitofrontal cortex (OFC), striatum, and thalamus, as well as in other regions although less consistently reported, such as the anterior cingulate and dorsolateral prefrontal cortices. Additionally, the hypothesis for primary striatal pathology in OCD finds support in some structural MRI studies which found a reduced striatal volume in patients. An increased activity in the amygdala and insula has been found in a minority of studies, particularly the one with washers. Several fMRI or PET studies have found, after a successful treatment of OCD symptoms, the normalization of the metabolism of the aforementioned regions.

Limitations and Directions for Future Research

Gathered data for anxiety disorders show general trends in cognition although contradictory findings appear. Often deficits could be evidenced only in part of the

studies and the frequent use of limited samples makes it difficult to exclude some potential biases such as comorbidity or current or past treatment. The heterogeneity of the experimental designs also weakens the ability to provide firm conclusions. The classification of anxiety disorders may also not reflect the cerebral underpinnings of such disorders. However, increasing correlation studies between neuropsychological assessment and various neurophysiological assessments will enlighten the cerebral basis of such disorders. They will provide indications on the course of cerebral activations at different stages. Another enthusiastic direction will consist to integrate self-reference in neuropsychological assessment which may help to gather hypotheses proceeding from both experimental cognition and clinical psychology studies.

Glossary

Behavioral syndromes – Groups of behaviors that covary in their expression across situations or contexts within a species or population.

Eysenckian personality dimensions – Three dimensions known as Neuroticism, Extraversion, and Psychoticism which were discovered by Hans Eysenck (1916–1997) and his collaborators through factor analysis. Neuroticism describes emotional instability, depression, and vulnerability; Extraversion describes sociability, excitement-seeking, and activity; and Psychoticism describes aggressiveness, risk-taking, and unusual beliefs.

Factor analysis – A data reduction technique to redescribe the correlations among observed variables with a smaller set of unobserved latent variables.

Five-Factor Model – The predominant model of personality, which holds that five independent dimensions are sufficient to describe individual differences in human behavior, affect, and cognitive styles. These dimensions include Neuroticism (the reverse sometimes labeled Emotional Stability) and Extraversion dimensions similar to those of the Eysenckian model. Other dimensions include Openness to Experience (sometimes labeled ‘Intellect’ or ‘Culture’), embodying intellectual curiosity, fantasy, interest in esthetics, and liberal values); Agreeableness which captures altruism, kindness, modesty, and cooperativeness; and Conscientiousness which involves diligence, orderliness, dutifulness, and achievement-striving.

Orthologous genes – Genes in separate species that are descended from a common ancestral gene.

Personality – Behavioral, emotional, and cognitive dispositions that are consistent across time and situations.

Proximate causation – Genetic, developmental, physiological, and environmental reasons for why a particular phenotype exists.

Quantitative trait locus – Regions of DNA containing or closely linked to genes or transcription regulators that influence a trait.

Temperament – Behavioral and emotional dispositions that emerge early in development and are consistent across time and situations. Because of its restriction to behavioral and emotional expressions and its early

emergence, this term is often used in studies of infants or nonhuman animals.

Traits – Any measured physical, behavioral, emotional, or cognitive characteristic of an individual within a species. In psychology traits specifically refer to nonability measures such as personality or temperament.

Ultimate causation – Evolutionary explanation of why a particular phenotype exists.

Introduction

That animals, like humans, exhibit consistent individual differences in character or personality has been a long-standing observation among pet-owners and researchers alike. Personality refers to mostly stable individual differences in behavioral, affective, and cognitive predispositions. More narrow terms used to describe stable individual differences include temperament and behavioral syndromes, which emphasize measured or observed behaviors to the exclusion of possible cognitive or affective traits. Temperament is an older term which derives from human psychology research and is used to refer to individual behavioral differences that are stable across time and situations, for example, activity. The term ‘behavioral syndrome’ is more recent and has its roots in the study of behavioral ecology. Behavioral syndromes are defined as sets of correlated behaviors that are consistent across multiple situations. This paradigm explicitly ties behavioral variation to differences in growth, reproduction, and survival. While the approaches encompassed by these three terms differ broadly in the kinds of data considered, the species they are used to study, the traits they are compared with, and the background of researchers who practice them, they share a common goal of understanding and explaining differences on the individual level.

One characteristic that distinguishes animal personality, temperament, or behavioral syndromes from other aspects of animal behavior include their bases within individuals. That is to say, these characteristics of individuals are not elicited or caused by environmental situations or schedules of reinforcement, but, instead, indicate how an individual animal typically behaves

across a variety of situations. A second characteristic is their relative stability over time; while there is a considerable amount of debate about how to interpret the magnitude of the effects, most researchers studying human personality would agree that, in adulthood, while there is some change, an individual's standing on a particular personality dimension at one point in time is a fairly good predictor of their standing on that personality dimension at a later point in time. A final, though not often mentioned, characteristic is the emphasis, at least in animal personality or behavioral syndromes research, of studying multiple correlated traits or facets that make up broader dimensions, sometimes referred to as factors, domains, or dimensions.

Measurement of Personality, Temperament, and Behavioral Syndromes

How to measure dimensions of personality, temperament, or behavioral syndromes as well as how to distinguish between relatively good and relatively poor dimensions is crucial to the study of personality in all species. Broadly, there are two approaches to assessing animal personality: ratings and behavioral coding.

Rating Approaches

Ratings-based approaches originate from methods often used in human personality research. They share in common a reliance on judges familiar with the individual animals, the use of questionnaires for rating personality, and asking judges to base their ratings on their overall impressions of the animals. Typically ratings on these questionnaires are made on five- or seven-point Likert scales, true-false questions, or similarly quantitative responses. Some questionnaires are based on psycholinguistic approaches to studying human personality and ask judges to rate the degree to which each animal can be characterized by a series of personality descriptor adjectives (e.g., anxious). In some questionnaires, these adjectives are supplemented by sentences which attempt to resolve ambiguity or define the descriptor within the context of the species' behavior. Other questionnaires are more behaviorally oriented, that is, they ask raters to describe the animal with respect to specific behaviors, such as rate of aggressive interactions, as opposed to descriptor adjectives.

Behavioral Coding Approaches

Behavioral coding is rooted in ethological approaches to the study of behavior and are more commonly used in animal personality research than ratings approaches. They involve actually objectively measuring behaviors,

for example, by recording their frequency or assessing the strength of the response to some stimuli. There are two major subtypes of behavioral coding approaches. One approach can be described as naturalistic. Here, observers watch an animal in its natural environment or a captive setting and record its spontaneously emitted behavior on an ethogram. The second approach can be described as experimental. This method involves changing the animal's environment in some way and recording the animal's response. For example, in novel-object tests a new or unusual object may be introduced into an animal's natural environment or enclosure and the reactions of the animal to the object as well as how closely it approaches the object are recorded. A similar method may categorize the animal's behavior when handled by experimenters.

Reliability

Prior to using a particular measure of animal personality, one must determine its reliability. Reliability refers to the proportion of the animal personality score that is accounted for by the characteristics of the subject, sometimes referred to as true score variance. The remaining variance is referred to as error and is accounted for by any other factors, including specific judges, time of measurement, situational effects, and any other effects.

A common misconception is that the behavioral coding approaches are more reliable than ratings approaches. No studies support this view, and, in fact, a recent study of captive chimpanzee personality directly compared the reliabilities of ratings and behavioral coding methods. This study found that the mean reliability of ratings was substantially higher than the mean reliability of codings derived from focal animal sampling.

Validity

In studying animal personality it is also important to show that a personality measure demonstrates convergent and divergent validity. That is to say, is a personality measure related in expected ways to other measures or outcomes?

Convergent validity

Convergent validity refers to the degree to which a personality measure is correlated with measures or tasks that should tap the same construct. For example, we would expect that a rating measure of extraversion and a behavioral coding measure of time spent in proximity to conspecifics should be positively correlated. In short, measures of the same construct should be related.

Divergent validity

Divergent or discriminant validity refers to the degree to which a personality measure is not correlated with measures or tasks that reflect different constructs. That is to

say, it is indicative of the extent to which supposedly different constructs are distinct. For example, we would expect that a rating measure of neuroticism should only show negligible correlations with measures such as time spent in proximity to conspecifics.

Comprehensiveness

Recently, some have emphasized the importance of comprehensiveness as another criterion by which to judge personality measures. This criterion asks whether a measure captures all the personality differences of the animal or is limited to a select number of domains. A bottom-up behavioral repertoire approach to studying animal personality is one way to address these issues. This method involves behavioral coding and may enable researchers to find domains or dimensions of personality differences that are not revealed by the use of top-down ratings-based approaches, which are seen to impose a personality structure from one species (typically humans) onto another.

Factor Analysis

Factor analysis refers to a family of data analytic methods that can reduce a large number of variables into a smaller set of variables. It is based on the premise that the relationships among a set of manifest variables or traits arise because of a common underlying set of causes or latent variables, which cannot be directly measured. In the study of personality, manifest variables refer to the individual items making up the rating scale or individual behaviors whereas latent variables are personality dimensions such as five-human-like domains found in chimpanzees and the chimpanzee-specific domain of Dominance. These analyses are used in the study of personality in humans and nonhuman animals, and are more commonly used in studies that measure personality via ratings as opposed to behavioral codings.

Exploratory Factor Analysis

Of the two types of factor analytic techniques, exploratory factor analysis is the most commonly used. These techniques consist of methods such as principal-components analysis and principal-axes analysis. These approaches have in common that the researcher does not pre-specify the nature of the latent variables, that is, which items they define. Instead, he or she determines the number of factors believed to be sufficient to explain the intercorrelations among variables, extracts these factors, and then interprets factors based on how strongly items reflect or load on these factors. This last procedure often first involves rotating the factors, which serves to rescale the loadings so that high

loadings are as close to 1 or -1 as possible and low loadings are as close to 0 as possible.

Confirmatory Factor Analysis

An equally important but more seldom used technique is confirmatory factor analysis. Here the researcher pre-specifies the nature of the latent variables, that is, indicates which manifest variables they believe will be explained by which latent factors. The researcher then tests whether the pre-specified factors adequately explain the intercorrelations among items. A researcher may also wish to compare multiple sets of pre-specified factors to determine which best explains the intercorrelations of the items with the fewest possible parameters.

This technique is most commonly used when researchers, based on prior studies using exploratory factor analysis, already have strong ideas concerning the nature of the factors or if they wish to compare the factors of two different samples or species. For example, confirmatory factor analysis was recently used to test whether the rhesus macaque personality factors identified in one sample replicated in a new sample.

Correlates of Animal Personality Measures

Behavior

A fundamental question regarding measures of animal personality, in particular those based on ratings, is whether they are related to behavior. There is considerable evidence in a range of primate species that measures of personality obtained via ratings are, in fact, correlated with behaviors in ways consistent with the definitions of the factors. For example, extraverted zoo chimpanzees are more oriented toward their conspecifics than they are to members of the viewing public whereas this pattern is reversed for introverted chimpanzees; langur monkeys rated as more agreeable engaged in less aggressive behavior and more grooming; and rhesus macaques rated high in sociability in one context engaged in more affiliative behaviors in another context up to 4.5 years later.

In nonprimate species, because measurements are usually made using behavioral coding, the interest instead is finding ecologically meaningful correlates between behavioral domains. In stickleback fish, aggression, activity level, and exploratory behavior were strongly correlated only in populations that were subject to predation. Recently, this research has been extended to include birdsong: male collared flycatchers who scored higher in tests of exploratory behavior or risk-taking behavior sang from lower and higher posts, respectively.

Well-Being

One well-known feature of human personality is its relationship to measures of subjective well-being. Although it is correlated with other personality dimensions, too, on average, more emotionally stable and more extraverted people are happier than less emotionally stable and less extraverted people. The nonhuman work on personality and well-being has been limited to studies of chimpanzees and orangutans. In the case of chimpanzees, greater well-being was positively related to the chimpanzee-specific personality domain, Dominance, a broad factor that incorporates aspects of low neuroticism, high extraversion, low agreeableness, and low conscientiousness. More extraverted and conscientious chimpanzees also were rated as being higher on well-being than their introverted and unconscientious counterparts. A later study of orangutan personality revealed that orangutans who were rated as extraverted, emotionally stable, and agreeable had higher well-being scores than their introverted, neurotic, and disagreeable counterparts.

Health

Human personality is related to health outcomes and in several studies with long follow-up periods, personality dimensions have been related to all-cause mortality. In particular, low conscientiousness is strongly related to earlier death, though high neuroticism, low agreeableness, and low extraversion have also been linked to greater mortality risk. Studies of the relationship between human personality and health outcomes are limited in that ethical considerations bar the experimental procedures that could elucidate the mechanisms underlying the relationships. However, work on this relationship in primate models is making progress in revealing the causal mechanisms underlying these associations.

Corticosteroids

Studies of personality dimensions in nonhuman species have revealed relationships between these dimensions and hormone levels. For example, one study examined adult male rhesus macaques that were assessed on four personality dimensions and plasma cortisol concentration. Consistent with some studies of human neuroticism, this study found that monkeys rated as being higher in excitability had lower levels of basal cortisol in the PM phase. This study also found that higher levels of the confidence dimension were related to significantly higher levels of cortisol throughout the AM phase and higher levels of cortisol throughout the beginning, but not end, of the PM phase.

Also, in a study of cortisol and sedation stress in young chimpanzees, individuals who scored higher on the

behavioral dimension mellow showed higher peak cortisol levels and a more substantial increase in cortisol over time. Another study of juvenile chimpanzees showed some evidence that the same dimension was related to testosterone levels, though the effects of the chimpanzees' actual rank may have been a confound.

Studies of great tit lines selected for being fast explorers or slow explorers that were exposed to stressors (a social defeat in this case) showed that the fast explorers displayed a greater reduction in activity levels than slow explorers. However, slow explorers also showed increases in fecal corticosteroid metabolites, whereas no such increase was revealed among the fast explorers.

Reproduction

Evidence from several studies suggests that personality may be related to variables associated with successful reproduction. Captive-born cheetahs that were rated as being higher in a dimension named tense-fearful were more likely not to breed than those who were rated as being lower on this dimension. Also, in an experimental study, successful mate pairings in dumpling squid were those in which females with intermediate or high scores on a shy-bold dimension were paired with males who also displayed intermediate or high scores on this dimension. On the other hand, shy females were able to successfully mate with shy, intermediate, and bold males. A similar boldness-shyness dimension also leads to differential reproductive success in bighorn sheep; bold ewes exhibit an earlier age at primiparity and greater weaning success. Among red squirrels, female activity level was related to their offspring's growth rate but did not influence dates of birth or litter size. In common lizards, clutch size was found to correlate positively with the ability of females to tolerate conspecifics (a measure of sociality). Social females that can deal with high population densities have more opportunities to mate and reproduce.

Causes

Proximate Causes

Genetic influences

Heritability

Human personality dimensions are approximately 50% heritable, but what does this mean? Roughly, heritability is the proportion of variation in a trait between individuals in the same population that is due to genes that are passed down from parents. Heritability is not a measure of how biological a trait is, only how much of the differences between individuals can be accounted for by differences in genes.

The importance of heritability for the study of personality is in informing both the proximate and

ultimate causes of individual differences. Low heritability may suggest strong selection for a particular level of a personality trait. Estimates of heritability vary wildly between species, traits, and even between studies of the same trait in the same species. On the low end, boldness and aggression in three-spined sticklebacks has been found to have no heritability while dominance in chimpanzees was estimated to be 66%. Like any trait, the heritability of personality is a function of both selection and the amount of genetic and environmental variability underlying it.

Genomics

Two genome-wide scans have been carried out on humans to detect quantitative trait loci (QTL) connected with personality differences. One study used linkage with microsatellite markers to detect larger regions of each chromosome that explained variance in Psychoticism, Extraversion, Neuroticism, and social desirability as measured by the Junior Eysenck Personality Questionnaire. A second study conducted a genome-wide association scan and measured the personality traits Neuroticism, Extraversion, Openness to Experience, Agreeableness, and Conscientiousness using the Revised NEO Personality Inventory and identified several biologically plausible genes associated with each dimension.

Several other studies have considered personality or personality-like traits individually, particularly in conjunction with psychiatric disorders. The inability to replicate results from genome-wide association studies is not a fatal flaw for this type of research but simply an indication that other physiological and developmental evidence will be needed to determine how specific genetic variants result in personality and behavioral differences. A larger challenge is that the genes identified thus far explain such a small amount of phenotypic variance (on the order of 1%). Personality is indeed a complex trait in this sense, a product of many genes interacting with the environment.

Because of the complex genetic architecture of personality in humans, researchers often turn to model organisms, particularly mice. The strategy is to identify genes in the model species that are descended from a common ancestor with humans (i.e., the genes are orthologs). The assumption is that the orthologous genes carry out the same (or similar) functions in both species. Because the ultimate aim of studying individual differences with model organisms is usually in understanding psychiatric disorders, the focus is usually on traits such as neuroticism (sometimes called emotionality) that have strong correlates with anxiety- and depression-related disorders. For example, a region of chromosome 1 associated with emotionality in mice (as measured in novel-environment tests) was compared with the orthologous region that has been implicated in human neuroticism. A

key result from this comparison was that the exact disease-causing gene variants are unlikely to be shared across species.

A further outcome of investigations with mice is to separate genetically clusters of related behavioral phenotypes such as activity in open-field tests and mazes that are assumed to measure a single trait: anxiety. QTL analysis revealed a dimensionality of anxiety-related behaviors that was lost in a factor analysis of the phenotypic data.

Neurotransmitters and enzymes

There is mixed evidence for the role that variation in specific neurotransmitter transporters and receptors and related enzymes play in personality and behavior. Most work has centered around a small set of genes and their promotor: serotonin transporter (5-HTT or SLC6A4), dopamine receptor D4 (DRD4), and monoamine oxidase A (MAOA). Polymorphism in the serotonin transporter gene and its promoter region (5-HTTLPR) have been linked to neuroticism in humans and emotion in rhesus macaques. Variation in DRD4 has been associated with novelty-seeking in great tits, humans, and vervet monkeys, among other species. MAOA is a catalyst that breaks down the neurotransmitters serotonin, epinephrine, and norepinephrine. It has been linked to aggressive behavior in humans and several species of macaques.

However, various follow-up studies with humans have failed to replicate a link between 5-HTT and neuroticism and DRD4 and novelty seeking or extraversion. Rather than completely overturning the behavioral associations of these genes, these mixed results suggest that the pathway between genes and behavior is more complicated and not the action of single genes. Similarly, populations may differ in which gene variants are responsible for differences in personality and behavior.

Gene × environment interactions

The possibility that the environment may moderate the influence of genes on personality development has often been discussed and recently been explored. One area of emphasis has been on the MAOA gene. Low-activity MAOA genotypes have been related to aggression, anti-social behavior, and conduct disorder in humans. An orthologous gene (rhMAOA-LPR) was subsequently identified in rhesus macaques. A recent study of male rhesus macaques suggested that the effect of the low-activity genotype may be sensitive to the early rearing environment: mother-reared macaques with the low-activity genotype had higher aggression scores than mother-reared macaques with the high-activity genotype; peer-reared macaques with the high-activity genotype had higher aggression scores than peer-reared macaques with the low-activity genotype.

Ultimate Causes

Understanding variation in personality involves not just dissecting the genetic and environmental influences, but in discovering why such differences exist in the first place. This is a puzzle, namely because under direct selection one would expect the additive genetic variance of a trait to decrease. As such, multiple hypotheses have been offered to explain the maintenance of heritable variation in personality.

Neutral theory

The first possibility is that variation in behavioral, affective, and cognitive predispositions is the result of neutral evolution. Under this mode, all differences in a trait are due to mutations that are fixed or lost in the population through random genetic drift. The phenotypes resulting from each allele all have equal fitness, so there is no selection on the trait. However, the evidence connecting personality with differences in reproduction and health outcomes makes it unlikely that personality differences have zero fitness costs or benefits. Selection would have to be extremely weak to be overcome by genetic drift. More directly, there are many cases where, when measured, selection on personality traits have been found to be moderate. However, the neutral theory is not completely irrelevant for the evolution of personality. First, it reminds us that the origin of all genetic variation lies ultimately with mutation. Second, the neutral theory remains the null hypothesis against which all evolutionary propositions are tested.

Mutation-selection balance and balancing selection

After random drift, the next mechanism to consider is a balance between selection and mutation. If there is an optimal value of a personality trait (e.g., being moderate in neuroticism) that maximizes fitness, selection will move the population mean toward that optimal value. This elimination of genetic variation in the trait is balanced by the introduction of new variation via mutation. However, many characteristics of personality variation do not fit with the predictions of this explanation.

Another possibility that is better supported by the evidence is that some form of balancing selection accounts for the variation in personality traits. Thus, differing levels of the personality trait exist because each is related, in some way, to fitness benefits and costs. For example, in a species where females favor aggressive males, the benefit of being higher in some aggression-related trait may be offset by the higher likelihood of injury or death resulting from fights. Another example involves differences in life history within species, that is, that different levels of personality dimensions are

related to trade-offs between number of offspring reproduced and lifespan of the parent or viability of the offspring.

Environmental niches

Another possible way in which genetic variation in personality might be maintained is because the environment offers a multitude of niches in which different levels of personality may be successful. Thus, in a population there may be ways for individuals along all levels of extraversion or any other dimension to successfully survive and reproduce. Environmental heterogeneity can also lead to differing selection pressures among populations, such as whether stickleback behaviors were correlated resulted from differing predation rates. In addition to spatial variation, individual differences can also be maintained by temporal variation in selection pressure. For example, bold ewes are less susceptible to predation by cougars, but this only results in appreciable fitness differences when predation is high.

Conclusion

The abundance of individual differences is the only clear result that is consistent across all species where personality has been examined. The genetic architecture underlying personality and how its variation is being maintained are likely to differ between species, and a major goal will be to identify the broad patterns that explain the ultimate and proximate causes of individual behavioral proclivities. Measuring and validating personality and dissecting its complex genetic basis are key challenges in this area. What personality is and how best to study it will continue to provide much fuel for debate.

Glossary

Epigenesis – While different disciplines have different slants on the meaning of this term, what they all share in common is an attempt to capture the idea that developmental processes are context-dependent. In this view, gene products arise not only through the action of those genes, but also as a result of interactions with other genes as well as with nongenetic factors.

Evolutionary developmental biology – The core idea of this field of inquiry is that evolution acts through inherited changes in the development of the organism. From this perspective, the mechanisms that give rise to organisms over the course of their development are crucial for a full understanding of how evolutionary changes across generations are possible.

Homeostasis – This refers to the bodily mechanisms that regulate a number of physiological variables, such as blood pressure and blood glucose levels, within the narrow limits that the body requires. Such homeostatic regulation depends on negative feedback, where the output of the system affects the input. For example, an increased CO₂ level in the blood can lead to an increase in ventilation rate which, in turn, reduces the CO₂ level to the physiologically more appropriate level.

and nurture often subtly move to the conclusion that if we dig deeply enough we will find that the fundamental difference is made by a gene or a particular environmental input. Both conclusions are correct: hold the environment constant and we will find a critical contribution by a gene, and hold the genetics constant and we will find a critical contribution by the environment. Genes have evolved to function in a particular context, and that context includes other genes, subcellular and cellular processes, wider intra-organismic as well as inter-organismic interactions, and then, all manner of environmental influences from the physical world; that is, the epigenetic context within which genes functions are not only interesting, but also essential to our understanding of development. That epigenetic processes can have a profound influence on development is shown by the work arising from several laboratories that demonstrate that early experiences can be transmitted across generations. Molecular mechanisms, triggered by specific experiences, lead to particular genes being activated or inactivated and, in turn, these are transmitted to the next generation in their altered form. Therefore, it seems somewhat irrelevant to label any critical component of the network as more critical than any other, as all of the pieces working together are needed. Given this complex array of interactions, an important issue for the study of development, especially from an ethological perspective, is how these myriad influences manage to coalesce so as to produce consistent species-specific behavior, generation after generation.

A classic study, done by Gilbert Gottlieb, shows the subtle ways in which developmental context can lead to stable and consistent behavior across members of the same species. Upon hatching, ducklings are attracted to the species-typical maternal call. By rearing eggs so that the developing embryos do not experience hearing adult calls, such hatchlings are, nonetheless, able to show a clear preference for their species-typical maternal call. A lesser researcher would have jumped to the conclusion that the development of responsiveness to species-typical calls is impervious to environmental information. However, through an ingenious series of experiments, Gottlieb showed that the development of this responsiveness is dependent on hearing vocalizations, be they those of ducklings from neighboring eggs or those generated by the duckling itself. There are two major conclusions arising from these studies.

Introduction

For much of the last century, the study of behavioral development, similar to development more generally, was plagued by the nature/nurture problem. The problem of development was perceived as being one of apportioning the contributions of the genes (nature) and the contribution of the environment (nurture). By the end of the twentieth century and the beginning of the twenty-first, it became commonplace to accept that the nature-nurture debate had ended. Everyone seemed to be in agreement that development involves a continuous interaction of genetic and environmental information and that we should be focusing our attention on the interactive processes involved.

All modern textbooks on behavioral neuroscience and animal behavior subscribe to this interactive perspective. Interestingly though, even books written to expound the importance of the interactive relationship between nature

When Gottlieb examined the vocalizations of the developing ducklings, he found that they do not have any of the properties of the species-typical maternal calls. That is, experiences seemingly unrelated to what is being developed are necessary for that development to proceed. Many studies have confirmed this counterintuitive conclusion. For example, hatchling chicks denied of the opportunity to observe their own toes, fail to develop the ability to discriminate between food and nonfood items, and infant squirrel monkeys denied of the opportunity to feed on live insects, fail to develop the capacity to fear snakes. Most researchers are now sensitive to the fact that seemingly unrelated experiences may impinge on the development of the particular system they are studying, and that context matters when it comes to developing species-typical behavior. However, there is an underappreciated lesson to be learned from Gottlieb's work.

Consider the testing paradigm used by Gottlieb: a duckling is placed in a chamber with a speaker at each end, which gives the duckling a choice as to which sound to approach. The behavioral measure used is how much of the test period is spent near one speaker versus the other. In this context, what Gottlieb demonstrated is that ducklings exposed to their own vocalizations show a stronger preference for the species-typical maternal call than ones that hear no vocalizations whatsoever, and ones that hear their own vocalizations as well as those that emanate from neighboring eggs, show an even stronger preference. Finally, those exposed to their own vocalizations, those of their neighbors as well as those of adults, show the strongest preference of all. What Gottlieb did not report is that under altered environmental conditions, including that of not hearing anything, ducklings developed species-atypical behavior, such as showing avoidance of calls, or, for that matter, doing somersaults when hearing a call! While the environmental information affected the strength of the responsiveness to the species-typical maternal call, it did not create behavior unrelated to the theme of responsiveness to adult calls. In other words, development is constrained to generate particular themes, with contextual information – be it genetic or environmental – being used to achieve that end.

Passive and Active Forms of Constrained Developmental Change

An early proponent of the view that there are homeostatic processes that constrain developing systems to establish and maintain particular themes was Conrad Waddington, with his concept of canalization. He conceived of development to be similar to a ball rolling down a hill with grooves and protuberances; as the ball travels down hill, it is channeled to move in the paths of least resistance. The

height and angle of the slopes of the grooves ensure that once a ball begins a particular trajectory, it is difficult to shift to another. Studies have identified that evolved contexts can contain passive constraints that ensure that B can only occur because A has occurred or is present. However, in some situations, there may also be active processes that steer development along particular paths, compensating for the potentially disruptive influences of mild to moderately abnormal genetic or environmental information.

A beautiful example of the passive-contextual situation is illustrated by Ton Groothuis' studies on the development of social displays in black-headed gulls. Shortly after hatching, young gulls from all the nests in the colony cluster together and form a large, dense flock. A characteristic of these large gatherings of immature gulls is that they squabble: they peck and threaten one another. As the young ones grow, the rich repertoire of body signals and vocalizations that are used for communication as adults, gradually mature. If the young gulls are denied of the opportunity to squabble, the development of these signals is retarded or even incomplete. Although a logical inference would be that during the squabbling, the gulls are gaining valuable feedback from their opponents that helps shape the final form of the signals, it appears that the squabbling between the young gulls does not affect development in this direct manner. Rather, the squabbling elevates the circulating levels of testosterone in young gulls, and it is this extra testosterone that facilitates the development of their signals, probably by promoting the development of the relevant neural circuits. When young gulls, not housed socially, are treated with injections of testosterone, they not only develop the signals in the absence of squabbling, but they also do so prematurely – that is, at a younger age. Therefore, the reliable and normally present occurrence of squabbling ensures that the relevant hormones are kept at an appropriate level to effect the development of signaling behavior.

For some developmental processes, there may be active processes that compensate for disturbances in information. Consider the following possibility: embryos of all the vertebrate classes perform spontaneous movements. In experiments with chickens where these movements are inhibited, such as by injections of curare, a muscle paralyzing agent, the feet become gnarled and curled up, into postures similar to the 'clubfoot' that can occur in human infants. Indeed, clubfoot in humans is associated with a reduction in the experience of embryonic movements. Genetic mutations known to curtail such movements produce these abnormalities in the limb extremities, as does their arrest via environmentally induced means. Thus, whether due to genetic or environmental disturbance, disruption of embryonic movements leads to abnormal development in the joints of the feet. In

mammals, these movements begin by being produced spontaneously, but later, are also inducible by stimuli emanating from the embryo's own movements and those of its mother. In fish, they appear to remain primarily self-generated. Such class-level differences may arise from differences in opportunities for external stimulation to provide a reliable source of movement induction. These class-level differences illustrate how a reliably available environmental context can substitute for intrinsically driven behavioral change. Importantly, multiple sources of information can converge on the same processes to generate developmental changes – in this case, the formation of appropriately sculptured limb joints. But what are these common processes?

A clue to this question comes from understanding how collagen sheaths develop in the body muscles of fish. Collagen, a protein, is the major constituent of the fibrous network that encases the body in skin, and that forms the connective tissues, such as tendons, that link muscles to bones. Such fibers are under the dynamic control of a regulatory process. Fibroblasts are cells that move along collagen fibers and monitor the tension of those fibers. There is a range of stretching in such fibers that does not induce fibroblast action, but if the tension on the fibers is above or below that range, adaptive changes arise. Strands of collagen fibers that are stretched above a certain threshold are reinforced by adding more fibers and ones that are slack, below that threshold, are eroded. Thus, fibroblasts actively sculpt collagen fibers via a simple homeostatic device. Similarly, the collagen sheaths that separate the bundles of muscles (somites) along the body of a fish are shaped by the tensions produced by those muscles. During development, the spontaneous movements generate the forces that stretch these collagen sheaths, and so produce the context upon which fibroblasts monitor the differences in tension and so modify the development of the sheaths. Species-typical spontaneous movements acting on species-typical body morphology generate forces that induce the fibroblasts to sculpt the collagen sheaths into species-typical patterns. In turn, these developmental changes in sheath size, shape, and orientation lead to the development of muscle orientations that produce the species-typical patterns of force generation during swimming in posthatching fish. Again, either genetic mutations or altered environmental context can alter the production of the forces needed for the fibroblasts to do their job. Thus, if the disturbance is above the threshold that can be compensated for by the core homeostatic processes regulating development (the walls of Waddington's canals), then abnormal developmental outcomes emerge.

If the disturbances are within the tolerable range that the homeostatic mechanisms can provide compensatory change, then novel, but still functional, outcomes may arise. An intriguing example of this possibility has been

recently shown for the change in the beak size of Galapagos finches. A small, genetic change, leading to the prolonged production of a growth factor influencing embryonic beak development, leads to birds with larger beaks. However, while the growth factor influences the length of the beak, there are also compensatory changes that lead to beaks being deeper and alterations to the skull and muscles that accommodate these enlarged beaks. All these additional reconfigurations of beaks, skulls, muscles, and connecting tissues arise in compensation for the one change in the direction of the beak's growth; that is, the homeostatic mechanisms are sufficient to compensate for the one disturbance and produce a viable phenotype. This example illustrates that not all changes need to be specified by specific genes or environmental inputs, and that intrinsic homeostatic mechanisms are able to reorganize the developing system. In addition, it illustrates how developmental processes may play a key role in the evolution of new forms – small changes can modify how a common developmental tool-kit functions, and so how novel phenotypes can be generated. Applying the lessons that are being learned from the new field of evolutionary developmental biology (evo-devo) – which has been mostly focused on identifying the genetic side of that tool kit – to the evolution and development of behavior is still in its infancy, but this is certainly an exciting direction for the field to explore.

The homeostatic mechanisms, such as the fibroblasts monitoring tension in connective fibers, which enable species-typical organization to unfold during morphological development, have not yet been a major focus of study in behavioral development, and it is not until they are that we will be completely liberated from the temptation to subscribe a developmental event to the action of a gene or an environmental input. But recognizing that behavioral development, just like morphological development, involves physiological mechanisms that maintain stable homeostatic systems, is an important beginning, as it changes thinking of behavior as a privileged trait to one that is as biological as any other. Mechanisms that can modify the development of morphology are thus likely to apply to behavior also.

Types of Environmental Influences on the Development of Behavior

The example of embryonic movements alerts us to another valuable distinction when thinking about environmental influences on behavior. Fetal immobilization in young mammals, be they rats or humans, leads not only to abnormal joints, but also to a variety of other abnormalities, such as smallish lungs and stomachs. That is, embryonic movements are involved in the development of the structures engaged in the movement – the

move-your-feet-to-sculpt-the-joints-in-your-feet link – and ones not directly involved in the generation of the movements, lungs, and gastrointestinal tracts. The training of the system being performed makes sense, and such a direct link can focus our attention on the processes likely involved in the developmental transformation. This is not true for by-products that have no obvious connection – not only are we puzzled as to why the stomach is affected, but we are also ignorant as to why the absence of embryonic movements should lead to smaller, rather than larger, stomachs. Nonetheless, it is useful to separate those influences – be they genetic or environmental – that directly affect the developing system under study versus ones that do not. Perhaps, as our knowledge grows, we will one day be able to characterize meta-mechanisms that are triggered by these inputs and so understand the connections between them. We are not there yet, but at the conclusion of this article, an example of such a possible meta-mechanism is provided.

In our present state of ignorance, it is helpful to classify those behavioral systems directly sculpted by particular inputs and those indirectly influenced by such inputs. A useful term, proposed by Jerry Hogan, to capture this distinction is ‘prefunctional.’ A prefunctional behavior is one that needs not be rehearsed before it is expressed in its normal form – as was the case for the gull social signals. In other cases, future action is only possible because it was shaped by action-relevant experiences earlier in development – the proper formation of the limb joints arising from embryonic movements is an example. Both types of developmental outcomes, prefunctional and functional, likely depend on a host of indirect influences from environmental (and genetic) information. These indirect influences are well illustrated by the effects of embryonic movements on the development of internal organ size. Thus, by stating that a behavior is prefunctional is informative, without being burdened by any implication that it develops independently of environmental influences, as would be the case for most meanings of the terms ‘innate’ or ‘instinct.’ Prefunctional and functional components of behavior and their development are illustrated by work done on the development of dust bathing in chickens, a behavior that is used to remove excess oils and parasites from the feathers.

The dust-bathing sequence begins with the chicken scratching and pecking at the substrate. The chicken first drops one wing and then the other, while simultaneously shuffling its feathers. It then rolls on the ground, first onto one side, then the other, and finally squats, with its body feathers raised. More shuffling ensures that the dust released by the pecking, scratching, and wing movements is passed through the feathers to their base. Finally, the chicken stands up and gives its body a good shake to rid it of the excess dust. From hatching, it takes about 2 weeks for all of these behavioral elements to emerge, and

they appear in the chick in the order in which they are performed in the adult in the completed sequence. Thus, scratching the substrate emerges earlier in development than rolling onto the flanks. Furthermore, as these behavioral components emerge, the chicks are indifferent as to whether they are standing on sand or dust or on a wire-mesh floor devoid of any usable particles. That is, the behavioral components of dust bathing emerge independently of functionally useful feedback from the environment. In this sense, the actions of dust bathing emerge prefunctionally.

In contrast, after these behavior patterns emerge, the substrate on which the birds are reared can influence subsequent substrate preferences for dust bathing. Chicks raised with wood shavings prefer wood shavings to other possible substrates, such as sand or coal dust, and conversely, chicks raised on a substrate of coal dust prefer coal dust to other options. Clearly, the functional feedback experienced from the particular substrate material used influences the bird’s preferences for later substrate selection. Because both perceptual preferences for substrates and behavior-pattern formation may ultimately be traced back to requiring some important, indirectly acting, environmental input would seem to be confounding very different mechanisms. Rather, the identification of behavior that develops prefunctionally versus functionally provides us with valuable information as to the types of mechanisms that are likely to be involved and provides us with a starting point for designing research strategies.

Prefunctional versus Functional Developmental Change

The development of playful fighting in laboratory rats is sufficiently well understood to provide a useful illustration of how these distinctions can guide us in looking for specific mechanisms. Play fighting in rats involves attack and defense of the nape of the neck that, if contacted, is gently nuzzled with the snout ([Figure 1](#)). Such play fighting emerges in late infancy, just before weaning, peaks in the juvenile period and then continues well into adulthood, albeit at a low frequency. Similarly, there are age-related changes in the tactics of attack and defense that are used over this time period. These age-related patterns appear to unfold in the same manner whether animals have had prior experience with play fighting or not. That is, play fighting and the age-related changes that it undergoes are prefunctional. This does not mean that these changes are not dependent on environmental inputs.

In the case of age-related changes in the tactics of attack and defense, gonadal hormones and specific brain mechanisms are critical for the patterns to unfold as they do. In contrast, while gonadal hormones are important for determining the size of the juvenile peak in the frequency

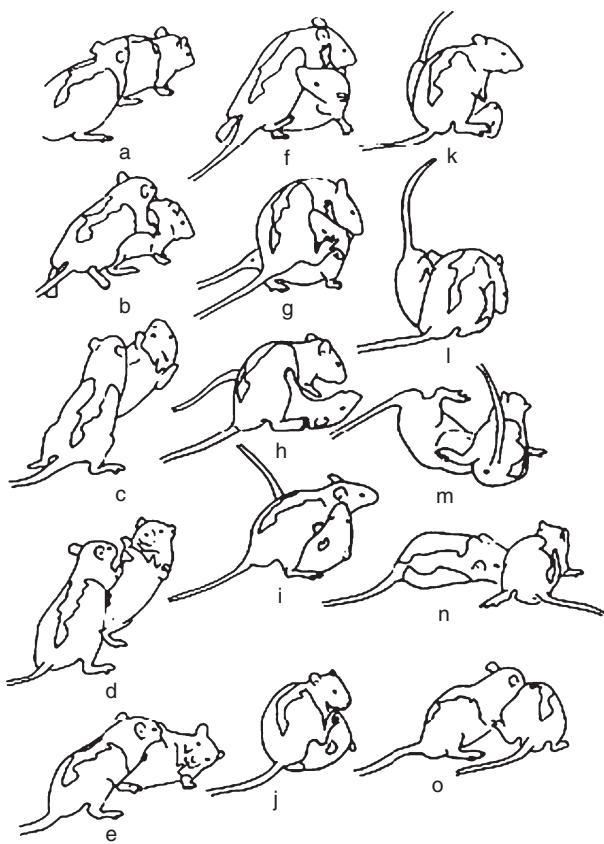

Figure 1 Two juvenile male rats, at about 35 days old, are shown engaging in a play fight. Note that the rat on the left lunges to reach the nape and the recipient acts to defend itself from such contact (a–h). Even when the defending rat is lying on its back, both it and its on-top partner continue to lunge at each other's napes (h–k). Finally, once the original defender pushes the attacker over and regains its standing posture, it, in turn, lunges at its partner's nape (l–o), continuing the play fight. From Pellis SM and Pellis VC (1987) Play-fighting differs from serious fighting in both target of attack and tactics of fighting in the laboratory rat *Rattus norvegicus*. *Aggressive Behavior*, 13(4): 227–242. © 1987, Wiley; reprinted with permission of Wiley-Liss, Inc. a subsidiary of John Wiley and Sons, Inc.

of play, they do not determine the shape of the age-related pattern. However, the experience of play fighting in the juvenile period has been shown to be critical for the development of postpubertal social skills. As young adults, male rats modify their play fighting and other social responses depending on the status of their partner – dominant males are responded to differently than to other subordinate males and females. Play-experience-dependent changes in social skills have been demonstrated to involve correlated changes in the anatomy of the neurons of the prefrontal cortex. Therefore, the development of social skills is functional, depending on experiences derived from engaging in social behavior. Indeed, the play fighting occurring in the juvenile period is organized differently to that which appears earlier or

later in development, and based on the form of those organizational differences, it is reasonable to infer that the pattern of play present in the juvenile period is organized so as to enhance the experiences that are relevant to the development of social skills. But these age-related changes in the organization of play fighting are not themselves dependent on functional experience to emerge as they do in the juvenile period. Thus, prefunctional changes in the organization of behavior are critical for the functional development of social skills.

It is worth reiterating that the prefunctional changes in play that emerge during the juvenile period are linked to particular environmental inputs; in this case, those inputs reside in the animals' own bodies in the form of particular levels of circulating gonadal hormones. But similar to other cases of prefunctional behavioral development, be it Gottlieb's ducklings, Groothuis' gulls, or changes in gut size in the absence of embryonic movement, knowing that there are indirect environmental influences on development is incomplete as an explanation for development. We still need to understand why those indirect environmental inputs produce the outcomes that they do, rather than a near infinite number of other possible outcomes. For behavioral changes that are functionally linked to behavioral development, the relevant environmental inputs usually have a more direct influence, shaping motoric, motivational, or perceptual capabilities that bias them to work one way rather than another. Practicing tennis, for example, can lead to a better performance on the court during an actual game, and some of this improvement can likely be traced to improvements in hand–eye coordination, but if practicing tennis improves chess playing, then where do we begin looking for the causal links? Thus, the distinctions between prefunctional and functional are sometimes a helpful guide to the researcher.

Conclusion

Instead of worrying about the sources of information relevant to behavioral development, we should focus on understanding the mechanisms by which information is incorporated into developing organisms and integrated to produce the outcomes that they do. Consider the classic work on visual development of mammals. The alternating neural columns on the visual cortex of a mammal, such as a cat, develop in response to competing inputs from the retinas of the two eyes. Thus, visual input is necessary for pattern formation in the cortex. However, before the eyes open, binocular anatomical patterning is developed in a part of the thalamus that receives input from the eyes (the lateral geniculate nucleus (LGN)), the relay point for visual information reaching the visual cortex. While visual information is not necessary in this case, information from the retina is needed. In this case, instead of light stimulating

the retinas, at the right age, the retina begins to be spontaneously active. Therefore, the patterning of both the LGN and the visual cortex depends on activity in the retina, but whereas for the LGN retinal activity is independent of incoming light, for the visual cortex, that retinal activity is triggered by light entering the eyes. It is possible that for the LGN spontaneous retinal activity is triggered by turning on some particular gene or cascade of genes, but what is important here? To understand the developmental changes in the brain, whether the source of the information or the common mechanism by which activity in retinal cells shapes the organization of neurons deeper in the brain?

The source of the critical information may be important in understanding the full context of the interacting developmental networks, and may also help guide researchers as to where to look next. However, the example of the patterning of the LGN and the visual cortex clearly shows that this is only a small part of the story. The processes by which organisms integrate information, and transform that information into particular outcomes is by far the bigger, and, as yet, less explored part of the story. The development of brains, not unlike the development of connective tissues, probably involves passive, contextually dependent processes, as well as active homeostatic mechanisms. The challenge for the future study of behavioral development is to identify and characterize those organismal processes that construct behavior in particular ways.

Glossary

- Imitation** – A song that is a good copy of a tutor song.
- Improvisation** – A song that resembles a tutor song, but which is substantially different in certain respects.
- Invention** – A song which cannot be traced to a tutor song.
- Sensitive period** – A relatively short period early in life when the bird is receptive to song memorization.
- Sensorimotor phase** – The phase during which the bird sings and tries to match its output to earlier-memorized songs; follows or overlaps the sensory phase.
- Sensory phase** – The phase of song learning during which the bird memorizes tutor song.
- Song** – A relatively complex vocalization used in interactions with males and/or female conspecifics. A single song (or strophe) is usually relatively short (usually 2–4 s) and is separated by a longer period of silence before the next song. In some cases, birds sing more continuously and individual songs can be quite long (e.g., 20 s or more in sedge warblers).
- Song crystallization** – A developmental phase in songbirds in which there is a transition in song from poorly structured vocal material (subsong or plastic song) to stereotyped, well-structured song patterns that are typical of adult birds.
- Song learning program** – The genetic-developmental program thought to underlie song learning in a species (or a race or population of a species).
- Song repertoire** – Defined in terms of song types or elements. Most birds form song elements into stable song types, but others (e.g., sedge warblers) improvise songs from their repertoire of song elements.

Bird Song as a Model System

Songbirds (oscine passerines) are one of the few animal groups in which individuals learn their vocal signals. Vocal learning has been found so far only in the humans, two other mammalian groups (cetaceans and bats), and two other avian groups (parrots and hummingbirds). Although other animal groups capable of vocal learning will probably be discovered in the coming years, vocal learning is clearly the exception in the animal kingdom: in most animals, individuals develop perfectly normal

species-typical vocal signals without having to hear models of these signals. Among vocal learners, songbirds stand out because of their complex vocal repertoires. Some songbirds show extraordinary powers of vocal mimicry, far exceeding human capabilities.

In the 1970s, it was discovered that songbirds possess a distinctive set of neural circuits dedicated to their vocal communication system. Research has since attempted to parse out the roles of different parts of the system in the perception, production, memorization, and learning of vocal signals. The bird song system has become a major model system in neurobiology in part because of its potential to provide insights into the neural mechanisms of learning and memory. The discovery of neurogenesis within the adult songbird song system, the first unambiguous demonstration of neurogenesis within the adult vertebrate central nervous system, was a key element in the establishment of the bird song system as a model system in neurobiology.

Parallels between Bird Song Learning and Human Language Learning

Yet another reason for the interest in the bird song system as a general model system is the number of parallels between vocal learning by songbirds and language learning by humans. These parallels were first pointed out by Peter Marler in a seminal 1970 paper. Six of these parallels are included here, with an additional parallel – social context – which will be discussed further in the section titled “Comparative differences in song bird learning.”

1. In both songbirds and humans, the vocal communication signals are learned.
2. This learning takes place during a sensitive period that begins soon after birth or hatching and concludes sometime later. There is some uncertainty as to when and how completely the sensitive period closes in humans, but it is generally accepted that second-language learning, unless started early in life, is considerably more difficult than first-language learning. The sensitive period for songbirds depends on the species, and is discussed in the section titled “Comparative differences in song bird learning.”
3. Dedicated neural systems underlie the perception, memorization, learning, analysis, and production of the vocal signals.

4. The sensory-memorization phase precedes the production phase. For example, infants understand more than they can say. Some songbirds do not even begin to practice vocalizing until they have memorized all the songs they will sing.
5. Related to the previous point, there is a babbling or subsong phase in which the individual practices vocalizing. The vocalizer presumably matches these productions to the models that were memorized earlier. The signals are refined until they ultimately reach the adult level.
6. Auditory feedback is essential for vocal learning, at least until the normal vocal repertoire has crystallized. Although deafening after this period can cause degradation of vocal signaling, auditory feedback after crystallization is generally less critical for maintenance of the vocal repertoire.
7. Vocal learning is inherently a social process.

Vocal Learning is a Social Process

The fact that people around the globe learn different languages is of course sufficient evidence that language is learned. The additional hypothesis that language must be learned in a social context seems self-evident. On the rare occasions that an individual has been isolated from human contact during development, language is inevitably deficient, but this of course is just one of the myriad clinical problems shown by such individuals. Extrapolation of this isolation test to songbirds is sometimes referred to as a Kaspar Hauser experiment, named after one such unfortunate human (although the story is partly apocryphal). Most songbirds when isolated from the sights and sounds of other birds from hatching until maturity develop abnormal songs (some exceptions are discussed below). Presentation of tape-recorded song to the isolated bird is often sufficient, however, for the bird to develop normal species song. It is this last fact that led many investigators to overlook this importance of social context for bird song learning.

While the importance of social contact is obvious for language learning in humans, the early studies of song learning in songbirds explicitly excluded social factors. They did so for both theoretical and experimental reasons. The original theoretical conception of song learning was derived from the classical ethological concept of imprinting, translated into the song-learning context by Thorpe, and then fully developed in the experiments of Marler and his colleagues. By analogy to the classical imprinting studies, it was supposed that the key stimuli for song learning would be very basic, processed by species-specific filtering mechanisms and that learning would occur during an early sensitive period. This view provided the rationale for the ‘tape tutor’ experiment, in

which all aspects of the species- and population-typical song-learning context were removed, the bird being isolated shortly after hatching and hearing song only through a loudspeaker in an isolation chamber. Besides fitting the theoretical view, the tape-tutor experiment also unquestionably provided more experimental control than would be possible were actual birds the song tutors. In a classic series of tape-tutor experiments, Marler showed that to develop normal song, a white-crowned sparrow male must hear conspecific song during an early sensitive period (roughly the second month of life); the bird will reject heterospecific song heard during this period, as well as conspecific song heard after the sensitive period.

Workers in the field became aware of the importance of social factors in song learning, however, with the discovery that birds learned more readily from live tutors than from tape-recorded song. Moreover, some of the rules of song learning derived from tape-tutor studies appeared to bend, if not break, when the song tutors were actual birds. For example, whereas tape-tutor studies had indicated that the sensitive period for white-crowned sparrow song learning closes at approximately 50 days, and that heterospecific songs are uniformly rejected, Baptista and Petrinovich showed that if a young white-crowned sparrow was exposed to a tape tutor through 50 days and thereafter exposed to a live tutor, the young bird would learn the song of the live tutor, and in some cases would do so even if he were a heterospecific tutor.

Field studies also provided a major impetus to the study of social factors. Although field studies cannot provide the experimental control of a laboratory study, they naturally bring into focus the social variables that are controlled out of laboratory experiments. To the question of when song learning occurs, field studies added the questions of where and from whom, and have given a new context for the questions of how many, which ones, and how accurately? Researchers doing the first field studies on song learning noted that learning appeared to occur later than indicated by the classical tape-tutor studies, post- rather than pre-dispersal, so that birds wound up learning songs not from their father and birds in the natal area, but from birds in the area where they would breed, often their neighbors of their first breeding season.

Despite the problems raised by field studies and by experiments with social tutors, the basic findings of the classical tape-tutor experiments have not yet been firmly contradicted in any species. In particular, although the sensitive period for song learning may extend much further into the first year for some species than was originally thought, for no species does it appear to be true that song learning is equally possible or equally likely at all points during the bird’s life. Moreover, even if a powerful heterospecific social tutor can overcome it, the preference for conspecific song found in tape-tutor

experiments, at least for some species, does suggest some form of tuning for conspecific song. Nevertheless, comparative studies of songbird species have revealed an amazing diversity in song-learning patterns, both between species and between different populations of the same species, and this diversity should warn us not to take any particular pattern of song learning, for example, that shown by white-crowned sparrows, as typical or fundamental. We return to this point in the section titled ‘Comparative differences in song bird learning’

What are the Social Variables in Song Learning?

Despite the recognition that social factors are critical in song learning, there is little understanding in the field of exactly how social variables shape song learning. The numerous comparisons of live versus tape tutors that have been made are usually indirect and often made across different studies. As researchers have pointed out, it is not at all clear what precise aspects of social stimulation influence song development, and indeed even whether the effects are ‘truly social’.

The difference between results derived from tape-tutor and live-tutor experiments can be viewed from another purely theoretical angle. The tape-tutor and live-tutor paradigms implicitly suggest different models of the song-learning process. The tape-tutor paradigm implies that song learning is essentially a process of overhearing or simple eavesdropping on a singing adult. In contrast, the typical live tutor setup – with the young bird stationed close to a singing adult bird – implies that the fundamental process involves direct interaction of the older bird (song tutor) with the young bird. However, both experimental setups are potentially unnatural: we do not know whether in nature the young bird learns from a song tutor singing solo and out of sight (as implied by the tape-tutor design), from a song tutor who is up close and interactive (as implied by the typical live-tutor design), or, perhaps, in some other way altogether.

A theory developed by Nelson and Marler combines the ‘simple eavesdropping’ and ‘direct interaction’ models of song learning by proposing that the first process describes the early phase of song learning, while the second process describes the later phase of song learning. According to this theory, in the first phase of song learning, the young bird memorizes many songs during the natal summer, many more songs than he will ultimately keep for his final repertoire. In the second, action-based phase of song learning, typically occurring early in the following spring, the bird counter-sings with his new neighbors as he tries to establish a territory, and selects from his earlier-memorized songs those that best match the songs of the birds he is now interacting with. Thus, the

Nelson–Marler theory incorporates the implicit models of both the tape-tutor and live-tutor paradigms: the early, memorization phase of song learning follows the simple eavesdropping model, while the later action-based phase conforms to the direct interaction model.

A third model, the social eavesdropping model, suggests an alternative way in which social interaction might affect song learning. The central idea is that the young bird learns by eavesdropping, not on solo singing, but on singing interactions between two or more birds. Recent field experiments on songbirds have shown that males base their decisions on whom to challenge and females their decisions on whom to mate with on information about the dominance relationship of the singing males, information which they extract when eavesdropping on singing interactions. The social eavesdropping hypothesis proposes that young birds too may use information they extract from singing interactions they overhear to decide which songs to learn or retain. The relative dominance status of the two birds might be one important dimension. This idea is similar to the social modeling theory, as developed by Pepperberg, which suggests that observation by the young bird of communication interactions between individuals who have mastered the communication system may be critical for vocal learning.

There is a second unique type of information a young bird could extract from the interactive singing (counter-singing) of two adults that he could not extract from solo singing of these same birds: contextual information relating to singing rules concerning the appropriate replies to particular songs in particular contexts. We take for granted that humans have to learn the rules of language, but animal communication systems – although simple compared to human language – do have their complexities, and do follow fairly intricate rules. In the study of bird song learning, the focus has always been on the learning of particular songs rather than the learning of how to use them, but the two processes may be intertwined. This is the case for human language learning of course. Although the attention in studies of human language learning has been focused on direct interaction, especially between parent and infant, it is necessarily the case that the infant can potentially learn much more about grammar and the rules of language by eavesdropping on conversations among older individuals.

Some evidence suggests that songbirds may preferentially learn by eavesdropping on singing interactions of other birds. In an experiment on young song sparrows (*Melospiza melodia*) using live tutors, Beecher and colleagues compared two types of song tutoring: that resulting from direct interaction with the song tutor, and that resulting from social eavesdropping, that is, overhearing the singing interactions of other birds. Subjects were exposed to the songs of four tutors during the early memorization phase (phase 1) of song learning and to

just two of them again in the later action-based learning phase (phase 2). Of the two tutors returning in phase 2 one became a subject's interactive tutor, while the other became the subject's overheard tutor, that is, was overheard interacting with another, yoked subject. Subjects learned (retained) more songs from their overheard tutor than their interactive tutor (about twice as many on average). This result is consistent with the social eavesdropping hypothesis, and not the direct interaction hypothesis.

In a totally different approach to the problem in the same species, Templeton and colleagues examined the response of juvenile male song sparrows in the field to simulated adult song contests and solo singing. Songs were presented from two speakers separated by 10 m and 50 m from the bird. Juveniles were more likely to move toward the speaker, approaching closer and more quickly, during the simulated singing interactions between the two birds than during solo song or control playback trials (solo song sparrow and heterospecific song, in fact, were equally unattractive to the birds). These results suggest that juvenile song sparrows are especially interested in eavesdropping song contests and that these types of social interactions may be particularly powerful tutoring events for song learning.

Comparative Differences in Song Bird Learning

The prevalent model of song learning is based on the classic studies of Marler on the white-crowned sparrow (*Zonotrichia leucophrys*). During the sensory or memorization phase, the young bird must hear tutor song, and during the sensorimotor phase, it attempts to match its vocal output to the songs memorized earlier. Learning can be demonstrated by isolating the bird during the sensory phase, or by deafening it just before the sensorimotor phase; both typically produce a bird that sings abnormal song. Since isolation and deafening are extreme manipulations, and because their outcomes are generally considered to be obvious, song learning is usually demonstrated instead by showing that the bird develops songs closely resembling the songs it was tutored on; this method is unambiguous so long as song learning takes the form of simple imitation (copying) of tutor songs (but as we will see, it does not always do so).

Despite the uniformity suggested by the outline of song learning just given, it has been long known that songbird species show many variations on this theme. However, in fact, the diversity of oscine song-learning programs is more extreme than is generally appreciated, and varies along at least the following five dimensions.

1. *When song is learned or how long the song repertoire is modified.* The period during which birds can learn songs ranges widely, from a brief sensitive period in the first few months of life (white-crowned sparrow), to the entire first year (chaffinch, *Fringilla coelebs*, indigo bunting) to throughout the lifetime (village indigobird, *Vidua chalybeata*, great tit, *Parus major*, pied flycatcher, *Ficedula hypoleuca*, willow warbler, *Phylloscopus trochilus*). Species in which birds add songs to their song repertoires after the first calendar year are referred to as open-ended learners, species in which they do not as closed-ended (or age-limited) learners. Although closed-ended learning has generally been the default assumption, in most cases there is no evidence to support this assumption: song-learning experiments typically are not extended beyond the first year, and longitudinal field data are rarely gathered. Thus, species assumed to be closed-ended learners might on closer inspection prove to be open-ended learners, as, for example, McGregor and Krebs discovered for great tits.

2. *How many songs a bird learns.* In about 70% of songbird species studied, males sing multiple song types. These song repertoires range in size from small (e.g., chaffinch, great tit, swamp sparrow, *Melospiza georgiana*, all <5) to moderate (e.g., song sparrow, western meadowlark, *Sturnella neglecta*, 10 or so) to large (e.g., western marsh wren, *Cistothorus palustris*, common nightingale, *Luscinia megarhynchos*, >100) to huge (e.g., brown thrasher, *Toxostoma rufum*, >1000). Small- to moderate-sized repertoires are most common. Several experiments in which species (song sparrows vs. swamp sparrows) or subspecies (eastern vs. western marsh wrens) with different repertoire sizes were raised in a common environment established that differences in repertoire size in these cases were due to genetically based differences in the underlying song-learning programs.

3. *Copying fidelity.* Although imitation is the hallmark of bird song learning – typically it is the criterion by which song learning is assessed – birds do not always copy tutor songs precisely. In different species (and sometimes in different populations of a species), song-learners appear to vary along a continuum ranging from imitation (faithful copying of tutor song), to improvisation (variations on the tutor material) to invention (bird develops species-typical songs that bear no obvious relation to the tutor material, and which might or might not even require song tutoring).

4. *Role of early song experience.* Because bird song learning was first demonstrated by showing that songbirds raised in isolation develop abnormal song, there has been a tendency to assume that isolation-rearing will always have this effect, and hence isolation conditions are usually omitted from song learning experiments. However, isolation does not always produce abnormal song. Three recently discovered examples are the grey catbird, the

sedge warbler, and the canary: these birds generate large, normal song repertoires when raised in song-isolation conditions. These birds probably need to hear themselves sing in order to develop their normal repertoires (though this has not been tested), but it is still surprising that they can develop their large repertoires of good species songs without ever hearing external conspecific song models.

5. Degree of canalization. In white-crowned sparrows and several other species, birds copy tutor material only if it fits tightly constrained species-specific parameters, and in these cases song learning would be classified as environmentally canalized (*sensu* Waddington). Other species are less selective as to what material they will copy for their songs. For example, in a common-environment experiment on two closely related species, Marler and Peters found that when presented with the same tape-recorded regime of song sparrow and swamp sparrow songs, song sparrows will copy heterospecific as well as conspecific elements, but swamp sparrows will not. Other species are capable of copying virtually anything they hear, the best-known examples probably being brown thrashers, northern mockingbirds (*Mimus polyglottos*), marsh warblers (*Acrocephalus palustris*), Indian hill mynahs (*Gracula religiosa*), and superb lyrebirds (*Menura novaehollandiae*).

Conclusion

The study of bird song learning is only about 40 years old, and is still in its relative infancy. Nevertheless, it is a system that has a tremendous potential as a model system, given (1) our considerable knowledge of the neurobiology of the songbird vocal control system, (2) its many parallels with human language learning, and (3) our ability to investigate how the system functions in both the lab and the field. A fourth potential advantage is simultaneously a significant problem: What do we do with the staggering diversity of song-learning programs observed in the songbird group (4000-plus species)? This diversity must give pause to any investigator who would consider

one particular songbird species – say the zebra finch (presently the most popular species in neurobiological studies) – as representing the songbird learning program. The field will need to address this problem and use this comparative variation as a research tool if we are to move into the next phase of this very fruitful research area.

Glossary

Fusiform gyrus – The part of the inferior surface of the temporal lobe that is involved in processing visual word forms (i.e., orthography).

Inferior frontal gyrus – The part of the lateral frontal lobe and consists of three subsections. Pars opercularis is superior and posterior and is involved in phonological processing. Pars orbitalis is anterior and inferior and is involved in semantic processing. Pars triangularis is in between these two subsections and is involved in syntax processing.

Inferior parietal cortex – The part of the lateral parietal lobe that is involved in integration between representations and consists of three subsections. Supramarginal gyrus arches over the upturned end of the lateral fissure, angular gyrus arches over the superior temporal sulcus, and inferior parietal lobule is superior to these two gyri and lies below the intraparietal sulcus.

Middle temporal gyrus – The part of the lateral temporal lobe in between the superior and inferior temporal gyri that is involved in processing verbal meanings (i.e., semantics).

Orthography – The writing system of a language that describes the nature of individual symbols used (e.g., graphemes) and the rules for writing these symbols (e.g., spelling).

Phonology – The sound system of a language that describes the nature of individual sounds used (i.e., phonemes) and the rules for combining these sounds (e.g., speech).

Semantics – The meaning system of a language that not only includes parts of words (i.e., morphemes) and individual words, but can also span phrases, sentences, and discourse.

Superior temporal gyrus – The part of the superior temporal lobe that is involved in processing auditory word forms (i.e., phonology).

Syntax – The grammar system of a language that includes the rules for constructing sentences.

have put forth the interactive specialization approach to functional brain development in humans. According to this approach, over development, there is increasing specialization of brain regions and pathways into systems that have different computational principles. Once these specialized systems have started to develop, there is increasing integration between these systems. This is likely to be a cascaded process because studies have shown that abnormal interactions between systems affect their development. The interactive specialization approach builds upon research on the networks of dynamical systems. Specifically, small-world networks have clusters of tightly interconnected nodes (e.g., specialized areas) with few long-distance connections between nodes (e.g., integration). These networks have several beneficial principles, including enhanced signal-propagation speed, computational power, and synchronizability.

The interactive specialization approach is supported by a body of behavioral and neuroimaging literature. Increasing specialization with development is consistent with the finding that there is synaptogenesis and pruning of synapses over childhood into adolescence that occur at different time points for different brain regions. Increasing specialization is also consistent with meta-analyses showing that brain activation patterns become more focal over development with greater activation of task-relevant regions and less activation of regions irrelevant to task performance. These age-related changes in the brain are consistent with behavioral evidence showing lack of specialization in infants and young children, for example, in the processing of color and motion. Increasing integration with development is consistent with the finding of gradual increases in white matter tracts over childhood into adolescence and with electroencephalogram evidence showing increasing coherence (i.e., correlation) between brain regions. There is also behavioral evidence for increasing integration between specialized systems, for example, in numerical development. In support of developmental changes in both specialization and integration, resting-state functional magnetic resonance imaging (fMRI) has shown age-related decreases in short-range connections suggestive of specialization and age-related increases in long-range connections suggestive of integration. This article presents data from neuroimaging in language and reading which suggest that these processes of specialization and integration characterize functional brain development in humans.

A Model of Development

Some have argued that a single cognitive process may involve the functional integration of many specialized areas. Consistent with this, Johnson and his colleagues

Over the past few years, a working model has been formulated of how auditory and visual word representations may be processed in the brain. This has been done using spelling judgments to index orthographic processing, rhyming judgments to index phonological processing, and meaning-relatedness judgments to index semantic processing, in both the visual and auditory modalities. This model suggests a left lateralized network with orthographic processing involving visual association areas, including fusiform gyrus; phonological processing involving auditory association areas, including superior temporal gyrus; and semantic processing involving amodal association areas, including middle temporal gyrus. Mappings between these representational systems seem to be mediated in part by heteromodal areas in inferior parietal cortex. These posterior systems are strongly interconnected with anterior systems in the frontal lobe that seem to play a critical role in modulating posterior representations. Studies have suggested that the anterior inferior portion of inferior frontal gyrus (i.e., pars orbitalis) is involved in semantic processing, whereas the posterior superior region of inferior frontal gyrus (i.e., pars opercularis) is involved in phonological processing. A region in between (i.e., pars triangularis) seems to be involved in syntax processing.

Representational Systems

Orthography

Behavioral research shows that reading acquisition is marked by greater elaboration of orthographic representations involving increases in the number of lexical representations, in the precision of these representations, and in the interconnectivity among these representations. fMRI studies show age-related increases in activation in fusiform gyrus when presented with words or nonwords in the visual modality (see **Figure 1**), suggesting a greater functional elaboration of this system. In addition, event-related potential (ERP) studies show an amplitude increase from kindergarten to second graders in early occipital responses when reading words and magnetoencephalography (MEG) studies show that early occipitotemporal activation when processing visual words is delayed in children compared to adults. Adults also show greater selective activation than children in left fusiform gyrus when processing visual word forms as compared to auditory word forms, suggesting that adults have a more specialized system for orthographic processing in response to task demands. In contrast to adults, children show greater overlap in brain activation when processing visual or auditory word forms. Although visual word forms seem to become more specialized, studies show increasing connectivity between orthographic and phonological representations over childhood. Altogether,

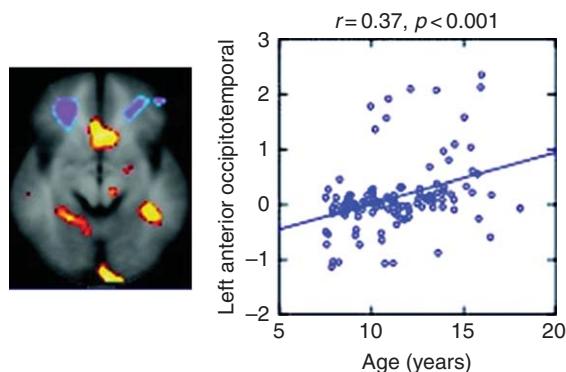

Figure 1 Developmental increases in fusiform gyrus during orthographic processing. Left brain image: correlation map between age and activation during a nonword rhyming task (partialed for accuracy). Areas in red and yellow indicate a positive correlation (note left anterior occipitotemporal cortex), and blue and purple indicate a negative correlation. Right scatter plot: correlation between age and left anterior occipitotemporal region of interest. From Shaywitz BA, Skudlarski P, Holahan JM, et al. (2007) Age-related changes in reading systems of dyslexic children. *Annals of Neurology* 61: 363–370.

these results suggest that orthographic representations become more elaborated and specialized with development, but that they also become more interactive with phonological representations.

Greater elaboration of fusiform gyrus has also been shown in learning studies in adults and greater specialization of fusiform gyrus over development has been demonstrated in other cognitive domains. Training in face recognition results in increased activation in fusiform gyrus, suggesting that elaboration of representations with learning occurs in other cognitive domains. Over development, increasing specialization in fusiform gyrus has also been shown during face processing. Although children and adults show a similar amount of activation in fusiform gyrus, it is distributed differently. Adults show greater activation in right medial as compared to lateral fusiform gyrus, whereas children show about an equal amount of activation in lateral and medial regions. In addition, studies have shown developmental increases in selectivity of responses to faces, natural objects, and manufactured objects. These studies suggest that elaboration and specialization of representations may be general characteristics of learning and development in the brain.

A greater role of left fusiform gyrus in orthographic processing seems to be related to developmental and learning-related reductions in activation in right fusiform gyrus. Developmental decreases in right fusiform gyrus activation have been shown for an implicit reading task that involved determining whether there was an ascending letter in visually presented words. Studies have also shown that learning to read mirror-reversed text in adults is associated with decreases in activation in inferior temporal regions in the right hemisphere and increases of

activation in left fusiform gyrus. Some have suggested that reading acquisition is initially a right-hemisphere process relying more on global visual forms, with greater engagement of the left hemisphere with increasing skill as analytic mappings are made between letters/symbols and phonemes/syllables.

Phonology

As with orthographic processing, phonological processing seems to be characterized by increasing specialization of representations. Six-month-olds show large ERPs over both left occipital and left temporal regions when listening to speech. During the first 3 years of life, there is a gradual reduction of the left occipital response so that at 36 months children show a reliable response to speech stimuli only over the left temporal region. In an ERP study that presented known and unknown auditory words to infants, 13- to 17-month-olds showed a differential response to these word types over frontal, parietal, and temporal sites in both hemispheres, whereas 20-month-olds showed a differential response only over temporal and parietal sites in the left hemisphere. Similar ERP effects have been reported when contrasting known words with nonsense auditory words. fMRI studies of auditory speech processing have similarly shown developmental increases from 21- to 39-month-olds in superior temporal gyrus activation and simultaneous decreases in occipital, frontal, and cerebellar regions (see **Figure 2**). The consolidation of the activation over left auditory cortex in all of these studies suggests that this region is becoming specialized for processing speech early in development. However, this increasing specialization seems to continue through childhood.

Older children show substantial overlap in brain activation associated with processing auditory or visual word forms. In contrast, adults show greater selective activation of left superior temporal gyrus when processing auditory as compared to visual word forms. There is also a developmental increase from childhood to adolescence in the connectivity between primary auditory cortex and superior temporal gyrus during spelling tasks in the auditory modality and during auditory narrative comprehension. In addition, there are developmental increases in left superior temporal gyrus activation during processing linguistic prosody. All of these findings suggest that the superior temporal region becomes more specialized for phonological processing over development.

Several studies with adults have shown increased activation in the superior temporal region associated with learning new phonological or auditory information. Adults learning Chinese tones, for example, show increased activation in left superior temporal gyrus. Increased activation in left superior temporal sulcus has been observed in French speakers learning to associate English auditory words with pictures. Widespread increases in activation in bilateral superior temporal gyrus have been shown when native Japanese speakers learn the non-native /r-l/ contrast of English. Finally, ERP studies show enhanced auditory cortical representations with musical training in children, in skilled adult musicians, and in adults learning new phonemic distinctions. All of these studies indicate that learning new auditory information is associated with increased activation in superior temporal regions, which may be associated with increasing elaboration of these sound-based representations.

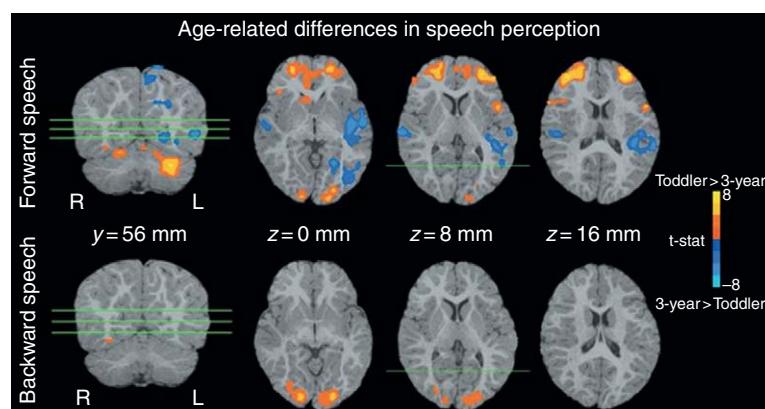

Figure 2 Developmental increases in superior temporal gyrus during phonological processing. Top row: 3-year-olds showed greater activation for listening to forward speech compared to rest as compared to toddlers in bilateral superior temporal gyrus and other regions (blues), and toddlers showed greater activation in other regions (reds). Bottom row: 3-year-olds and toddlers did not show a difference in superior temporal gyrus for backward speech compared to rest. From Redcay E, Haist F, and Courchesne E. (2008) Functional neuroimaging of speech perception during a pivotal period in language acquisition. *Developmental Science* 11(2): 237–252.

Semantics

As with orthographic and phonological processing, semantic processing seems to be characterized by increasing elaboration with development and learning. Behavioral studies have shown both a larger number of lexical entries and greater connections among these entries in older compared to younger children. Developmental increases in activation in middle temporal gyrus have been observed during a narrative comprehension task in the auditory modality. Developmental increases in activation in middle temporal gyrus have also been reported for semantic association judgment tasks in both the visual and auditory modalities (see **Figure 3**). Studies have also reported greater activation in middle temporal gyrus for weakly associated word pairs as compared to strongly associated word pairs, suggesting that developmental increases in this region are associated with semantic processing *per se* and not some other nonlexical process. Greater activation for weakly associated pairs may result from more extensive activation of the semantic system to identify distant relationships. The elaboration of semantic representations in middle temporal gyrus over development seems to be similar cross-linguistically, as age-related increases in this region have also been demonstrated in Chinese.

Learning studies suggest that the elaboration of semantic representations are not associated with development alone, as studies on adults have shown that semantic training results also in greater activation in middle temporal gyrus. Studies have also reported that higher

accuracy among children is correlated with greater activation in middle temporal gyrus on tasks that require a judgment of semantic association of word pairs and on semantic plausibility judgments to sentences, suggesting that children with lower accuracy have less elaborated semantic representations. Since children with lower accuracy seem to have underdeveloped semantic representations, they may rely to a greater degree on retrieval and selection mechanisms. A large body of research in adults suggests that greater activation in inferior frontal cortex is associated with more effortful retrieval or greater selection demands. The finding that lower accuracy is correlated with greater activation in inferior frontal gyrus during semantic tasks suggests that these children engage controlled processing to a greater degree. This interpretation is consistent with studies showing connectivity from inferior frontal gyrus to middle temporal gyrus is stronger in children with lower accuracy during semantic tasks in both the auditory and visual modalities.

Behavioral research suggests that as children become more skilled readers, they rely less on semantic representations for rapid word recognition. As the mapping between orthography and phonology becomes more automatic, semantic representations may have less opportunity to influence this rapid process. This behavioral effect is supported by brain imaging studies that show only children, and not adults, activate middle temporal gyrus during rhyming and spelling tasks in the visual and auditory modalities. Children also show greater middle temporal involvement while processing

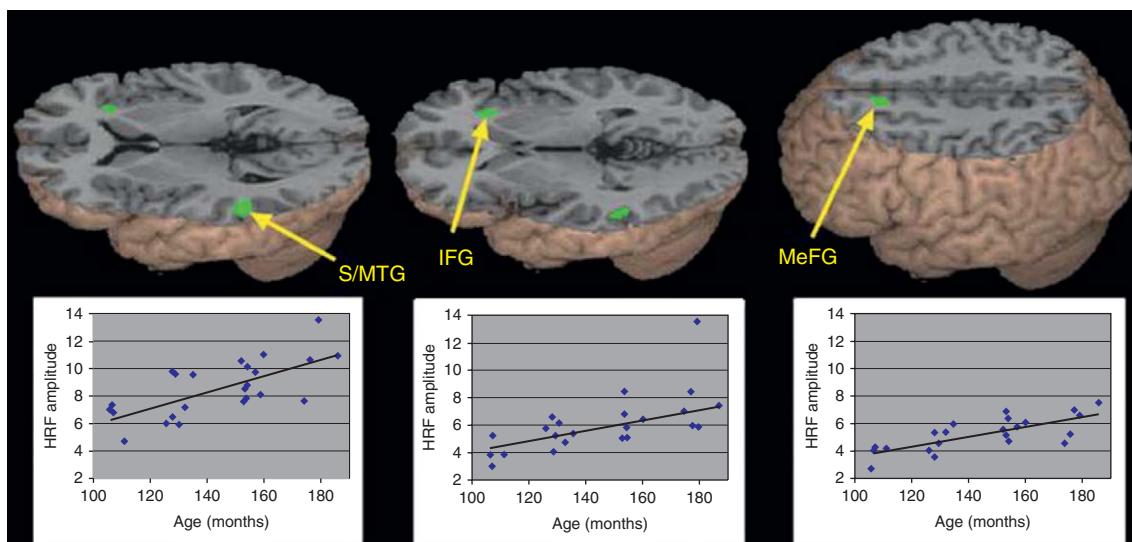

Figure 3 Developmental increases in middle temporal gyrus during semantic processing. Top brain images: correlation between age and activation during a meaning relatedness judgment to auditorily presented words in left middle temporal gyrus among other regions (green). Bottom scatter plots: correlation between age and activation in left middle temporal gyrus and other regions. From Chou TL, Booth JR, Burman DD, et al. (2006) Developmental changes in the neural correlates of semantic processing. *Neuroimage* 29: 1141–1149.

synonyms during a phonological task involving homophone judgments (e.g., plain–plane) to visual words. The middle temporal gyrus activation suggests that children are activating semantics during tasks that do not require access to these representations for correct performance. The reduction in activation in middle temporal gyrus with development suggests that semantics may play a reduced compensatory role as reading acquisition proceeds. This is not to imply that high-skill readers have a less elaborated semantic system, but rather that their more developed orthographic and phonological processing allows semantics to have less influence on rapid word recognition.

Syntax

Studies examining grammatical processing also suggest increasing specialization with development. An ERP study of toddlers examined activation associated with processing closed class words (e.g., prepositions and conjunctions) that are purported to index-syntactic processing. Twenty-month-olds showed similar negative potentials over the left and right hemispheres, 28- to 30-month-olds showed a more prominent negative potential over the right hemisphere, whereas the 36- to 42-month-olds showed only a negative potential over the left frontal region. Other studies suggest that these left anterior ERP negativities associated with syntactic processing show a prolonged developmental time course, because they appear to be qualitatively different between children and adults until about 6 years of age. Both the more diffuse bilateral activation and the consolidation of responses in left frontal regions in younger children suggest increasing specialization with development. Studies that have directly compared syntax to semantic processing using fMRI are consistent with these ERP studies. They report that children show greater overlap in activation in inferior frontal gyrus as compared to adults (see **Figure 4**), again suggesting developmental increases in specialization.

Greater involvement of left inferior frontal gyrus in syntax processing is also associated with language learning in adults. There is greater activation in inferior frontal gyrus for grammatical as compared to ungrammatical strings after learning an artificial grammar; and there is greater activation in inferior frontal gyrus over training sessions when learning an artificial grammar. Studies suggest that the increase of inferior frontal gyrus activation with learning is specific to grammatical and not ungrammatical forms in these artificial languages. Further, learning syntactic rules that follow universal grammar results in increased activation in inferior frontal gyrus, but learning rules that do not follow universal grammar does not result in increases in activation in inferior frontal gyrus. Altogether, these results suggest that inferior

frontal gyrus plays an increasing role in syntactic processing with learning and development.

Parietal Integration

One of the central skills associated with reading acquisition is the development of automatic and accurate mappings of orthographic to phonological forms. This increase in automaticity is associated with increasing elaboration of the connections between these systems at different levels, including grapheme–phoneme, onset–rime, and whole-word connections. Several studies in adults suggest that inferior parietal cortex is involved in extracting statistical regularities between orthography and phonology. Studies also show developmental differences in inferior parietal cortex during tasks that require mapping between orthography and phonology. Adults show greater activation than children in this region during rhyming tasks in the visual modality and spelling tasks in the auditory modality. Developmental differences on similar tasks have been replicated when comparing younger to older children (see **Figure 5**). Developmental increases in inferior parietal cortex have also been shown in Chinese for a rhyming task in the visual modality. Altogether, these studies suggest a developmental increase in the elaboration of the system for mapping between orthography and phonology.

The change of activation in inferior parietal cortex in adults when learning new relationships between orthography and phonology seems to be similar to the developmental differences reported for this region. Studies have shown that learning to associate new orthographic information with phonological information modulates activation in this region. For example, Japanese speakers learning to make associations between Korean letters and speech sounds produced more activation in angular gyrus early in training and functional connectivity of this region with posterior inferior temporal gyrus increased with learning. Another study compared the neural correlates of three training approaches to learning nonwords. Both phonological (rhyming judgments) and orthographic (letter judgments) training produced greater activation in angular gyrus as compared to semantic training, consistent with the involvement of this region in mapping between letters and sounds.

Inferior parietal cortex is a heteromodal region that appears to be involved in the integration of many different representational systems, not just orthography and phonology. There are developmental increases in activation in inferior parietal lobule during semantic association judgments to both visually and auditorily presented word pairs. This age-related increase has also been demonstrated for Chinese in meaning tasks in the visual

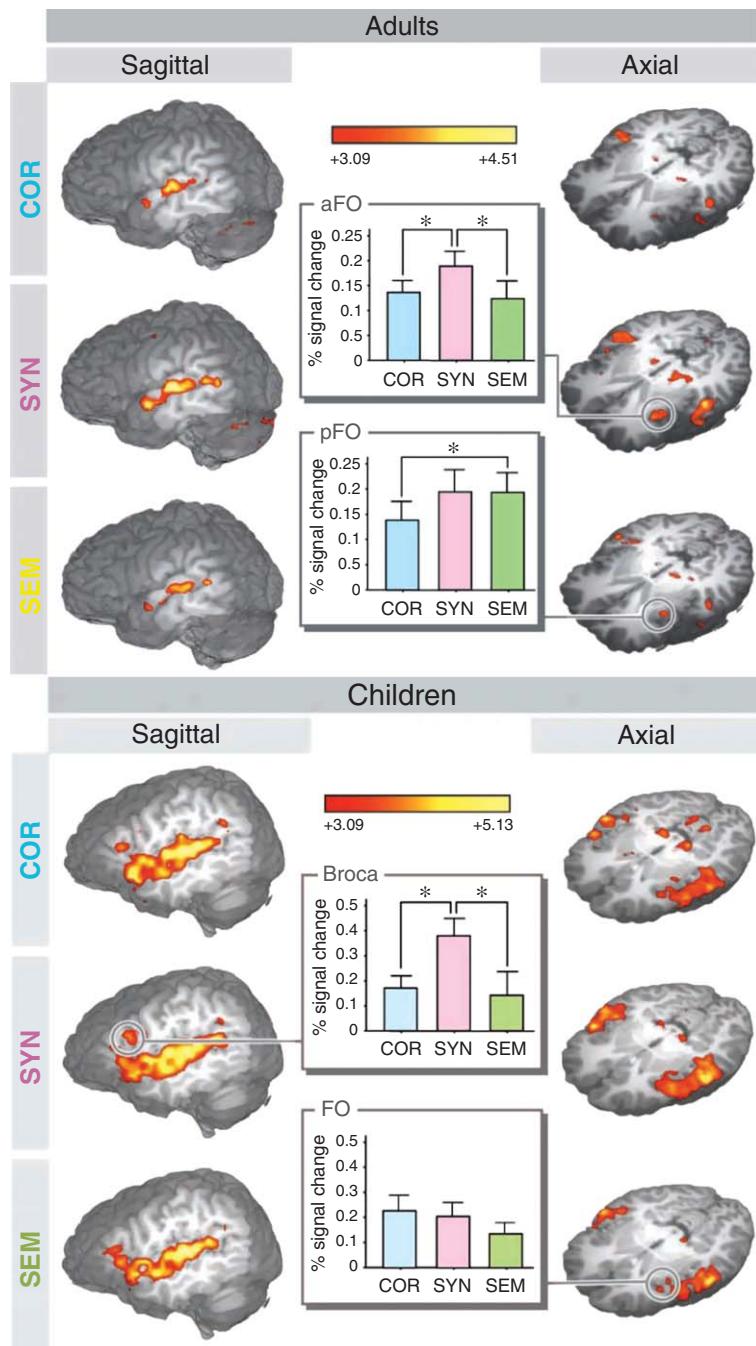

Figure 4 Developmental increases in specialization of inferior frontal gyrus during syntax processing. (Top) Adults showed greater activation in anterior frontal operculum (aFO) for syntax violations (SYN) compared to semantic violations (SEM) or correct sentences (COR). They showed greater activation for semantic violations compared to correct sentences in posterior frontal operculum (pFO). (Bottom) Children did not show differences in frontal operculum for the different sentence types. From Brauer J and Friederici AD (2007) Functional neural networks of semantic and syntactic processes in the developing brain. *Journal of Cognitive Neuroscience* 19(10): 1609–1623.

modality. Activation in inferior parietal lobule is also modulated by association strength, with strongly associated pairs producing greater activation in this region as compared to weakly associated pairs. The modulation by association strength suggests that the developmental

increase in activation of inferior parietal lobule is directly related to semantic processing and not to some other nonlexical process. The locus of activation in inferior parietal cortex for semantic tasks is different from the locus for rhyming tasks, suggesting that this region has

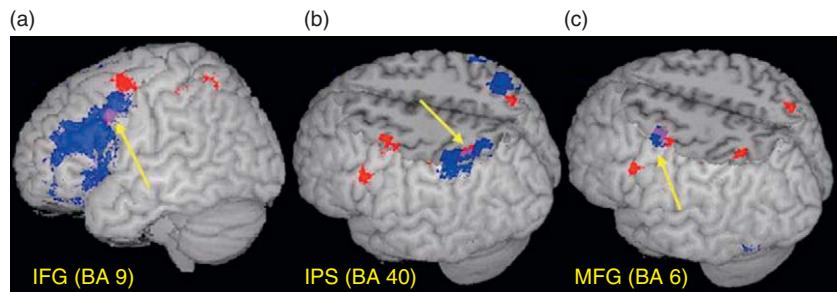

Figure 5 Developmental increases in inferior parietal cortex during a task requiring integration between representations. Developmental increase in activation in a rhyming task in the visual modality (red) overlaid on other maps. (a) Blue represents conflicting (e.g., pint–mint, grade–laid) versus nonconflicting (e.g., lake–cake, press–list) words in inferior frontal gyrus. (b) Blue represents correlation between the differential activation for conflicting compared to nonconflicting conditions and accuracy in conflicting conditions in intra-parietal sulcus. (c) Blue represents developmental increase in activation in the perceptual condition in middle frontal gyrus. From Bitan T, Cheon J, Lu D, Burman DD, Gitelman DR, Mesulam MM, and Booth JR. (2007) Developmental changes in activation and connectivity of phonological processing. *Neuroimage* 38: 564–575.

distinct areas involved in different kinds of integration, both of which show developmental increases in activation. This specialization within inferior parietal cortex may be similar to that shown for the anterior inferior portion of the inferior frontal gyrus in semantic processing and for the posterior superior portion of the inferior frontal gyrus in phonological processing.

Frontal Modulation

One of the most robust neuroimaging findings is that increased activation of the inferior frontal gyrus is associated with both development and learning. Developmental increases in activation have been shown in cross-sectional fMRI studies for silent verb generation to auditorily presented concrete nouns, verbal semantic fluency to auditorily presented categories, category judgments to visually presented words, ascending letter judgments to visually presented words, and for rhyming judgments to visually and auditorily presented words. Developmental increases have also been shown in longitudinal fMRI studies during verb generation to auditorily presented words. Developmental increases have also been established in Chinese for meaning judgments to visually presented words. Most of artificial grammar learning studies in adults also show increases in inferior frontal gyrus activation. Although there are many studies showing acquisition and maturational effects in the inferior frontal gyrus, the specific role of this region in learning and development has not yet been clearly defined.

Dynamic causal modeling (DCM) has been used to clarify the nature of the developmental increase in activation in inferior frontal gyrus. This technique allows the examination of patterns of effective connectivity between brain regions by looking at how the directionally specific influence of one brain region on another is affected by an

experimental manipulation. In a study with adults, a spelling task in the visual modality was marked by converging influences from other brain regions on intraparietal sulcus, whereas a rhyming task in the visual modality was marked by converging influences on superior temporal sulcus, suggesting that these regions are sites of integration for processing task-selective information – orthographic processing for spelling and phonological processing for rhyming. In both tasks, modulating influences also converged on inferior frontal gyrus. As each task also modulated the influence of inferior frontal gyrus on the task-selective region, it was proposed that inferior frontal gyrus is involved in top–down modulation of task-selective regions in a way that differentially enhances their sensitivity to task-relevant information. A developmental study showed that the preferential influence of inferior frontal gyrus on the task-specific integration site was stronger in adults than in children. In other words, there were developmental increases in the modulation of inferior frontal gyrus on intraparietal sulcus for spelling and on superior temporal sulcus for rhyming. This result suggests that stronger activation in inferior frontal gyrus in adults reflects their relatively greater top–down modulation of posterior task-selective regions. A later study replicated this developmental increase, within children and adolescents, in the effective connectivity of inferior frontal gyrus on superior temporal sulcus during a rhyming task in the visual modality. This study additionally showed that this developmental increase was specific to words with conflicting orthographic and phonological representations (e.g., pint–mint, grade–laid) as compared to nonconflicting representations (e.g., lake–cake, press–list) – suggesting the enhancement of relevant representations when irrelevant representations are conflicting (see **Figure 6**). The weaker top–down modulation in younger children also suggests that they may be more strongly driven by perceptual input. Consistent with this,

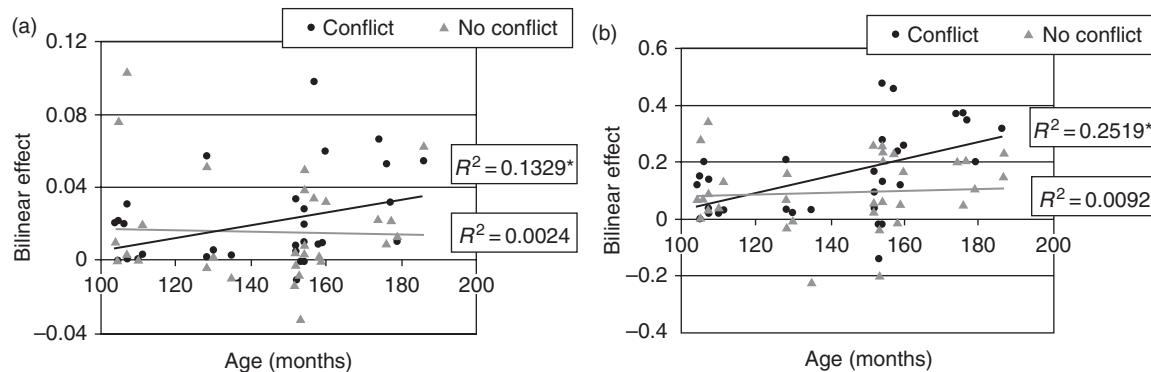

Figure 6 Developmental increases in effective connectivity of inferior frontal gyrus on posterior regions. Correlation of age with the modulatory effects of conflicting and nonconflicting conditions on the converging connection from inferior frontal gyrus (a) and fusiform gyrus (b) into lateral temporal cortex during a rhyming task in the visual modality. The proportion of variance in the modulatory effect explained by the correlation with age is presented. From Bitan T, Cheon J, Lu D, Burman DD, Booth JR. (2009) Developmental increase in top-down and bottom-up processing in a phonological task: An effective connectivity, fMRI study. *Journal of Cognitive Neuroscience* 21(6): 1135–1145.

connectivity from fusiform gyrus to superior temporal sulcus also shows developmental increases for conflicting representations.

The weak modulation of prefrontal cortex on posterior regions in children may explain the ineffective cognitive control and increased susceptibility to interference from irrelevant stimuli that has been observed in children. Weaker top-down modulation may also be the underlying mechanism for the diffuse and less fine-tuned brain activation patterns observed in children compared to adults. In similarity to the developmental effects, learning in adults seems to be associated with increasing connectivity. Learning an artificial grammar is associated with increasing connectivity of left inferior frontal gyrus with left parietal lobe and right inferior frontal gyrus. Increasing connectivity with learning has also been shown in other cognitive domains, such as spatial and object processing.

The developmental increase in connectivity as revealed by DCM is consistent with several other lines of research. Neuroimaging studies have shown developmental increases in white matter through adolescence in left, but not right, arcuate fasciculus that connects anterior and posterior language regions in the left hemisphere. Neuroimaging studies have also shown increases through adolescence in white matter of the corpus callosum that connects the right and left hemispheres. Together, these studies suggest that development is characterized by prolonged increases in white matter and this may allow for the more efficient and rapid communication between brain regions. These developmental differences in white matter appear in contrast to studies that show synaptic pruning through adolescence and neuroimaging studies that show complex patterns of increases and decreases of

gray matter over development. These changes in synaptic pruning and gray matter may be associated with specialization, rather than integration, processes.

Conclusions

This article reviewed what is currently known about the neural substrate of reading and language development. Development seems to be characterized by increasing elaboration and specialization of orthographic, phonological, semantic, and syntax representations to specific regions in the left hemisphere. These principles of elaboration and specialization seem to be characteristic of other cognitive processing domains and many of these age-related changes also seem to characterize learning of written and oral language in adults. However, studies are needed that directly compare learning in adults to developmental changes in order to more thoroughly evaluate the skill-learning hypothesis that assumes the neural basis of behavioral and cognitive development in children is similar to skill acquisition in adults.

Effective connectivity is an advance over conventional analyses because it can determine the directional influence of one brain region on another and allows an examination of the dynamics of neurocognitive networks. Work on effective connectivity suggests that prefrontal cortex plays an increasing role over development in top-down modulation of posterior representational systems in reading and language. The neuroimaging literature is broadly consistent with the interactive specialization approach that argues human functional brain development is characterized by increasing specialization of brain regions as well as increasing integration between

brain regions. However, further research should elucidate how the processes of specialization and integration influence one another at different age points, in different brain regions and languages.

Glossary

Apoptosis – A pattern of programmed cell death, involving a series of specific biochemical events leading to characteristic cell morphology and death.

Neurogenesis – The process by which neurons are generated during development (and adulthood), through mitosis of precursors.

Neurulation – An early step of organogenesis in vertebrate embryos, beginning with the formation of the neural plate and ending with the closure of neural tube (the future nervous system).

Patterning genes – Families of proteins controlling transcription of other genes and playing a key role in the control of neuronal fate during development.

The diverse cognitive, social, emotional, sensorimotor, and vegetative functions of the brain depend on multiple networks of interacting neurons, which are surrounded by (and actively communicate with) supportive glial cells. These functional networks emerge from neuron populations that arise during the earliest periods of embryonic development. In this article, we describe the morphogenetic, molecular, and genetic mechanisms that regulate the generation and movements of cells required to elaborate region-specific populations whose interconnections form functional networks. We highlight general developmental principles including roles of patterning genes and signaling centers in brain formation.

Morphological Development of the Nervous System

Nervous system development is traditionally viewed as a sequence of events including precursor cell proliferation, mitotic cell cycle withdrawal, cell migration, axon and dendrite formation, neurotransmitter system expression, axon outgrowth to targets, synapse elaboration, and selective neuron survival based on appropriate target innervation. Separation of these events into discrete processes is more a pedagogical convenience than a fact, since many of these processes occur simultaneously, not only within brain regions, but also in the same cell. This is important to recognize, since it alters the way in which we

build conceptual models about possible effects of changing one process, and how it may in fact alter several concurrent processes.

Several principles guide our understanding of brain development. First, different brain regions and neuron populations are generated at distinct times and exhibit specific temporal schedules, a fact that influences the consequences of developmental insults. Second, the sequence of cellular processes comprising ontogeny predicts that abnormalities in early events necessarily lead to differences in subsequent stages, at times very distant from the initial insult. Third, specific molecular signals, such as extracellular growth factors, play roles at multiple developmental stages of the cell. Thus, changes in expression or regulation of a ligand or its receptor, by environmental insults or genetic mechanisms, will have effects on multiple developmental and maturational processes. In this review, we illustrate developmental processes relevant to both humans and rodents, since interspecies translation is a valuable goal.

The Neural Plate and Neurulation

The nervous system of the human embryo first appears between 2.5 and 4 weeks of gestation. During development, emergence of new cell types, including neurons, results from interactions between neighboring layers of cells. On gestational day 13, the embryo consists of a sheet of cells. Following gastrulation (day 14–15), which forms a two-cell-layered embryo consisting of ectoderm and endoderm, the neural plate region of the ectoderm is delineated by the underlying mesoderm, which appears on day 16. The mesoderm forms by cells entering a midline cleft in the ectoderm called the primitive streak. After migration, the mesodermal layer lies between ectoderm and endoderm and induces overlying ectoderm to become the neural plate. Induction usually involves release of soluble growth factors from one group of cells, which in turn bind receptors on neighboring cells, eliciting changes in nuclear transcription factors, which control downstream gene expression. In some cases, cell–cell contact-mediated mechanisms are involved.

The neural plate, whose induction is complete by 18 days, is a sheet of columnar epithelium and is surrounded by ectodermal epithelium, which will form the skin. After formation, the edges of the neural plate elevate, forming the neural ridges. Subsequently, changes in intracellular

cytoskeleton and cell–extracellular matrix attachment cause the ridges to merge in the midline and fuse, a process termed neurulation, forming the neural tube, with a central cavity presaging the ventricular system (**Figure 1**). Fusion begins in the cervical region at the hindbrain level (medulla and pons) and continues rostrally (anteriorly) and caudally (posteriorly). Neurulation occurs at 3–4 weeks of gestation in humans, and its failure results in anencephaly rostrally and spina bifida caudally.

Regional Differentiation

After closure, the neural tube expands differentially to form major morphological subdivisions that precede the major functional divisions of the brain. These subdivisions are important developmentally since different regions are generated according to specific schedules of proliferation and subsequent migration and differentiation. The neural tube can be described in three dimensions, including longitudinal, circumferential, and radial. The longitudinal dimension reflects the rostrocaudal organization, which most simply consists of brain and spinal cord. Organization in the circumferential dimension, tangential to the surface, represents two major axes: in the dorsoventral axis, cell groups are uniquely positioned from top to bottom. On the other hand, in the medial-to-lateral axis, there is mirror-image symmetry, consistent with right–left symmetry of the body. Finally, the radial dimension represents organization from the innermost cell layer adjacent to the ventricles to the outermost surface, and exhibits region-specific cell layering. At 4 weeks, the human brain is divided

longitudinally into the prosencephalon (forebrain), mesencephalon (midbrain), and rhombencephalon (hindbrain). These three subdivisions or vesicles divide further into five divisions by 5 weeks, consisting of the prosencephalon which forms the telencephalon (including cerebral cortex, hippocampus, and basal ganglia) and diencephalon (thalamus and hypothalamus), the mesencephalon, (midbrain), and the rhombencephalon yielding metencephalon (pons and cerebellum) and myelencephalon (medulla). Morphological transformation into five vesicles depends on region-specific proliferation of precursor cells adjacent to the ventricles, the so-called ventricular zones (VZs), as well as programmed cell death (see below).

In the circumferential dimension, organization begins very early and extends over many rostrocaudal subdivisions. In spinal cord, the majority of tissue comprises the lateral plates, which later divide into dorsal or alar plates, composed of sensory interneurons, and motor or basal plates, consisting of ventral motor neurons. Two other diminutive plates, termed the roof plate and floor plate, are virtually absent in maturity, however, play critical regulatory roles as growth factor signaling centers in the embryo. Indeed, the floor plate induces midbrain precursors to differentiate into dopamine-secreting neurons of the substantia nigra. Similarly, the roof plate induces dorsal neuron cell fate in the spinal cord. In the absence of roof plate, dorsal structures fail to form, such as cerebellum, and midline hippocampal structures are missing as well. Finally, in the radial dimension, the organization of layers is subdivision specific, produced by differential proliferation of VZ precursors and cell migration, described below.

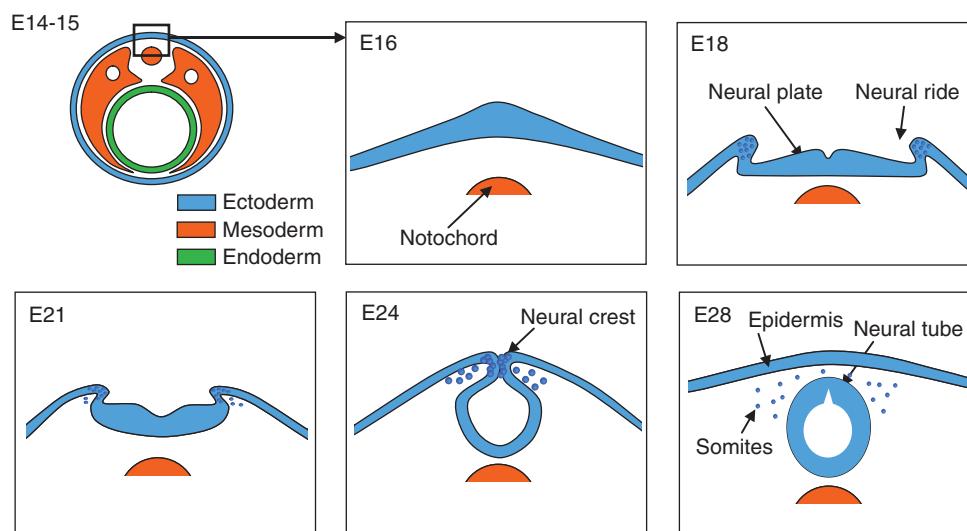

Figure 1 Mechanisms of neurulation. Neurulation begins with the formation of a neural plate in response to soluble growth factors released by the underlying notochord. The neural plate originates as a thickening of the ectoderm that results from cuboidal epithelial cells becoming columnar in shape. With further changes in cell shape and adhesion, the edges of the plate fold and rise, meeting in the midline to form a tube. Cells at the tips of the neural folds come to lie between the neural tube and overlying epidermis, forming the neural crest that gives rise to the peripheral nervous system and other structures.

The Ventricular and Subventricular Proliferative Zones

The distinct patterns of precursor proliferation and migration in different regions generate the radial organization of the nervous system. In each subdivision, final population size depends on the interplay of regulated neurogenesis with programmed cell death (see below). Precursor proliferation occurs primarily in two densely packed regions during development. The primary site is the ventricular zone (VZ) lining the walls of the entire ventricular system, and contributes to all brain regions. For select regions however, including cerebral cortex, hippocampus, and cerebellar cortex, precursors from the VZ migrate to secondary zones where they generate a more restricted range of cell types.

In the early embryo, neural tube VZ progenitors are arranged as a one-cell layer thick, pseudostratified neuroepithelium. The bipolar VZ precursors have cytoplasmic processes that span from the ventricular to the outer pial surface of the brain. During the cell cycle, the VZ appears multilayered, or stratified, because cell nuclei undergo movements, called interkinetic nuclear migration. New cells are produced through the cell cycle, which comprises four stages: mitosis (M), when nuclei and cells divide; G1, when cells double in size before dividing again; S-phase, when cells synthesize DNA and replicate chromosomes; and a brief G2 period, followed by M phase. Precursor cell division (M phase) occurs at the ventricular margin, producing two new cells (Figure 2). The progeny then reenter G1 as they move outward toward the pia. Under the influence of extracellular signals, these cells become committed to another round of division, marked by entry into S-phase, which occurs near the upper VZ margin. After replicating DNA, during G2, the nuclei move back down to the ventricular surface where they undergo mitosis and divide. The role of nuclear migration is not known, though it may allow nuclei access to environmental cues produced

by postmitotic cells that effect subsequent proliferation and gene expression.

At the earliest stages, VZ cells divide to increase the pool of progenitors before producing postmitotic neurons. Subsequently, during the prolonged period of neurogenesis, with each cell cycle on average, a cell divides giving rise to both a postmitotic neuron and another precursor that continues to divide, serving as a stem cell. At the end of neurogenesis, precursor division gives rise to two postmitotic neurons only, greatly increasing neuron production and depleting the precursor pool. The newly born neurons do not remain in the VZ, but instead migrate out to their final destinations, such as the cerebral cortical plate, traveling along the processes of radial glial cells (Figure 3). Like the bipolar VZ precursors described above, radial glia have one process associated with the ventricular surface and the other reaching the pial surface, a morphology consistent with the recent discovery that radial glia are in fact the dividing VZ precursors that produce cerebral cortical neurons. These neurons generated within localized VZ domains, known to express distinct patterning genes migrate to specific functional areas, though active debate remains concerning the relative roles of early expressed VZ genes versus in-growing thalamic afferents in determining cortical neuronal fate and function.

In addition to this general plan of neurogenesis in the VZ, secondary proliferative zones produce specific neuron populations in particular regions. For example, in cerebral cortex and thalamus, the subventricular zone (SVZ) produces astroglial cells, which can generate both oligodendrocytes and astrocytes. Moreover, recent studies in rodents, and likely relevant to humans, demonstrate convincingly that excitatory neurons of the upper cortical layers (2–4) are generated in the SVZ from precursors that do not bear radial processes, indicating distinct sets of regulatory mechanisms. In the hippocampus, secondary zones include the hilus, and, after puberty,

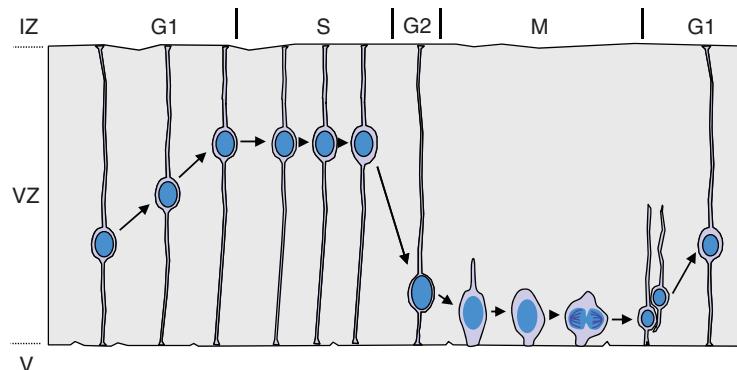

Figure 2 Interkinetic nuclear migration in the ventricular zone. During each cell cycle, nuclei move from the ventricular surface at G1 to the border of the ventricular zone where it enters S phase. Nuclei move down during G2, and reach the ventricular surface where they undergo mitosis. Asymmetric division leads to the generation of a postmitotic cell that leaves the ventricular zone to produce a neocortical neuron, while the remaining stem cell continues to divide. IZ, Intermediate zone; VZ, ventricular zone; V, ventricle. Modified from Jacobson 1991.

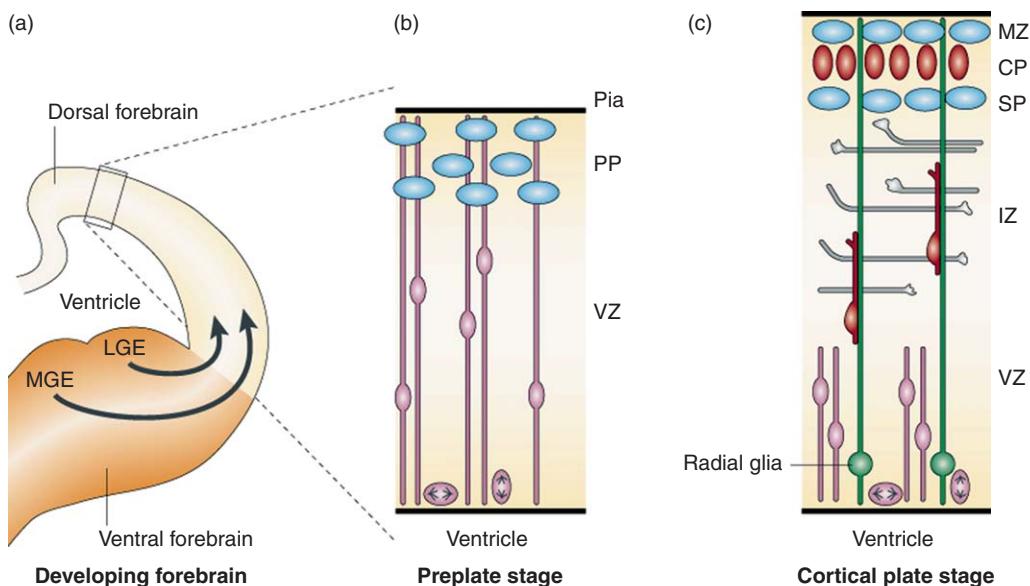

Figure 3 Schematic drawing of radial and tangential migration during cerebral cortex development. (a) A coronal section of one-half of the developing rat forebrain. The dorsal forebrain gives rise to the cerebral cortex. Medial ganglionic eminences (MGEs) and lateral ganglionic eminences (LGEs) of the ventral forebrain generate neurons of the basla ganglia and the cortical interneurons. The arrows indicate the tangential migration route for γ -aminobutyric acid interneurons to the cortex. The boxed area (enlarged in (b) and (c)) shows the developing cortex at early and late stages. (b) In the dorsal forebrain, the first cohort of postmitotic neurons migrate out from the ventricular zone (VZ) and create a preplate (PP) below the pial surface. (c) Subsequent postmitotic neurons will migrate along radial glia through the intermediate zone (IZ) and take position in the middle of the preplate, creating a cortical plate (CP) between the outer marginal zone (MZ) and inner subplate (SP). Ultimately, the CP will be composed of six layers that are born sequentially, migrating in an inside-to-outside pattern. Horizontal processes in the IZ represent axon terminals of thalamic afferents. From Nadarajah B and Parnavelas JG (2002) Modes of neuronal migration in the developing cerebral cortex. *Nature Neuroscience* 3: 423.

the subgranular zone that produces dentate gyrus granule neurons life long, the basis of adult neurogenesis. Finally, in newborn cerebellum, the overlying external germinal layer (EGL) generates granule neurons for several weeks in rodents and for 7–20 months in humans. After neurogenesis is complete, the VZ differentiates into ciliated epithelial cells forming the ependymal lining. Underlying this layer, undifferentiated cells of the SVZ, referred to as subependyma, have been identified as a neural stem cell population, capable of proliferating and generating neurons and glia throughout life.

Radial and Tangential Patterns of Neurogenesis and Migration

Throughout the nervous system, newly generated neurons normally migrate away from proliferative zones to achieve final destinations. There are three patterns of migration, including two radial patterns that are observed on cells originating from the VZ, referred to as inside-to-outside and outside-to-inside, and a third involving non-radial or tangential migration of cells, some of which originate in secondary proliferative zones.

In developing cerebral cortex, the most well-characterized mechanism is radial migration from underlying VZ to appropriate cortical layers in inside-

to-outside fashion. In addition, however, inhibitory γ -aminobutyric acid (GABA) interneurons that are generated in ventrally located medial ganglionic eminences (**Figure 3**) reach the cortex through tangential migration in the intermediate zone along axonal processes or other neurons. The phylogenetically older hypothalamus and spinal cord exhibit the reverse order of cell generation. The first formed postmitotic neurons lie superficially and late-generated cells localize toward the center. Furthermore, cells do not always lie in direct extension from their locus of VZ generation. Rather, some groups of cells migrate to specific locations, as observed for neurons of the inferior olfactory nuclei. Another distinct pattern is observed in the hippocampus, which involves both radial and nonradial patterns of neurogenesis and migration. The pyramidal cell layer, Ammon's Horn CA 1–3 neurons, is generated in a typical outside-to-inside fashion in the dorsomedial forebrain for a discrete period, from 7 to 15 weeks of gestation in human, and exhibits complex migration patterns. By contrast, the other major population, dentate gyrus granule neurons, starts appearing at 18 weeks, and exhibits prolonged postnatal neurogenesis, originating from several migrating secondary proliferative zones. The neurons in developing cerebellum also exhibit both radial and tangential migration. Purkinje cells leave the fourth ventricle VZ and exhibit radial migration,

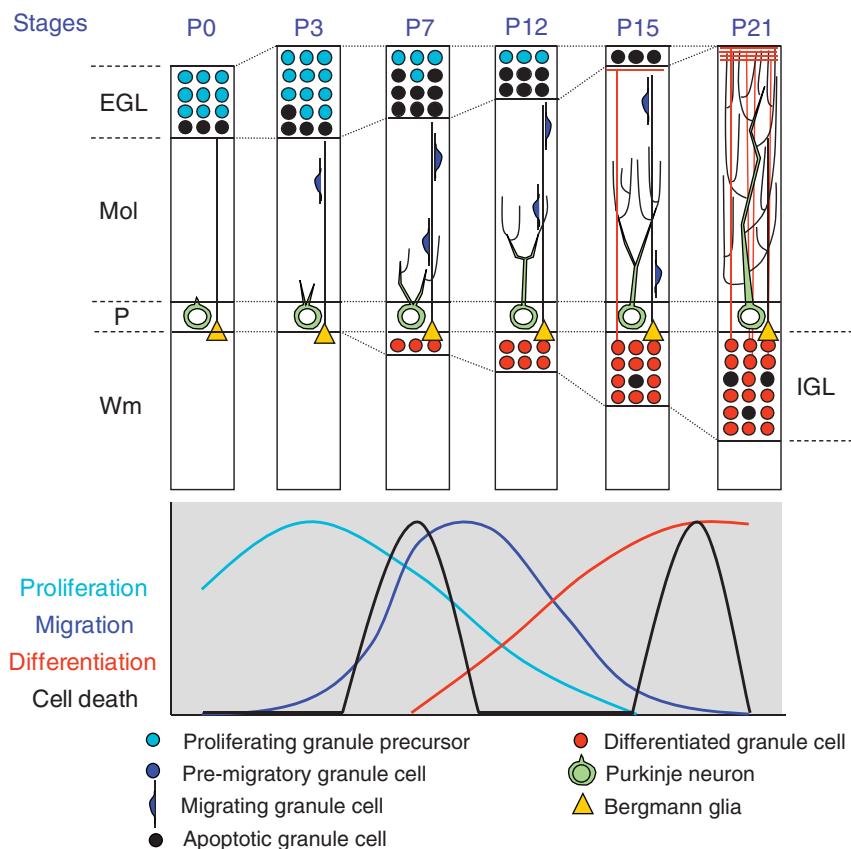

Figure 4 Neurogenesis, migration, and differentiation of granule cells during cerebellar development. Granule cell precursors proliferate in the external germinal layer. After exiting the cell cycle, they migrate through the molecular layer and past the Purkinje neurons to reach the internal granule layer where they differentiate and make synapses. Neurons that do not migrate properly or that do not establish proper synaptic connections undergo apoptosis. EGL, external germinal cell layer; Mol, molecular layer; P, Purkinje cell layer; IGL, internal granule cell layer; Wm, white matter.

whereas other precursors from the rhombic lip migrate tangentially to cover the cerebellar surface, establishing the EGL, a secondary proliferative zone. From EGL, newly generated granule cells migrate radially inward to create the internal granule cell layer (**Figure 4**). Finally, granule interneurons of olfactory bulb exhibit a different kind of migration, originating in the SVZ of the lateral ventricles overlying the striatum. These neuroblasts divide and migrate simultaneously in the rostral migratory stream in transit to the bulb, on a path comprised of chains of cells that support forward movements.

Neuronal Differentiation

After newly produced neurons and glial cells reach their final destinations, they differentiate into mature cells. For neurons, this involves outgrowth of dendrites and extension of axonal processes, formation of synapses, and production of neurotransmitter systems, including receptors and selective reuptake sites. Most axons will become insulated by myelin sheaths produced by oligodendroglial cells. Many of these events occur with a peak period from

5 months of gestation onward. During the first several years of life, many neuronal systems exhibit exuberant process growth and branching, which is later decreased by selective pruning of axons and synapses dependent on experience, while myelination continues for several years after birth and into human adulthood. To innervate diverse distant targets, neurons extend axons, which travel a complex route, passing through various structures. The growth cone is the structure located at the tip of axon, which ensures proper elongation in response to numerous guidance molecules. The growth cone has rod-like extensions called filopodia that bear on their surfaces receptors for specific guidance cues present in extracellular matrix (**Figure 5**). Interactions between filopodial receptors and environmental cues cause growth cones to move forward, turn, or retract.

Developmental Cell Death

Developmental cell death is a reproducible and spatially and temporally restricted death of cells that occurs during the organism's development. Programmed cell death

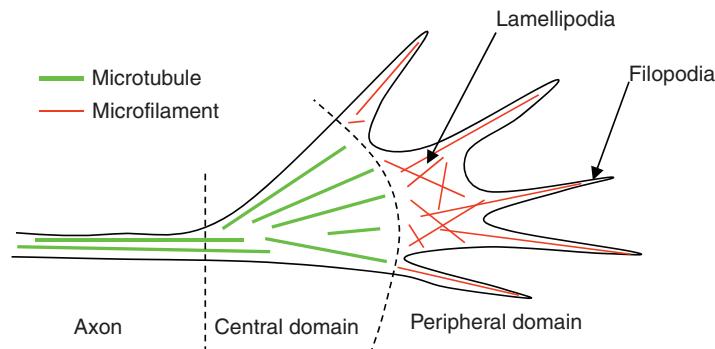

Figure 5 Structure of the growth cone. The cone is subdivided into two domains: the central domain, which contains mitochondria and microtubules, and the peripheral domain, which contains veil-like lamellipodia and spike-like filopodia. In the lamellipodia, microfilaments consisting of actin form a meshwork, while in filopodia they have the same orientation. Cell surface receptors on growth cone processes sense extracellular guidance cues to control navigation.

occurs at multiple stages, interacting with neurogenesis and differentiation with precise and complex mechanisms. Three types of developmental cell death have been described: (1) phylogenetic cell death that removes structures in one species that served evolutionarily earlier ones, such as the tail or the vomeronasal nerves; (2) morphogenetic cell death, which sculpts the fingers from the embryonic paddle, is required to form the optic vesicles and the caudal neural tube; and (3) Histogenetic cell death, a widespread process that allows removal of select cells during development of specific brain regions. Developmental cell death not only contributes to eliminate differentiated neurons that failed to establish proper connections, but also occurs in neural precursors and immature neurons.

Based on morphological criteria, three types of programmed cell death have been described. The first type, apoptotic cell death, is the most common, and is characterized by chromatin condensation and membrane blebbing, followed by nuclear fragmentation and cell shrinkage. Autophagic degeneration involves contiguous groups of degenerating cells and features autophagic vacuoles and pyknotic nuclei. Much less common are nonlysosomal disintegration and cytoplasmic-type cell death, forms that exhibit similarities to necrosis. As apoptosis, is the major type of developmental cell degeneration, underlying molecular mechanisms has been extensively examined. Mechanisms of apoptotic cell death are divided into three phases (Figure 6). First, a regulatory phase, termed ‘initiation,’ involves integration of multiple death and survival signals. These signals converge toward common components, such as initiator caspases, cysteine-containing aspartate-specific proteases that serve as a switch to initiate (or not) cell degeneration. Subsequently, in the case of cell death ignition, the second phase called ‘execution’ begins. During the execution phase, effector enzymes such as caspases-3 and -7 are activated and cleave specific substrates, leading to the last and irreversible step of

programmed cell death called ‘apoptosis.’ Apoptosis refers to the final events of programmed degeneration, when exposed chromosomal DNA between the nucleosomes is cleaved by a caspase-activated DNase (CAD), cytoskeletal components are disassembled, and plasma membranes swell into vesicles termed apoptotic bodies. The cell is then dismantled and phagocytosed without any release of its contents, which would otherwise induce a damaging inflammatory response.

Regulators of Developmental Processes

Morphological conversion of the nervous system through the embryonic stages, from neural plate through neural tube to brain vesicles, is controlled by interactions between extracellular factors and intrinsic genetic programs. In many cases, extracellular signals are soluble growth factors secreted from regional signaling centers, such as the notochord, floor or roof plates, or the surrounding mesenchymal tissues. The precursor’s ability to respond (competence) depends on cognate receptor expression, which is determined by patterning genes whose proteins regulate gene transcription.

Patterning Genes

The term patterning genes connotes families of proteins that serve primarily to control transcription of other genes, whose products include other transcription factors or proteins involved in cellular processes, such as proliferation, migration, or differentiation. Patterning genes exhibit combinatorial interactions as well as distinct temporal sequences of expression and function, acting in a hierarchical fashion. At the most general level, regionally restricted patterning genes participate in specifying the identity, and therefore function, of cells in which they are expressed. Initially, nervous system induction begins at

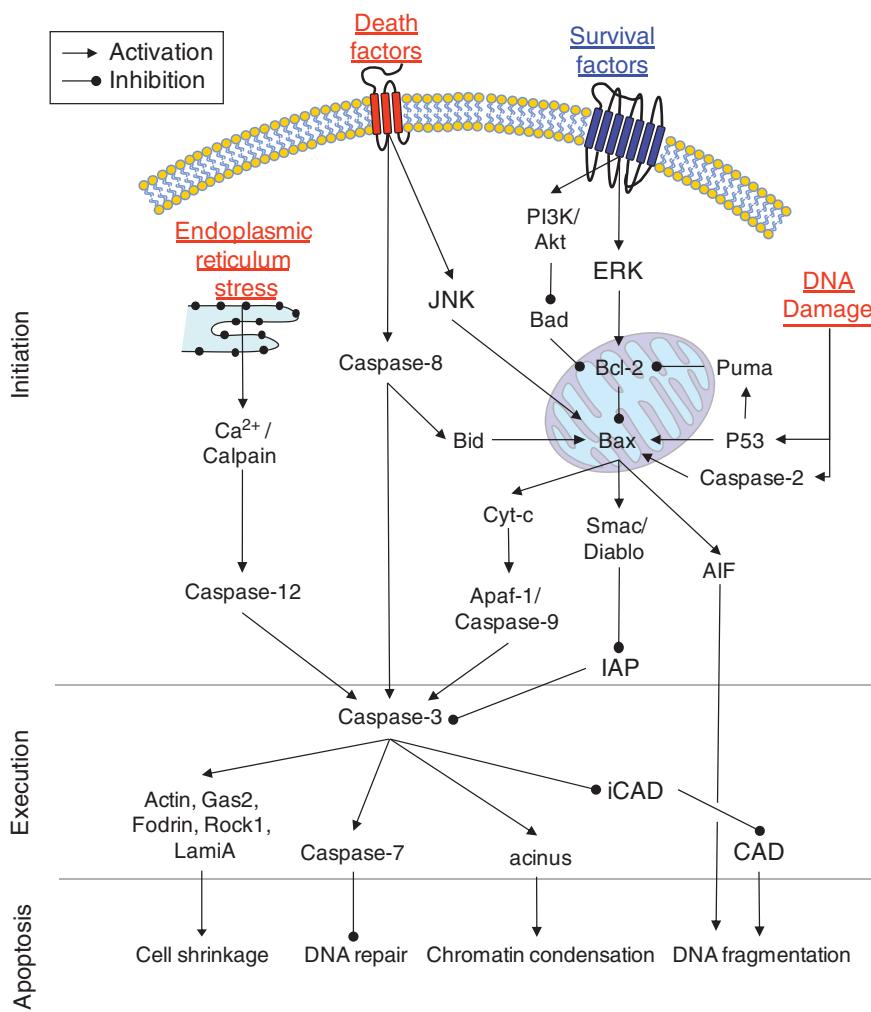

Figure 6 Regulation of apoptosis. Various positive and negative signals are integrated to trigger caspase activation. Caspases are present in cells as inactive zymogens and are converted into their active form through cleavage of the proenzyme. Each caspase cleaves its substrates at specific aspartate residues; thus, initiator caspases cleave effector caspases leading to their activation. AIF, apoptosis inducing factor; Apaf-1, apoptotic protease-activating factor-1; Bax, Bcl-2 associated protein; Bcl-2, B cell lymphoma-2; CAD, caspase-activated DNase; Cyt-c, cytochrome-c; ERK, extracellular-regulated protein kinase; IAP, inhibitor of apoptosis proteins; JNK, c-jun N-terminal kinase; PI3K, phosphatidyl inositol triphosphate kinase; Smac, second mitochondria-derived activator of caspases = DIABLO.

the neural plate stage when the underlying mesenchyme, surrounding epidermal ectoderm, and the notochord produce signaling molecules that affect the identity of the neighboring cells, leading to neural tube formation and closure. Subsequent subdivisions of the brain, and of cerebral cortex specifically, are identified by regionalized gene expression in the proliferative VZ of the neural tube, a ‘protomap’ that leads to subsequent differentiation of distinct types of neurons in each mature (postmitotic) region. Thus, the protomap of the embryonic VZ apparently predicts the cortical regions it will generate, and may instruct the hierarchical temporal sequence of patterning gene expression. It appears that the different genes underlie multiple stages of brain development, including (1) determining that ectoderm will give rise to

nervous system (as opposed to skin); (2) defining the dimensional character of a region, such as positional identity in dorsoventral or rostrocaudal axes; (3) specifying cell class, such as neuron or glia; (4) defining when proliferation ceases and differentiation begins; (5) determining specific cell subtype, such as GABA interneuron, as well as projection pattern; and (6) defining laminar position in the region, such as cerebral cortex.

Patterning genes have been intensively studied in the telencephalon, where signaling centers are localized to the edges of the cortex. In the dorsal midline, there are several centers, including the anterior neural ridge, an anterior cranial mesenchyme secreting FGF8 and Shh, among others, the roof plate, and at the junction of the roof plate with the telencephalic vesicle, the cortical hem

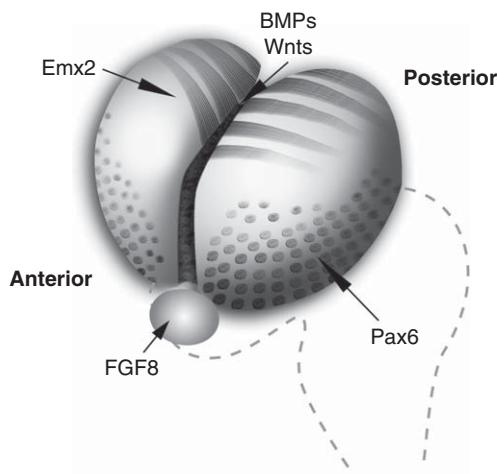

Figure 7 Patterning genes and signaling centers in the developing cerebral cortex. This schematic diagram shows a lateral-superior view of the two cerebral hemispheres of the embryonic mouse, sitting above the midbrain and hindbrain (broken lines). The anterior-lateral extent of Pax6 gene expression is indicated by circles. The posterior-medial domain of Emx2 expression is indicated by stripes. The genes exhibit continuous gradients of expression that decrease as they extend to opposite poles. The signaling factor fibroblast growth factor 8 (FGF8) is produced by and released from mesenchymal tissue in the anterior neural ridge, which regulates Pax6 and Emx2 expression. In the midline, bone morphogenetic proteins (BMPs) and Wingless-Int proteins (Wnts) are secreted from other signaling centers, including the roof plate and the cortical hemis. Courtesy of E. DiCicco-Bloom and K. Forgash.

(**Figure 7**). Other factors originate laterally at the junction of the dorsal and ventral forebrains, as well as from midline basal forebrain structures themselves. These inductive signals tend to work in opposing pairs of gradients, such as BMPs dorsally and Shh ventrally, or retinoic acid rostrally and FGFs caudally. Altogether, the synthesis, release, and diffusion of these inductive growth signals from signaling sources produce concentration gradients that impose distinct neural fates on responsive cells, carried out by inducing discrete regions of transcription factor gene expression.

Regulation of Neurodevelopment by Extracellular Factors

In addition to interacting with patterning genes to specify different brain regions, extracellular factors serve to regulate directly cell proliferation, migration, differentiation, and survival (**Table 1**). Extracellular factors are known to stimulate or inhibit proliferation of VZ precursors and originate from the cells themselves, termed autocrine, neighboring cells/tissues, or paracrine, or from the general circulation, as in endocrine, all sources known to affect proliferation in prenatal and postnatal developing brain. However, in addition to stimulating reentry of cells into

the cell cycle, termed a mitogenic effect, extracellular signals also enhance proliferation by promoting survival of the mitotic population, a trophic action. Stimulation of both pathways is necessary to produce maximal cell numbers. A number of mitogenic growth factors are now well characterized, including (1) those stimulating proliferation, such as basic fibroblast growth factor (bFGF), EGF, IGF-I, Shh; (2) those inhibiting cell division, such as pituitary adenylate cyclase-activating polypeptide (PACAP), GABA, and glutamate, and members of the TGF superfamily; and (3) those such as neurotrophins (BDNF and NT3) that promote survival of both precursors and newly generated progeny. The effects of mitogenic signals depended critically on the stage-specific program of regional development. In the cerebral cortex VZ of the embryonic rat, proliferation is controlled by pro-mitogenic bFGF and antimitogenic PACAP, which are expressed as autocrine/paracrine signals. At later stages, when gliogenesis predominates, bFGF affects glial numbers selectively. Similar to cerebral cortex, later generated populations of granule neurons, such as in cerebellum and hippocampal dentate gyrus, are also sensitive to growth factor regulation.

More generally, extracellular growth factors thus not only interact with local patterning genes, but also control precursor cell proliferation, differentiation, and survival during brain development. Since these processes respond to growth factors, there is also the possibility that traumatic events (e.g., hypoxia, maternal/fetal infection, and toxicant exposure), inflammatory conditions and pharmacotherapies, which alter growth factor expression, may have an impact on the developmental processes in unforeseen ways to contribute to brain dysfunction.

Glossary

Circadian rhythms – Biochemical, physiological, and behavioral processes occurring in a cyclic fashion with a period of about 24 h (*circa diem* = about a day). A circadian rhythm is roughly a 24 h cycle of living entities, including plants, animals, fungi, and cyanobacteria. The term ‘circadian,’ coined by Franz Halberg, comes from the Latin *circa*, ‘around,’ and *diem* or *dies*, ‘day,’ meaning literally ‘approximately 1 day.’ The formal study of biological temporal rhythms, such as daily, tidal, weekly, seasonal, and annual rhythms, is called chronobiology. Circadian rhythms are endogenously generated, and can be entrained by external cues, called *Zeitgebers*, the primary one of which is daylight. These rhythms allow organisms to anticipate and prepare for precise and regular environmental changes.

Epigenetics – Heritable changes in phenotype (appearance) or gene expression caused by mechanisms other than changes in the underlying DNA sequence. These changes may remain through cell divisions for the remainder of the cell’s life and may also last for multiple generations. Nongenetic factors cause the organism’s genes to behave (or ‘express themselves’) differently. The best example of epigenetic changes in eukaryotic biology is the process of cellular differentiation. During morphogenesis, totipotent stem cells become the various pluripotent cell lines of the embryo which, in turn, become fully differentiated cells. In other words, a single fertilized egg cell – the zygote – changes into the many cell types including neurons, muscle cells, epithelium, blood vessels, etc., as it continues to divide. It does so by activating some genes while inhibiting others.

Neuroplasticity – Is the changing of neurons and the organization of their networks and, thus, their function by experience. This idea was first proposed in 1892 by Santiago Ramón y Cajal – the proposer of the neuron doctrine though the idea – was largely neglected for the next 50 years. The brain consists of nerve cells or neurons (and glial cells) which are interconnected, and learning may happen through changing of the strength of the connections between neurons, by adding or removing connections, or by adding new cells.

‘Plasticity’ relates to learning by adding or removing connections, or adding cells. During the twentieth century, the consensus was that lower brain and neocortical areas were immutable in structure after

childhood, implying that learning only happens by changing of connection strength, whereas areas related to memory formation, such as the hippocampus and dentate gyrus, where new neurons continue to be produced into adulthood, were highly plastic. This belief is being challenged by new findings, suggesting all areas of the brain are plastic even after childhood. Furthermore, studies determined that environmental changes could alter behavior and cognition by modifying connections between existing neurons and via neurogenesis in the hippocampus and other parts of the brain, including the cerebellum. Decades of research have now shown that substantial changes occur in the lowest neocortical processing areas, and that these changes can profoundly alter the pattern of neuronal activation in response to experience.

Prenatal stress – Prenatal stress refers to stress imposed on the fetuses via the pregnant mother. Prenatal maternal stress is exposure of an expectant mother to distress, which can be caused by stressful life events or by environmental hardships. The resulting changes to the mother’s hormonal and immune system may harm the fetus (and after birth, the infant’s) immune function and brain development. In the context of this article, prenatal stress was accomplished by submitting pregnant females to individual physical restraint thrice daily (at 09:00, 12:00, and 17:00 h) for 45 min in transparent plastic cylinders (7 cm diameter and 19 cm long) and exposure to bright light. This was performed daily during the last week of pregnancy until delivery. Control pregnant females were left undisturbed in their home cages.

Sleep-wake cycle – Daily successions of sleep and wake episodes as defined by electroencephalographic recording. A sleep disorder (somnipathy) is a medical disorder of the sleep patterns of a person or animal. Some sleep disorders are serious enough to interfere with normal physical, mental, and emotional functioning. A test commonly ordered for some sleep disorders is the polysomnogram. Due to rapidly increasing knowledge about sleep in the twentieth century, including the discovery of rapid eye movement (REM) sleep and sleep apnea, the medical importance of sleep was recognized. The medical community began paying more attention than previously to primary sleep disorders, such as sleep apnea, as well as the role and quality of sleep in other conditions. By the 1970s in the USA,

clinics and laboratories devoted to the study of sleep and sleep disorders had been founded, and a need for standards arose. Sleep medicine is now a recognized subspecialty within internal medicine, family medicine, pediatrics, otolaryngology, psychiatry, and neurology in the USA. Certification in sleep medicine shows that the specialist: "has demonstrated expertise in the diagnosis and management of clinical conditions that occur during sleep, that disturb sleep, or that are affected by disturbances in the wake-sleep cycle. This specialist is skilled in the analysis and interpretation of comprehensive polysomnography, and well-versed in emerging research and management of a sleep laboratory."

Introduction

Early adverse events induced long-term alterations in behavioral and neuroendocrine responses to stress. Early environmental triggers or stressors may thus have a permanent rather than a transient effect on the organism. In fact, the activity of nongenetic factors (epigenetics) early in life that result in the permanent organization or imprinting of physiological systems is known as perinatal programming. In the human, intrauterine growth retardation and low birth weight are considered indexes of prenatal stress, and these intriguing findings have spawned the fetal origin hypothesis of adult cardiovascular disease, and more recently, metabolic syndrome. When pregnant females are submitted to extreme conditions like stress and/or undernutrition, which induce reduced birth weight, their offsprings display persistent alterations in metabolic and endocrine function that are associated with emotional and cognitive performance through life. Interestingly, postnatal manipulations such as cross-fostering, handling, and environmental enrichment can counteract these effects, while other manipulations such as neonatal corticosterone administration and maternal separation have effects similar to those of prenatal stress.

Maternal glucocorticoids – one of the most important actors of the hypothalamic–pituitary–adrenal (HPA) axis – have been proposed to mediate the relationship between low birth-weight and various medical conditions such as hypertension, type 2 diabetes, ischemic heart disease, and different types of cognitive and behavioral disorders in adulthood. Glucocorticoids act both at the periphery and in the brain to reorient energy resources of the organism. Glucocorticoids bind to two types of intracellular receptors – mineralocorticoid and glucocorticoid

receptors (MRs and GRs, respectively). Activation of these receptors modify, by genomic mechanisms, the transcription of key regulatory proteins. Glucocorticoids play an essential role in development and many bodily functions, including inflammation, adaptive immunity, cognitive processes, and response to stress. While short-term activation of the HPA axis allows adapting to the challenge, in the long run this can be detrimental for the organism. Resistance to glucocorticoids can occur in many diseases, including autoimmune disorders, respiratory disease, lymphoma, and depression. Thus, chronic environmental exposure to abnormal concentration of glucocorticoids, as in repeated stress episodes, can have permanent effects in animals and humans. Epigenetic regulation (DNA methylation, histone acetylation, and histone methylation) is also a crucial process for the normal development and function of the nervous system, ranging from cell differentiation and neuronal plasticity to behavior such as learning and memory, sleep, and anxiety. Developmental dysregulation of the epigenome under the effects of glucocorticoids could be at the origin of various pathological conditions, including psychiatric disorders. Recent findings point, for instance, to an epigenetic regulation of GRs in the hippocampus of suicide victims with a history of childhood abuse.

Perinatal life is a period of increased plasticity, especially for the stress system, and is therefore particularly sensitive to epigenetic factors. Thus, events occurring early in life, acting through abnormal maternal hormones and/or behavior, can alter the trajectory of the programming of the HPA-axis response to stress. For example, increased mothering behavior was found to produce stable alterations in DNA methylation and chromatin structure. The resulting increase in transcription of the GR gene impacts on the feedback regulation of the HPA axis. Furthermore, early adverse life events that expose the organism to high levels of glucocorticoids have strong, long-term effects on the behavioral and neuroendocrine response to stressors, including growth, metabolism, reproduction, and the inflammatory/immune response. In order to study the response to stress while avoiding the obvious ethical dilemmas that are involved in human experimentation, different animal models have been developed since 1957 to assess the effects of perinatal stress on the activity of the HPA axis and circadian rhythms.

Another facet of the animal model of perinatal stress is the occurrence of several behavioral and neuroendocrine abnormalities in adult animals born from stressed mothers that parallel those found in human depression. These abnormalities can be reversed by chronic antidepressant treatment.

Early Life Events, HPA Axis, and Related Behaviors

Exposure to prenatal stress results in increased responsiveness of the HPA axis to stress. Levels of both types of corticosteroid receptors (MRs and GRs) are reduced in the hippocampus of adult offspring, revealing a possible mechanism for the deficit of the HPA-axis feedback-process by which glucocorticoids downregulate their own production. These abnormalities are sex dependent. Moreover, prenatal stress accelerates age-dependent alterations in the HPA axis. Indeed, the period of hyporesponsiveness of the HPA axis is abolished in newborn rats that have been prenatally stressed and circulating glucocorticoid levels are increased in middle-aged prenatally stressed animals when compared to those of controls. Female prenatally stressed rats durably exhibit attenuated corticosterone secretion in response to an intense inescapable footshock. In males, prenatal stress also results in the hyporesponsiveness of the HPA axis when animals are exposed to an alcohol challenge. These results indicate that the HPA-axis alterations induced by prenatal stress vary according to sex, as well as to the nature and intensity of the stressor. The hyperactivity of the HPA axis observed both in male and female prenatally stressed rats is accompanied in adult rats by increased anxiety-like behavior in males, and an increased behavioral response to novelty in both males and females. Data on the impact of prenatal stress in females are more controversial. In general, the effects of perinatal restraint stress (PRS) on anxiety are less marked in females and

possibly even contrary to those in males, as evidenced by the decreased anxiety-like behavior observed in prenatally stressed females (**Figure 1**). In contrast, depression-like behavior has been observed both in males and females. Prenatally stressed male rats also show a decrease in benzodiazepine receptors in the hippocampus, which could explain the high level of anxiety reported in this gender.

Prenatal stress alters not only reactive adaptation (the stress response), but also predictive adaptation by changing the circadian rhythms. In fact, prenatal stress increases corticosterone secretion at the end of the light period in both males and females, and throughout the diurnal cycle only in females. These effects could be mediated, at least in part, by a reduction in hippocampal MRs/GRs at specific times of the day. Alterations in circadian corticosterone activity are associated with disturbed circadian behavioral cycles, increased REM sleep, and sleep fragmentation. Enhanced levels of corticosterone are positively correlated to anxiety-like behaviors and sleep disorders. Altered sleep may be a mediator of the relationship between anxiety and eating disorders. Excessive fetal exposure to glucocorticoids could also be a common early-life factor which accounts for the association among hyperinsulinemia, hypertension, and hyperleptinemia often seen in individuals of low birth-weight. There is also some clinical evidence on the possible association of leptin levels with depression. In this regard, it is interesting to note that prenatal stress alters feeding behavior and metabolism. A possible explanation for this effect is that the postnatal leptin surge functions as

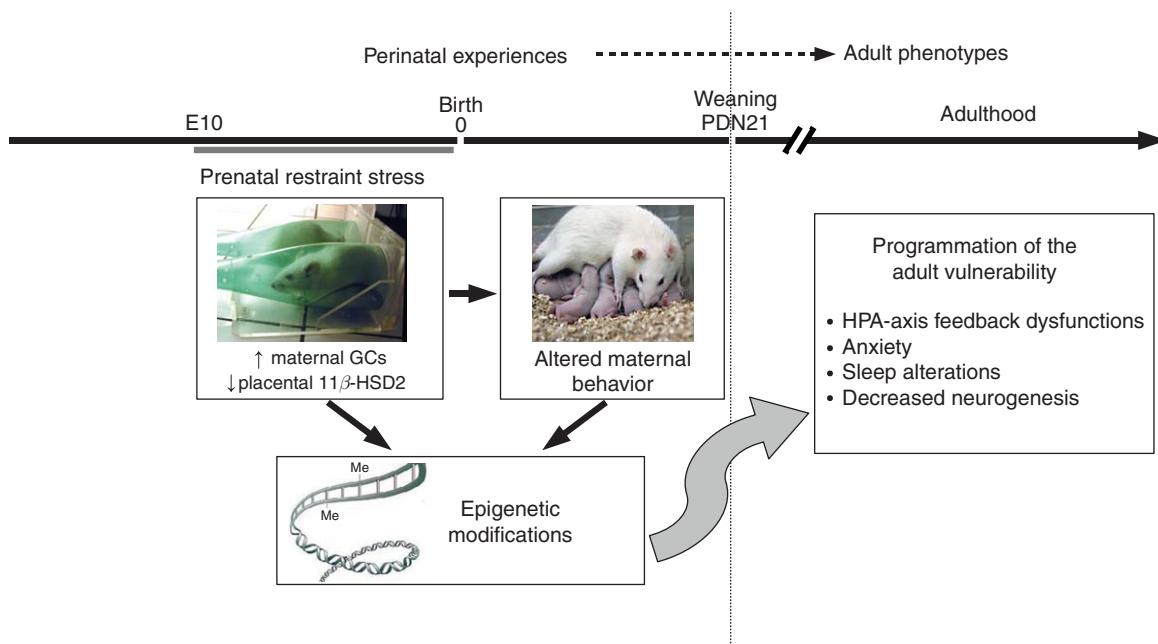

Figure 1 Perinatal experiences contributing to adult phenotypes. GC = glucocorticoid; HSD = hydroxy steroid dehydrogenase.

a developmental factor for hypothalamic projections involved in energy balance and prenatal stress reduces leptin levels in the offspring. Prenatally stressed male rats also display decreased plasma growth hormone (GH) levels at birth and hypoglycemia associated with a reduction in the expression of glucose transporter proteins (GLUT1) in the placenta at the same stage. Together, these findings indicate that maternal stress induces long-lasting disturbances in feeding behavior and increase the risk for type 2 diabetes mellitus. These developmental alterations could be due to the adverse glucocorticoid environment as well as to changes in maternal behavior and interaction with pups during the neonatal period.

Prenatal stress also increases the vulnerability to psychostimulants and other substances of abuse. It also has no effect on the average ethanol preference of female rats, as measured by the consumption of a 5% alcohol solution, either in the basal situation or after a procedure of conditioned fear. However, the strong inter-individual differences in baseline ethanol preference become exacerbated, in the sense that the high-ethanol-preferring rats that have been prenatally stressed still consume ethanol at a high level after conditioned fear whereas their nonstressed controls decrease their preference. Prenatal stress has no effect on ethanol preference in low-alcohol-preferring rats. These results suggest that early adverse events could induce epigenetic modifications that lead to an increased vulnerability to alcohol preference in adult female rats. PRS did not modify alcohol preference in males. Surprisingly, however, chronic alcohol consumption tended to impair spatial recognition in control male rats, but improved memory performance in male PRS rats. This effect of alcohol could be mediated, at least in part, by metabotropic glutamate (mGlu1) receptors, given that chronic ethanol exposure increases these receptors in PRS rats.

The impact of prenatal stress on glucocorticoid secretion and behavior is apparent earlier than its impact on cognition. Cognitive alterations are observed later in life and could be one consequence of early HPA-axis hyperactivity. Interestingly, a positive correlation between adrenal weight and latency to reach the hidden platform in the Morris water maze test was found in old prenatally stressed female and male rats. The effect of prenatal stress on spatial memory in females varies as a function of age, probably in relation to hormonal fluctuations. Prenatal stress alters memory in juvenile female rats but improves it in young adults.

Prenatal Stress and Hippocampal Plasticity

The influence of prenatal stress on neuronal plasticity has been studied in the hippocampus, where it reduces neurogenesis and increases the expression of the

polysialylated form of the neural cell adhesion molecule (PSA-NCAM) and brain-derived neurotropic factor (BDNF), probably as a compensatory effect of decreased neurogenesis. Prenatal stress reduces also the expression and activity of type-5 mGlu5 receptors in the hippocampus. This is relevant because mGlu5 receptors are implicated in the regulation of both synaptic plasticity and neurogenesis, in addition to anxiety. Prenatal stress also affects the expression of Homer proteins, critical to glutamatergic signaling, in the brains of offspring. Numerous proteins and RNAs have been implicated in epigenetic control. Among these, genes encoding tissue-specific transcription factors contribute to epigenetic status but have functions that are not necessarily required to establish or to maintain this status *per se*. Prenatal stress acts at both the transcriptomic and proteomic level with a reduction in the phosphorylation of cAMP response element binding (CREB) proteins, and downregulation of several proteins involved in signaling, protein processing, and cell-proliferation cascades. As discussed above, several lines of evidence point to epigenetic mechanisms as mediators of the long-term propagation and amplification of pre/perinatal stress, which could lead to behavioral changes via alterations on neuronal plasticity. This hypothesis is supported by the fact that stress-signaling nuclear hormone receptors, such as MR and GR, are key transcriptional factors with mainly negative activity. It is thus very conceivable that their inhibitory activity is memorized through epigenetic DNA methylation patterns in the regulatory regions of glucocorticoid target genes, leading at least in part to the effect called perinatal programming. MR and GR both bind to glucocorticoid-response elements (GREs), but only the GR can interfere with the transcriptional activity of other DNA-bound transcription factors, such as activator protein-1 (AP1) complex, nuclear factor-kappa B (NF- κ B), phosphorylation of CREB (pCREB), etc., inducing a general reorientation of cell activity. Over the last decade, a variety of studies have established a firm link between chromatin and transcription. One such example is the extensive work on various histone post-translational modifications which correlate strongly with dynamic transcriptional activity. Various protein modifications finely tune the cellular functions of each protein. Understanding the relationship between post-translational modifications and functional changes is essential for the comprehension of signaling at this level. Altogether, these observations make glucocorticoids a perfect candidate able – from early during development until all along through life – to program from the single cells to the entire organism, via DNA transcription and remodelling, protein expression, metabolism and circadian regulation, to behavior such as feeding and sleep. Until now, mechanistic studies on epigenetic influence of perinatal programming have

mainly focused on the role of serotonin as an epigenetic factor able to act on chromatin remodeling.

Prenatal Stress as an Animal Model of Depression: Predictive Value

Chronic treatment with antidepressants is effective in reverting alterations induced by prenatal stress at the behavioral and neurobiological level. Prenatally stressed rats, therefore, represent an interesting animal model for the evaluation of the efficacy of pharmacotherapeutic interventions in psychiatric disorders such as depression. Furthermore, results obtained in the last decade have proven the validity and the interest of this rat animal model as a model of epigenetic programming. In summary, prenatally stressed rats display long-term impairment of feedback inhibition in the HPA axis and prolonged stress-induced corticosterone secretion, which has been attributed to the observed decrease in central GRs. This is associated with a generalized disorganization of circadian rhythms and several behavioral abnormalities that are positively correlated to glucocorticoid levels and include anxiety, immobility in the forced swim test, learning impairments, and paradoxical sleep. Concomitantly with the dysfunction in the feedback inhibition of the HPA axis, prenatally stressed rats display higher hippocampal expression of the early activation gene *c-fos* under basal conditions and a blunted Fos-protein response after exposure to stress.

Conclusion

Prenatal stress leads to long-term consequences at the behavioral and neurobiological level in the offspring of stressed mothers, with increased vulnerability to anxiety- and depression-like behavior, drug administration, and memory impairment. Among the mechanisms involved in these behavioral alterations, the hyperactivity of the HPA axis plays a crucial role in both the reactive (response to stress) and predictive (biological rhythms) adaptive processes. This altered adaptation or allostatic load is characterized in prenatally stressed male rats by decreased neurogenesis, altered mGlu and ionotropic glutamatergic neurotransmission, changes in brain GRs, and increased Fos, PSA-NCAM, and BDNF expression. Prenatally stressed female rats seem to be less sensitive in terms of hippocampal plasticity. Despite the hyperactivity of the HPA axis, they display reduced anxiety-like behavior and improved learning. As far as mechanisms are concerned, the high maternal corticosterone levels and altered maternal behavior following prenatal stress probably contribute to the long-term effects that are apparent in the offspring through epigenetic modifications.

Glossary

Affects – These are subjectively experienced feelings whose primary experience characteristics are various types of positively and negatively valenced arousal states in the brain that can be monitored by various approach and avoidance behaviors. Affects can occur in three major domains: (1) emotional arousals, (2) sensory stimulations, and (3) bodily homeostatic imbalances (yielding the three major types of affects – emotional, sensory, and body regulatory). Among the emotional affects, those emerging from SEEKING, LUST, CARE, and PLAY are primarily positive, and those emerging from RAGE, FEAR, and GRIEF are primarily negative.

Conditioned place preference (CPP) – A common behavioral test to evaluate whether animals have had rewarding or punishing experiences (positive or negative affect), as determined by whether they exhibit preferences or aversions to spatial locations (e.g., two- or three-chamber choice boxes) where they had specific types of experiences.

Dual-aspect monism – This is an ontological view, assuming that certain natural processes have both easily measurable and hidden aspects, and it provides an epistemological approach to study hidden aspects of nature. In other words, a measurable aspect of a phenomenon, such as the neural circuitry that generates emotional-instinctual behavior patterns, is used as a proxy to estimate the neural circuitry that is critical for generating the affective state that corresponds to the measurable behavior.

Endophenotype – A simpler component of a complex behavior pattern that can facilitate analysis of the underlying neurobiological mechanisms. The concept has been used extensively in psychiatry as a special kind of biomarker that can replace conceptual entities such as psychiatric syndromes and thereby help divide complex psycho-behavioral symptoms into clear and stable phenotypes that can be more definitively linked to underlying neural networks and genetic substrates.

Instincts – These are functional processes that are largely built into the organizational-functional structure of the brain. They are inherited tools for living, and hence are strongly controlled by the way genes construct the functional architecture of the brain. This does not mean that they are not refined and fine-tuned by their use during early development.

Limbic system – A system of functionally related neural midline structures in the brain that are primarily involved in distinct emotional and motivated behaviors. The concept started with the Papez circuit (the interconnected loop of hippocampus, fornix, mammillary bodies, mammilo-thalamic tract, dorsomedial thalamus, cingulate gyrus and frontal cortex, cingulum bundle and back to hippocampus), and elaborated by Paul MacLean. With additional anatomical work and functional analysis of related structures, especially the amygdala, hypothalamus, and periaqueductal gray, an extended limbic system concept emerged to highlight the territory in the brain that needs to be studied to understand basic emotions. The concept has been largely verified by human brain imaging studies as the primary regions of the brain that are critically important for the generation of primary-process emotionality.

Neuropeptides – Types of protein-like molecules made in the brain that serve as neurotransmitters or neuromodulators as well as hormones in the endocrine system. They are made up of short sequences of amino acids (usually 3–40) that are active in controlling information flow between neurons and also commonly function as hormone-type regulators of visceral processes within the gastrointestinal system.

Periaqueductal gray (PAG) – The neural tissue, also known as the Central Gray surrounding the central canal (aqueduct of Sylvius) in the midbrain. It is a convergence zone for all of the primary-process emotional systems of the brain, and appears to be the lowest region of the brain from which coherent emotional responses can be evoked by localized electrical and chemical brain stimulation. The ability of higher brain regions, such as amygdala and hypothalamus to maintain various emotional responses, such as rage, depends on the integrity of the PAG.

Posttraumatic stress disorder (PTSD) – This is a chronic anxiety disorder that emerges from repeated exposure to stressful and terrifying events. It is a common ailment from exposure to warfare, and used to be known as shell-shock and also arises from assaults, rape, and traumatic accidents. In humans, it is accompanied by chronic feelings of anxiety, fear, terror, and helplessness, and is often accompanied by sleep problems, irritability, and depression. It can be modeled in animals by various stressors that chronically change

the emotional phenotype of animals to persistent wariness.

Primary-process emotions – Primary-process emotions arise from evolutionarily provided subcortical operating systems (i.e., they are genetically provided networks that generate instinctual emotional behaviors and the associated affective states). In contrast, secondary-process emotions reflect basic emotional learning and memory processes as reflected, for example, in classical and operant conditioning; and tertiary-processes are the higher emotional functions, best studied in humans, that include thoughtful deliberations commonly based on episodic/autobiographical memories and capacities for symbolic thought and communication.

The Neuroscience of Emotions

'Emotion' is a way for labeling a very special set of brain-mind processes characterized by unique ways of behaving, feeling and thinking, accompanied by a host of autonomic changes in the body that sustain emotional behavior patterns. The behavior can be instinctual (i.e., largely programmed genetically via specific brain networks), although it connects up with a large variety of learning capacities. The study of emotions is one of the most important endeavors in behavioral neuroscience and among the most difficult and neglected. It is important because it links directly to major human concerns where emotional feelings are excessive, as in most psychiatric disorders. It is difficult because the concept of emotions is integrally linked to internal feeling states (affects). It is neglected because the attribution of internal psychological states to animals is still considered taboo because of the stigma of anthropomorphic thinking. This dilemma needs to be resolved by data rather than debate.

Even though emotional behaviors can be easily monitored in animals, it is debatable whether affective experiences are open to scientific inquiry in nonhuman species. This dilemma has been largely resolved if one is willing to accept various reward and punishment paradigms, especially conditioned place preference (CPP) and conditioned place aversion (CPA) paradigms as indicative of the existence of internal affective states. However, additional problems arise from the great variety of approaches to emotional theorizing that exist in the massive literature on human emotions, with most ideas being at high cognitive levels (attributions) which are unworkable in the behavioral neuroscience laboratories. However, if the defining characteristics of emotions are their distinct affective and behavioral states, our inability

to penetrate the cognitive-experiential states of other animal is no great problem. It is the definition of the affective state that is psychologically most crucial. Let us consider the diversity of theoretical perspectives in the field – before moving to the problem of dealing with internal affective-emotional states in other animals.

To simplify, we can categorize theories of emotions into three major types: (1) basic emotion theories, (2) componential theories, and (3) social constructivist theories. The basic emotion view holds that all mammalian brains contain a variety of emotional networks that generate a variety of distinct behavioral and physiological patterns accompanied by emotional feelings; hence, emotional systems are evolved tools that animals inherit in order to respond effectively to a variety of archetypal life challenges that face all higher organisms. The componential view suggests that a variety of physiological, behavioral, and psychological components are developmentally constructed into coherent emotional response systems, with higher regions of the brain providing the integrative ability to make wholes out of the many component parts. The constructivist view is that higher cognitive processes, arising from learning, thinking, and living in specific cultural contexts determines our emotional complexities from very simple beginnings, namely the neurobiological ability to have two primitive bivalent types of experiences – primal positive and negative affects.

Many of the controversies surrounding these views arise from different investigators being interested in at least three different levels of analysis of this complex problem. At the foundational primary-process level, the big question is whether there are genetically in-built emotional systems in the brain, and if so, what is their nature? The most effective way to resolve this question is using localized brain stimulation to evoke emotional behaviors, and to evaluate whether animals care about such states – namely, will they turn them on or off, and whether they can serve as rewards or punishments. Of course, soon after birth, practically all animal actions include acquired aspects, so at this secondary process level, investigators inquire how animals learn new emotional responses, both behavioral and physiological (classical conditioning of fear responses is an excellent modern example of this kind of work). Finally, at the highest level of analysis, it is clear that certain organisms think about their place in the world, so investigators of human emotions must consider tertiary process – how various higher cognitive, thoughtful mental processes change during emotional states.

Clearly, research on animals can effectively clarify the first two aspects of emotionality, while only human work can clarify higher mental changes that emerge during emotional arousals. At the basic level, one must characterize the natural unlearned behavior patterns that

characterize emotional episodes and their neural controls, and that requires a primary-process, neuroethological approach.

The Classic Biological Theories of Emotions

Modern ethological studies of emotional behavior patterns were inaugurated by Charles Darwin in his 1882 work on *The Expression of Emotions in Humans and Animals*. In line with this seminal work, basic emotion theory in humans has been based on a close study of the characteristic facial emotional displays that are evident in all human cultures that have been studied. This has led investigators such as Paul Ekman and Cal Izard to postulate anywhere from six to eight basic emotions (fear, anger, joy, sadness, interest, and sexuality at a minimum). Although social constructivists have correctly indicated that culture often modifies the display rules that people use to express emotions, the analysis of ethologically indexed activities of basic emotional circuits in animals generally supports the conclusions reached by facial analysis in humans. The fact that the animal neuroethological work and human facial analysis have converged, working completely independently of each other, affirms the correctness of the basic emotion view of primary-process emotionality across mammalian species. The constructivist views work best at tertiary-process levels.

Perhaps the most famous conjecture about emotions was the componential-constructivist James–Lange theory that postulated that emotions arose from higher brain mechanisms reading-out the peripheral bodily changes when animals were aroused. To this day, this theory remains without solid neuroscientific support, even though it is clear that peripheral influences, especially hormones such as adrenalin, cortisol, thyroxin, and many other circulating factors, can modify emotional intensities. In fairness to James, it should be mentioned that he had subsidiary theories such as the conclusion that every instinctual behavior was accompanied by changes in affective feelings. In any event, Walter Cannon’s rebuttal of the James–Lange theory highlighted brain networks, especially thalamic ones, as being the key to understanding emotionality.

This idea was made more elaborate by the postulation of widespread emotional networks by James Papez (neuronal loops from hippocampus via the fornix to mammillary bodies, mammillothalamic tract to dorsomedial thalamic regions which project to medial frontal cortical regions, including cingulate gyrus, which transmit information back to the hippocampus via the cingulum bundle). This loop was postulated merely on anatomical considerations and the fact that rage

accompanies hippocampal damage following viral infection with rabies. Only the medial thalamus, frontal cortex and anterior cingulate remain as major players in emotionality to this day, and their participation in social emotions such as separation distress is well established.

The heuristic value of the Papez circuit idea was affirmed by scientists who damaged the core of the temporal lobes (amygdala and ventral hippocampus). The resulting Kluver–Bucy syndrome, where animals were emotionally fearless, hypersexual, and undiscriminating in their feeding and social habits, suggested that such higher brain areas did disrupt emotional stability.

The Papez circuit idea also served as the foundation for the visceral-nervous system or limbic system concept of Paul MacLean. The limbic system is a midline subcortical–cortical locus for primary-process emotional processing that has been amply supported by modern brain imaging with everyone now including insula, orbitofrontal cortex, medial frontal, and anterior cingulate cortices in the control of emotionality and most probably participating in higher (cognitive) regulatory capacities as well. However, all these higher brain functions are supported by even more ancient subcortical emotional networks.

Emotions and Brain Stimulation

The best causal evidence for various primary-process emotional networks in the brain has arisen from localized electrical stimulation of the brain (ESB) studies. Various emotional-action states can be evoked by ESB (*vide infra*), and when animals are asked if they like or dislike such brain arousals, they routinely indicate that they do as indicated by their eagerness to turn on (self-stimulate) or turn off (escape) such evoked arousals. They also exhibit CPPs and CPAs to environments associated with such internal affective events. At times one will get fearful behaviors but animals do not learn to avoid the stimulation using operant tasks (lever presses), but they do avoid such states using CPA paradigms.

Thus, not only is it clear that various basic emotional behaviors emerge from arousal of diverse emotional networks concentrated in these ancient midline regions of the brain (well connected with higher medial cortical structures), but it is equally clear that such arousals are accompanied by affective (positively and/or negatively valenced) internal feeling states. Humans commonly give us verbal reports of corresponding feelings of emotional arousals when stimulated in these brain regions, especially the subcortical parts of these networks. It is noteworthy that the emotional states evoked from higher brain regions such as the amygdala and hypothalamus are dependent on the lower integrative regions of the brain such as the periaqueductal gray (PAG) of the midbrain.

Indeed, stimulation of these lower reaches provokes the most powerful behavioral and affective effects at the lowest current levels indicating the primacy of the lower levels in the hierarchical control of emotionality.

Still, the evidence-based conclusion that animals experience emotional states is not yet universally accepted in behavioral neuroscience. Most investigators prefer to use the traditional terminologies of rewards and punishments, but it is becoming increasingly clear that such global concepts need to be broken down into distinct varieties. Indeed, it is possible that the concept of reinforcement largely reflects the way affective processes operate within the brain. This proposition can finally be tested since we know quite a bit about the neurochemistries that control distinct emotional–instinctual behaviors.

Affects clearly come in many different varieties. In addition to emotional affects, there are a large variety of sensory affects such as the desirability of sweetness, and homeostatic affects such as hunger and thirst. Although such processes exist in animal brains, the fact that they cannot be directly observed has led to the general acceptance that anthropomorphic–subjective terminologies (first-person experiences) are not acceptable in traditional third-person observational sciences. However, the living mammalian brain is not a rock or cabbage; it does apparently have a point of view. It does have various feelings. Affective states are now widely accepted in human brain research, and the best evidence indicates that they are elaborated by subcortical brain regions shared by other mammals. That is a clarion call for scientists to begin considering blending third- and first-person observations. If such experiences also do, in fact, exist in animal brains, a compromise must eventually be found between the internal and external perspectives to certain cross-mammalian brain functions such as the basic affective states.

Emotional Feelings as Envisioned by Different Modern Schools of Neuroscience

Modern investigations of emotions in animal models reflect the diversity of approaches evident in human research. Some feel that bodily changes are the most important aspect of the problem. Others believe that emotional feelings are a very critical dimension. Yet others are most fascinated by change in learning and associated cognitive issues. Although all agree that these levels of analysis are important, they disagree dramatically over the most difficult problem of emotional research, how affective feelings emerge from brain emotional arousals.

The Behavioral Neuroscience Approach to Emotions

Prominent investigators, such as Joe LeDoux and Edmund Rolls, who take a strict behavioral neuroscience perspective, have claimed that emotional feelings are secondary to behavioral issues in emotion research, and suggest that potentially only humans have internal emotional experiences. LeDoux has suggested that emotional feelings can only arise when sophisticated higher working memory systems such as those found in the dorsolateral prefrontal cortex, process unfelt emotional information from below to generate a conscious experience of emotions. Rolls suggests that emotional feelings may only exist in organisms with enough higher brain power for the symbolic processing that permits humans to speak – for him language is an essential feature for humans to experience emotional feelings. Such perspectives lead many behavioral neuroscience investigators to restrict their research to the description of spontaneous and learned behavioral and physiological changes accompanying emotional arousals. Talk about emotional experiences in animals is discouraged as being scientifically irrelevant. They subsume all such nervous system functions under the concepts of positive and negative reinforcements.

The Cognitive Neuroscience Approach to Emotions

The analysis of human emotions using modern brain imaging (functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) studies) has motivated cognitive scientists to vigorously study brain changes during various emotional tasks. Abundant work has now implicated a large number of brain regions that dramatically overlap the classic limbic system concept in processing emotional states (including most commonly arousals in anterior cingulate, insular, and various frontal cortical regions, especially medial frontal and the more ancient orbitofrontal regions). There is a general consensus that emotional feelings arise from high, cognitive regions of the brain. The most seminal statement of this view is Antonio Damasio's somatic marker hypothesis, a variant of the James–Lange perspective, which proposes that emotional feelings arise when bodily commotions during emotional states map onto the somato-sensory regions of cortex. Damasio's work with PET imaging has also highlighted arousals of many of the subcortical regions relevant for basic emotions in animal brain-stimulation studies, but his theoretical view has been that arousals within these ancient circuits are not sufficient to experience emotional arousals.

The Affective Neuroscience Approach to Emotions

A final approach to emotional feelings is based on the idea that ingrained emotional action tendencies and basic emotional feelings arise from essentially the same networks concentrated in subcortical regions of the brain. Paul MacLean and Jaak Panksepp represent this tradition, and both have proposed that emotional feelings arise from subcortical regions that integrate unconditional emotional behaviors and associate physiological changes. This is premised on the simple fact that brain sites from which various emotional behavior sequences are evoked are, by all measures used, capable of sustaining diverse reward and punishment processes.

The Affective Neuroscientific, Dual-Aspect Monism View of Emotional Feelings

The confluence of the neural substrates for basic emotional behaviors and basic emotional feelings within the brain provides a straightforward strategy for unraveling how primary-process affective states are engendered within the brain. This simple strategy is called dual-aspect monism, and envisions that some aspects of coherent brain function are easily observed (unconditioned behaviors) while other corresponding aspects (feelings) are not. Thereby, brain mechanisms for unconditioned emotional behaviors can be used as a proxy for monitoring primary-process emotional feelings: for instance, the neural substrates of instinctual angry behaviors reflect the substrates of angry feelings; similarly, natural playful behaviors reflect socially joyful playful feelings, and so forth. This strategy, easily falsified, allows the translation of facts about basic emotional circuits that can only be well studied in animal models to generate predictions about how basic human emotional feelings are constructed.

In this affective neuroscience view, various basic emotions are concentrated in sub-neocortical regions of the brain. The number of basic emotions is determined by how many distinct emotional patterns can be evoked by localized electrical stimulation of subcortical brain regions. At present there is substantial evidence for brain networks that mediate anxiety (FEAR), anger (RAGE), sexual arousal (LUST), maternal nurturance (CARE), separation distress (PANIC) and the social joy arising from energetic physical engagement during youth (PLAY), as well as subtle ones that have not been fully conceptualized in most human theories – for instance a generalized appetitive motivational SEEKING system that mediates exploration, foraging, and the search for and interest in life-supporting resources. This system is

rather reflexively still called ‘the brain reward system’ by many.

Indeed, from this neuroethological perspective, the ascending so-called mesolimbic/mesocortical dopamine ‘reward’ system should not be called ‘the reward system of the brain’ but the appetitive motivational SEEKING or ‘wanting’ system that allows animals to pursue each and every kind of positive reward and also to seek safety from punishments. The ‘reward-prediction error’ hypothesis of this system may be misguided since it conflates correlates and causes: recordings from the source dopamine cell bodies in the ventral tegmental area (VTA) only tell us what the system is listening to, they do not necessarily tell us anything about the ‘information’ or ‘state control process’ that the system is passing onward in the brain. As Walter Freeman has emphasized, each level of neural activation reinterprets its inputs. Information does not simply get passed on within the brain but different levels of organization in the brain may speak their own functional languages. A main language of ascending VTA dopamine systems is the mediation of appetitive eagerness as opposed to the rewards from consuming resources such as food and water.

The emotional primes above are capitalized to label specific neural networks that mediate both the spontaneous behavioral expressions of those emotions as well as the associated feelings. Since science only studies the parts of nature, and never the wholes, the capitalizations also highlight that the emotional circuits are important primary-process parts of emotional wholes that are typically discussed in human research. In other words, these brain parts may be critical neural components for the construction of emotional wholes, suggesting how various levels of theorizing in human research (*vide supra*) could be integrated.

Emotion-Cognition Interactions

There is general consensus that the emotional feeling and cognitive information-processing aspects of the brain are highly intertwined. Most emotions in humans are aroused by cognitive attributions – evaluation of the meaning of events. However, from a neuroscience perspective, cognitions and basic emotions also need to be separately conceptualized and studied. This has become an enormous dilemma in modern human brain imaging of emotional-affective processes. If people are exposed to various emotional stimuli and one tries to concurrently evaluate affective change, then one may be conflating the affective changes that are occurring with the cognitive judgments about those affective changes. Indeed, Georg Northoff and his group advise that to minimize such confounds, cognitive judgments should always be harvested after affective brain scanning sessions are

finished. In doing this, the prominent finding is that arousals in many of the higher brain regions that light-up during emotional tasks are negatively correlated with affective change, while changes in lower subcortical regions, highlighted by animal brain stimulation studies, are positively correlated to affective change. This supports the idea that basic affects are, in fact, mediated by the subcortical networks that control instinctual emotional behavioral arousals.

Such findings are consistent with abundant animal data, where self-stimulation and aversion are evoked more easily by electrical and chemical stimulation of subcortical rather than cortical regions of the brain. Indeed, there is abundant data from human brain imaging that higher cortical processes typically tend to inhibit affective arousal, and that intense emotional feelings are often accompanied by reduced neocortical arousals. This suggests that higher and lower brain regions implicated in emotional processing are in a seesaw-type balance, and that intense emotional feelings arise from ancient subcortical regions that all mammals share in a remarkably homologous form. Indeed, abundant data from PET imaging of emotional feelings in humans are consistent with this conclusion. In short, it appears that while subcortical regions are more influential in generating emotional feelings, higher neocortical regions elaborate cognitive awareness and thoughtful contemplations of those feelings, processes that often go astray in psychiatric disorders.

The Neurochemistries of Emotions

Perhaps the most powerful understanding of how the brain controls specific emotions will arise from the analysis of the underlying neurochemical substrates. Although early in the neurochemistry revolution, it was thought that chemical coding of behavior did not exist in the brain, the discovery of hosts of neuropeptides indicates that there is, in fact, such neuromodulatory coding of large-scale emotional and motivational ‘state reactions’ of the brain. Still, it is true that the classic neurotransmitters such as glutamate, γ -amino butyric acid (GABA), acetylcholine, dopamine, norepinephrine and serotonin, which participate in all animal behaviors, do not specifically control any single emotion. They modulate all emotions.

Much greater emotional specificity is found among the neuropeptide networks. Of the basic emotional systems noted above, it is clear that substance P figures heavily in RAGE circuitry. FEAR circuitry includes corticotrophin releasing factors, alpha-melanocyte stimulating factor, cholecystokinin, and a host of less well studied neuropeptides such as diazepam binding inhibitor. LUST circuitry is heavily influenced by luteinizing hormone-

releasing hormone, oxytocin and vasopressin. CARE circuitry includes oxytocin, as well as prolactin and endogenous opioids. PANIC/separation-distress circuitry is regulated by the above social neuropeptides as well as very robustly inhibited by mu-opioids. PLAY, the least studied system, is regulated by opioids and also apparently by thyrotrophin releasing hormone and insulin-like growth factor-1. The SEEKING circuitry receives input from many of the above neuropeptides but also has more intrinsic controls through neuropeptides such as neurotensin and orexin excitatory influences, and dynorphin inhibitory ones. The specific motivational systems such as thirst are heavily regulated by angiotensin, and energy balance by a host of neuropeptides including leptin, ghrelin, melanocortin, orexin, neuropeptide Y, and agouti-related peptide. Genetic analyses of emotions, especially with the assistance of knockout mice, are now much more feasible than ever before.

All of these chemistries are new targets for human psychiatric drug discovery, and all need to be evaluated more extensively for affective-emotional changes in humans. So far there is only abundant data for endogenous opioids and oxytocin. However, it is clear that the former can reduce sadness and depression, while the latter produces warm-loving social feelings and intensifies feelings of confidence and trust. It is to be anticipated that some of these neurochemical networks will allow more precise regulation of emotional distress in psychiatric patients than is presently possible.

Basic Emotions and Psychiatric Disorders

It is generally recognized that most psychiatric disorders reflect the imbalances in the emotional dynamics of individuals. If so, the various psychiatric syndromes, which are medical concepts, need to be related to imbalances of basic emotional circuits. In other words, the emotional networks provide a uniquely important set of endophenotypes for future discussions of a variety of emotional disorders. Since each of the basic emotions is regulated quite specifically by neuropeptide circuits, one can imagine a new era of psychiatric medicinal development that is based on our understanding of and ability to manipulate the underlying neuropeptide circuits, such as agonists for those that contain endogenous opioids (for reducing grief/sadness), oxytocin (for promoting pro-social motivations), neuropeptides such as neurotensin (for promoting appetitive arousal and interest), and antagonists for corticotrophin releasing factor (CRF) (for reducing stress, anxiety, and depression), antagonists for cholecystokinin (CCK) (for reducing posttraumatic stress disorders (PTSDs)), substance P (for reducing anger and irritability), dynorphin (for reducing depression and lassitude), just to name a few.

Basic emotions are fundamental powers of the human mind that are of utmost importance for both mental health

and mental disorders. All mammalian brains inherit a variety of emotional dispositions as ancestral tools for living. Among the underlying neural networks, those for SEEKING, FEAR, RAGE, LUST, CARE, PANIC/GRIEF, and PLAY, are of critical importance for generating primary-process affective states – basic psychological states such as urgent interest/desire, anxiety, anger, eroticism, nurturance, sadness, and joy. These fundamental emotional powers of the mind, which are closely affiliated with a variety of bodily states and non-specific brain arousal systems (e.g., norepinephrine and serotonin), concurrently generate distinct emotional action tendencies as well as raw feeling states that rapidly get linked to a variety of events in the world through classical conditioning and other basic learning mechanisms.

When these ancient emotional forces of the human brain become tempestuous – dysregulated beyond our understanding – overwhelming psychological problems can emerge. In humans, emotional imbalances are invariably accompanied by cognitive changes – entangled in attributions, ruminations, and all sorts of hopes, plans, and worries. The FEAR system is especially important for promoting generalized anxiety disorders, neurotic disorders, and specific phobias. One can produce symptoms of PTSD simply by repeatedly stimulating this system, leading to increased limbic permeability whereby minimal stimuli develop the capacity to resurrect full-blown PTSD symptoms. New affect balance therapies may help strengthen one's emotional muscles in ways that can counteract the effects of various past traumas and perhaps inoculate emotional circuits against future adversities.

In short, the continued behavioral neuroscientific study of the evolutionary complexities of basic emotional processes may yield enormous dividends for understanding the foundation of human nature and the neural vicissitudes that lead to psychiatric disorders. What a deep neurobiological/psychoneurological understanding of brain emotional systems, and their associate affects, provides is a vision of brain functions that has enough cross-species ecological validity to allow translating between foundational mental states in animals and primitive psychological forces that contribute substantially to human psychiatric disorders.

Animal research has now clearly indicated that the basic emotions along with their raw feelings (affects) are concentrated subcortically, arising from evolutionarily dedicated brain circuits. Indeed, from a global perspective, there appears to be a seesaw balance between these ancient tools for living and the higher cortical-cognitive processes that interface more directly with the external world. When emotions are aroused, higher brain functions are often constricted into obsessive channels. Higher cognitive activities, on the other hand, can inhibit subcortical

emotional arousals, explaining the efficacy of cognitive behavioral therapies.

Such findings have had salutary effect on modern brain imaging, which is often more effective at highlighting higher rather than lower brain functions, since action potentials are typically much more rapid in upstairs than in the highly functionally overlapping areas found subcortically. Thus, when humans are confronted by emotional stimuli in scanners, special care must be taken to reduce cognitive-affective cross-talk. For instance, if people are presented with emotionally provocative stimuli, one should avoid asking people about their emotional experiences while being scanned. That forces them into a cognitive mode, with higher brain arousals, that may disrupt subcortical affective processing. One should analyze the feelings off-line, after scanning – after the brain changes in response to emotional stimuli have been harvested. When such procedures are used, one typically finds that affective change to various emotion-provoking stimuli typically correlates positively with very deep subcortical regions on the midline of the brain, while correlating negatively with arousals in higher neocortical regions.

Clearly, basic (primary-process) emotions are concentrated in deep subcortical regions we share with the other animals. The manner in which these ancestral voices of the genes are parsed by living in the world – learning (secondary processes) and thoughts (tertiary processes) – is regulated much more by higher regions of the brain that are much harder to study neuropsychologically in animal models.

Evolution of Emotions

Glossary

Altruism – Behavior in which the actor incurs a cost (up to and including death) in order to benefit another individual.

Emotions – Essentially human constructs used as a shorthand to refer to the range of subjective feelings to which humans are exposed in their conscious actions (to a lesser or a greater degree).

Evolution – The view (usually credited to Charles Darwin) that new species (and their attributes) are derived by the forces of natural selection acting on pre-existing organisms. Essentially more organisms are produced than can flourish, so some of them do better as a consequence of their (often slight) variations. A change in the environment can alter which organisms (or attributes) benefit. It can be contrasted with the view that organisms are separately created.

Kin selection – Occurs when a gene is selected because it increases the reproductive success of relatives of the bearer of the gene. Genes can be selected in such circumstances because genetic relatives are more likely than chance to possess copies of the same gene. Kin selection gives rise to kin-directed altruism. In general, the higher the level of relatedness, the higher the level of altruism.

Starting with Darwin, evolutionary explanations have been proposed for a wide range of emotions. There are at least two ways to situate emotions with respect to evolutionary theory: they may be viewed as adaptations, or they may be viewed as by-products of adaptations. If an emotion is an adaptation, we can immediately say several things about it. To begin with, we can presume that its evolutionary function relates to the voluntary behavior it motivates. Thus, fear motivates avoidance or escape, whereas rage motivates some forms of aggression. In addition, we can say something about the emotion's evolutionary history. For instance, we can presume that, at each stage in its evolution, the resulting successful emotional disposition had behavioral effects that, on average and relative to other existing variants, enhanced its bearers' inclusive fitness (i.e., its ability to make genetic contributions to the next generation).

Probably not all emotions are Darwinian adaptations; some may be better construed as by-products of adaptations. Archer has argued, for example, that grief results from the maladaptive overstimulation of evolved attachment mechanisms, in particular, responses associated with separation from the object of attachment. These reactions usually lead to adaptive patterns of thought and behavior, such as a preoccupation with the lost person and a desire to locate them. However, when the person is deceased, these reactions cease to be adaptive, and constitute the phenomenon of grief. Thus, grief itself is not an adaptation, but can be traced to adaptive aspects of the mind.

It seems worth initially illustrating some of the varied emotions that have been postulated in our species and attempting to link them to physiology and to context.

The Nature of Emotions and Their Evolution

The Oxford English Dictionary defines emotion as "A mental 'feeling' or 'affection' (e.g., of pleasure or pain, desire or aversion, surprise, hope or fear), as distinguished from cognitive or volitional states of consciousness." There has been considerable debate about the actual nature of emotions. They have, at various times, been viewed as feelings accompanying primary instincts (e.g., flight), or even reflections of the internal, physiological changes (e.g., increased heart and respiratory rates) induced by an emotional stimulus (e.g., a predator). At the very least, what we call emotions can be linked to generally reliable patterns of internal changes, relatively precise and recognizable situational contexts, and accumulated experiences.

Anger

Anger or 'rage' is an important emotion that is linked to threat and attack (aggression), both of which are phenomena with wide-ranging and sometimes subtle emotional and biological consequences to our species. Aggression (whether physical or verbal) is actually a highly heterogeneous phenomenon. Attack can, in some cases, be a product of fear (e.g., defense by a cornered subordinate), rather than anger. In such cases of defensive aggression, there is activation of the sympathetic nervous system. Other forms of physical attack (e.g., by a predator on a prey) seem to be accompanied by minimal signs of internal physiological change or arousal (e.g., there is no activation of the sympathetic nervous system). It is also

clear that angry individuals can be socially inhibited from actually expressing this emotion. Conversely, individuals (e.g., in a military context) can be trained to kill or injure members of their own species without much involvement of anger as an emotion. Having said that, anger is an emotion that is relatively easy to recognize in our species and one with which we are all familiar. Conflict is also a characteristic of virtually every animal species that has been investigated. Indeed, it has been argued that competitive (as opposed to defensive) forms of intra-specific threat and attack, whether directly concerned with the acquisition of food, a mate, a territory, or enhanced social status, are all broadly designed to increase the organism's relative fitness.

Fear

Fear is another important emotion, and is associated with a variety of behavioral responses aimed at protecting the individual from threatening situations. These responses include escape, avoidance, warning displays, defensive aggression, submission, and immobility. In many cases, our fears appear to be tuned to specific threats that our ancestors faced. Research has shown that people are more likely to form some phobias than others (an example of the phenomenon of preparedness). These phobias relate to threats faced by our hunter-gatherer ancestors. Even people living in modern environments are more likely to develop phobias related to ancestral threats, such as snakes and spiders, than they are of developing phobias related to items much more dangerous to them in their modern environments, such as guns, electrical outlets, and fast cars. Similarly, there is ample evidence that laboratory rats and mice retain many of the behavioral responses of their wild progenitors.

Love

Natural selection may also account for the origin of other, more complex emotions. This includes the emotion of love. Like aggression, the word love covers a range of phenomena, including romantic love and the love found among kin (familial love). It is not difficult to imagine the possible significance of romantic love in reproduction. Fisher has suggested that the early stages of romantic love keep couples together for long enough to conceive, whereas attachment or companionate love (which involves deep affection but a lower level of sexual passion) keeps them together until weaning, at around 4 years. Relationships often end after this, as one or both partners may fall passionately in love with someone else. Other forms of love, such as that between parents and their genetic offspring, can be given plausible evolutionary rationales.

Jealousy

Another example of a complex emotion claimed to have an evolutionary origin is jealousy. The suggestion is that, in a monogamous species with high male parental investment, jealousy prompts behavior that lessens the chances that one's mate will engage in extrapair copulatory activity. A large body of research attests to the fact that men are more distressed than women about sexual infidelities. This may be an evolved tendency designed to motivate mate guarding behavior and thereby ensure paternity. Women, on the other hand, appear to be more distressed about emotional than sexual infidelities – that is, about their mate forming a close emotional bond or falling in love with another female. This may be because a male's emotional involvement, more than sex, signals a potential loss of investment in the women and her offspring. A wide variety of evidence demonstrates the sex difference in jealousy. One study, for example, found that men preferentially recall details of sexual infidelity, whereas women preferentially recall details of emotional infidelity. Such findings make good evolutionary sense.

Do Nonhuman Animals Have Emotions?

Some commentators argue that emotions are unique to *Homo sapiens* and that talking about them in other animals is, at best, an expression of anthropocentrism. Others see nothing wrong in assuming that nonhuman animals share many of these characteristics that humans have found generally beneficial to their individual survival and their ability to pass on their genes. Many find it easier to acknowledge emotions in animals with a high degree of resemblance to human beings than they do for species that are more distantly related to us. They often do this on the basis of linking emotions to phenomenological consciousness or sentience (defined as the ability of an entity to recognize something it is like, e.g., what it is like for a bat to be a bat, or for an octopus to be an octopus). The Stanford Encyclopedia of Philosophy notes that “there is broad commonsense agreement that phenomenological consciousness is more likely in mammals and birds than it is in invertebrates... while reptiles, amphibians and fish constitute an enormous grey area.”

Given the recent flurry of interest in whether fish have sentience and the capacity to suffer (as well as being part of that grey area), it seems instructive to pose the question “do fish show emotions?” The answer has relevance to our position for other vertebrate groups. A number of authorities conclude that the evidence suggests fish do indeed have sentience and the capacity to suffer. Chandroo and co-workers maintain that the “affective states of pain, fear and stress are likely to be experienced by fish in similar ways to tetrapods.” Others conclude that fish can

experience fear-like states and probably have the capacity for suffering.

There are various difficulties associated with this issue. Part of the problem is the word ‘sentient’. In some usages, it is simply a synonym for ‘animate’ or ‘responsive to sensory stimuli’. Fish are certainly not inanimate and respond to nociceptive (pain-related) and other stimuli. Others describe sentience as a state of elementary or undifferentiated consciousness. For example, Broom claims “a sentient being is one that has some ability to evaluate the actions of others in relation to itself and third parties, to remember some of its own actions and their consequences, to assess risk, to have some feelings and to have some degree of awareness.” This is very much like the definition of phenomenological consciousness.

In relation to fish (or any other nonhuman animal), one could adopt one of two positions. First, one could regard emotions as being conscious states. This would imply that animals lacking phenomenological consciousness could not have emotions. Conversely, if a particular animal possesses phenomenological consciousness, it could have emotions and the question then becomes, are the emotions experienced by the animal the same as ours? Second, one could take the view that emotions do not necessarily have to be conscious states, but can be defined purely in functional, behavioral, and/or physiological terms. This would imply that, whether or not an animal has phenomenological consciousness, it could still have emotions. The only question is, does it have the same emotions we have or a different set?

The question of consciousness in other animals is thorny, especially when it comes to animals very different than ourselves. For this reason and others, it is probably best to take the second approach. There are then two ways to tackle the question of emotions in other animals. One is to think: “Fear is what I feel in situation X and what I assume other humans feel in situation X. In comparable situations, do other animals experience the same thing as us?” But this is a very anthropocentric approach, and is thus not perhaps the best way to proceed. A second way to approach the question would be to take a comparative perspective maintaining that, in certain situations, humans and other animals act in a comparable manner in response to threatening stimuli. Their senses become fully engaged, they retreat and adopt a defensive posture and their autonomic nervous systems are activated. Although there are differences among species in the details of these actions, they are all clearly evolved solutions to the same general selective pressure, that is, dealing with certain kinds of threats to life and bodily integrity. Furthermore, with some animals (e.g., humans and chimpanzees), the behavioral elements are very similar, presumably because they result from the activation of modified versions of mechanisms inherited from a recent common ancestor. Thus, they have a shared evolutionary

function and, in some cases, a high level of shared evolutionary history. These are important commonalities, and therefore we should gather these behaviors under the same heading: fear. Certainly, there are differences in these behaviors across species. But what they have in common is more important. This way of looking at things treats human fear not as the prototypical case which other animals have or do not have, but rather as just one example of a more general phenomenon in nature.

Some Animal Models of Emotions

Clearly many scientists, who use laboratory species in areas such as psychopharmacology, do so because they regard the animals as having emotional experiences that are not too different from those found in human beings. Naturally, if emotions are, in any sense, evolved, this is a wholly appropriate way to screen potentially psychoactive drugs. Willner has proposed a useful list of features diagnostic of properly validated animal models of psychiatric disorders. In addition to predictive validity (the action of the drug in the model should generally correspond to that seen clinically), the model should have face validity (the diagnostic characteristics of the model and the psychiatric disorder should be similar) and construct validity (the theoretical rationale should be convincing). It should be noted (perhaps in support of the evolutionary emphasis) that there has been a recent move from traditional psychological to ethological models rooted in the animal’s naturalistic behavior.

Anger or Hostility

A rather heterogeneous battery of tests with rats and mice has been used in the laboratory to tap into the emotion of anger. Some tests assess competitive motivations, others defensive or even predatory motivations. Although this makes it difficult to clearly relate the threat and attack recorded to anger, it has been pointed out that some forms of clinically relevant human aggression are expressions of hyper-fearful emotion and psychopaths may show behavior with parallels to predation.

Anxiety

Rats and mice have traditionally been used in tests to assess potential anxiogenic and anxiolytic drugs using the open field, social interaction, two-chambered light-dark transition, and elevated plus-maze tests that all utilize these rodent’s apparent fears of novelty, strangers, bright lights, open spaces, and heights. More ethological tests have utilized the ultrasonic distress calls of mouse neonates and the mouse defense test battery where mice respond to cues from predatory rats.

Depression

Human depression is described as “a debilitating phenomenon with major depressive episodes lasting at least 2 weeks and with core symptoms of depressed mood and markedly suppressed interest and lack of reactivity to pleasurable stimuli.” Rats and mice have been used in a behavioral despair model where they are forced to swim in a confined space. Rodent models have also been developed where animals are subject to chronic unpredictable substantive (e.g., electric shocks, cold water immersion, and light-dark rhythm reversal) or chronic mild (e.g., cage tilt, wetting of cage bedding, and changes to lighting) stressors. Finally (and more ethologically), others have explored loss of social status in the rat as inducing depression-like symptoms. In some cases, the effects of depression-inducing models on anhedonia (a condition where rewards are ineffective), noted above as a symptom of human depression, are studied by looking at reductions in the rate of intracranial self-stimulation of reward centers in the animal’s brain.

Although some human emotions such as social phobia do not appear amenable to developing meaningful animal models, the above items suggest that some emotional constructs have utility, at least across the class *Mammalia*.

Relating Emotions to Evolution

It seems appropriate to consider the lines of evidence and debate that have led people to conclude that emotions are subject to evolutionary pressures. These are largely focused on the human species, and can be divided into a number of broad categories.

Sociobiological Theories

One line of evidence concerns the fact that certain aspects of emotional behavior are predictable from sociobiological theories.

Kin selection theory

Hamilton’s kin selection theory (KST) assumes that individuals will tend to favor others with whom they share a higher than average proportion of genes (i.e., relatives). KST helps to predict emotional responses to individuals of differing degrees of genetic relatedness. For example, greater relatedness is associated with greater emotional closeness. Similarly, it has been found that grief following the death of a loved one increases as a function of relatedness.

Parental investment theory

A number of sex differences in emotional expression make good sense in light of Trivers’s parental investment

theory. Littlefield and Rushton suggested that grief would be positively correlated with average levels of parental investment for a sex. Consistent with this prediction, they found that, on average, mothers grieved the death of a child more than fathers. Based on this work, Archer made the interesting observation that, in species with a low male parental investment, such as polygynous elephant seals, males would not be expected to grieve the death of offspring at all, whereas in monogamous species, males would be expected to grieve.

There are other examples. Campbell has argued that, due to differences in parental investment, females are more valuable to offspring than males, and this is one reason they have evolved greater restraint in regard to risk taking. Consistent with this view, she has found that, though females are just as susceptible to anger as males, they are less likely to engage in direct aggression. This appears to be because they are more fearful than males about the potential consequences of aggression.

Reciprocal altruism theory

Another theory that helps make sense of the suite of human emotions is Trivers’s reciprocal altruism theory (RAT). RAT suggests that people have evolved to engage in patterns of reciprocal exchange, and to avoid the problem of being cheated (i.e., helping someone who does not return the favor). Trivers suggests that, to enact this behavioral strategy, we are equipped with a set of emotional response patterns. Anger and dislike motivate us to withdraw help to cheaters, or to punish them. Gratitude and a sense of obligation motivate us to reciprocate help received from others. Guilt occurs when we fail to reciprocate help, and may be a way of avoiding reprisals. These and other emotion reactions make good sense in light of RAT, which helps bolster the case that they have an evolutionary origin.

Direct Evidence for Evolutionary Origin

There is also more direct evidence that emotions have an evolutionary origin. This includes Ekman’s research showing the apparent cross-cultural universality of many of the basic emotions. Many emotions are associated with facial expressions and displays that appear to be universal among human beings. These include happiness, anger, sadness, fear, disgust, and surprise. The case for the evolutionary origin of emotions is further bolstered by the fact that analogs of several facial emotional expressions are found in nonhuman animals, and are elicited by similar situations. There is therefore strong evidence that at least the basic repertoire of emotions has an evolutionary origin.

General Conclusions

Although behavior is not directly subjected to evolutionary forces, it seems likely that there is some commonality in the emotions displayed by a range of animal species. The commonalities suggest that nonhuman animal models of human emotions are relatively meaningful and that one should take into account these phenomena when considering animal welfare.

Glossary

Abnormal aggression – Aggression that is different from offense in that it is nonresponsive to important inhibitory factors such as the sex and age of a conspecific opponent, submissive signals of the opponent, or target sites for bites and blows.

Aggressive display – Actions that precede attack and may provide signals that an attack is imminent. Different displays accompany offensive versus defensive aggression, but both may involve tactics that facilitate the actual attack behaviors, rather than serving simply as displays or signals.

Defensive aggression – Defensive aggression is a response to high-level threat, particularly when an animate threatening stimulus is contacting or within contact distance to the subject and it is difficult for the latter to escape.

Offensive aggression (offense) – Offensive aggression is aggression in the context of resource control. It typically occurs between conspecifics and, especially in social species, is aimed at target sites that may hurt, but seldom seriously damage, the opponent.

Resource – An object or event such as access to an opposite sex conspecific in breeding condition that facilitates the survival of an animal's genes. Adaptive resources may vary for animals of different species, age, sex, and breeding condition.

Target site – A site on the body of a conspecific opponent where bites and blows are aimed during offensive attack. These sites typically enable the attacker to hurt the opponent and claim relevant resources, without seriously endangering a potentially related animal.

or internal events (reactive aggression; emotional aggression), or the result of deficient inhibition (impulsive aggression), as opposed to a behavior based on expected gain (instrumental aggression). Attempts to provide a biologically based parcelling of aggression that may apply to both human and nonhuman animals has tended to focus on the analysis of its functions. Two such functions have been identified: controlling biologically important resources (offensive aggression) and thwarting bodily attack (defensive aggression).

Offensive Aggression

Offensive aggression is a major mechanism of resource control. In offensive aggression, an individual attempts to defeat or intimidate its opponent into abandoning its claims to a resource, leaving it for the winner. Resources are objects or relationships that are important to the extended reproductive fitness of an individual, facilitating the enhanced representation of that individual's genes in the next generation. Control of such resources is highly adaptive, and behaviors that facilitate this control would be expected to evolve as features of the biobehavioral repertory of most complex animal species. Some important features of resources that make them valuable enough to be fought over are the degree to which they promote extended reproductive fitness, their sequesterability, and their scarcity.

Most offensive aggression is aimed at conspecifics; they are the animals most likely to live in the same habitats and utilize the same resources as the focal animal. Indeed, particular resources may sometimes be uniquely important, to a given species. However, the most direct determinant of an adult animal's reproductive, adaptive, success, its sexual access to an opposite-sex conspecific in breeding condition, is consistent across all sexually reproducing species. Interspecies hybrids are almost always sterile, so this core resource for a particular animal is of little value to nonconspecifics, sharply limiting the motivation for interspecies offensive attack. In fact, many species that are capable of interbreeding have evolved elaborate patterns of courtship activities and displays that serve to discourage breeding among nonconspecifics. The degree to which a resource can be sequestered is also especially high in the case of reproduction: a female in

Conceptualizing Aggression

Animal aggression has often been categorized in terms of specific antecedents (e.g., pain-elicited aggression; isolation-induced aggression) or on the types of animals involved (e.g., male–male fighting; maternal aggression). Human aggression has more often been divided into categories reflecting whether it is seen as a reaction to external

breeding can, in principle, be totally sequestered from competitors if sufficient time, muscle, energy, and skill are put into the effort.

The sequesterability of some resources may vary for different species. Food for a predator—the prey—is often a substantial item, whereas herbivores tend to eat small items like grass, leaves, or fruits. While predators or scavengers on larger prey frequently fight over food, ungulates and other grazers show little tendency to do so: it is simply unproductive to risk the perils and uncertainties of a fight over such resources. Notably, however, several primate species have been reported to fight over ripe fruits. This suggests that the magnitude of the individual food item, which is clearly related to its sequesterability, is the operative factor, rather than the distinction between predator and nonpredator species. If the resource cannot be sequestered, or if it is not limited in availability (scarce) the very real dangers inherent in aggression may make it unprofitable for an animal to show aggression over that resource.

Offensive Aggression: Mechanisms for Reducing the Cost of Aggression

Fighting is dangerous. Each aggressive episode has the potential to produce damage to the initiator as well as to its opponent. Mechanisms that can achieve the functional goals of aggression without risking its dangers are adaptive. Among these mechanisms are several that are seen in many animal species: dominance relationships and territoriality. These ‘super resources’ initially must be gained in the same manner as other resources, through competition and, usually, fighting. There appear to be some exceptions: in spotted hyenas and some primate groups, not to mention humans, inheritance of the mother’s status may establish dominance without significant fighting. Once a dominance hierarchy or a territory has been established, it tends to confer priority of access to important resources without additional fighting unless the resource holder is specifically challenged. Dominance relationships may be long-lasting, as in species with small social groups in which every individual is familiar with every other, or, it may be occasion-specific, as in the rutting seasons that precede breeding in seasonal breeding species.

Territoriality involves the territory holder(s) marking and patrolling a space to deny entry to same sex conspecifics or members of other groups. The resident-intruder model, in which an unfamiliar same-sex conspecific is introduced into the subject’s home cage, constitutes a commonly used example of aggression based on territoriality. As with dominance relationships, variants to this pattern are frequent, including tolerance of same-sex individuals until they are mature or intrude on the prerogatives of the dominant. Harem-holding species, in

which dominant males strongly monopolize the reproductive services of females and nondominant males are much less likely to breed at all, show strong sexual dimorphism: Males are larger than females, and the larger the male the more likely it is to be dominant. In contrast, monogamous species, in which male–male fighting plays a much smaller role in reproduction, tend to show little sexual size dimorphism.

Dominance relationships may be particularly advantageous in situations in which the presence of a cohesive group provides additional sentinels, alternative targets for predators, or group defense against predators. Thus, unlike strict territoriality, dominance hierarchies usually include tolerance of the presence of sexually mature same-sex individuals (male except for a few species, such as spotted hyenas, where females are dominant), so long as these animals do not present challenges to the dominant. However, strategies to circumvent the dominant’s priority of access to some particularly important resources have also evolved. For example, DNA analyses have made it clear that ‘sneak mating strategies’ by subordinate or strange males may result in a substantial portion of offspring in some territorial or dominance hierarchy species being sired by these animals.

Both dominance relationships and territoriality often involve a further emergent resource: control over the actions of conspecifics. This becomes clearer in primate groups and clearest of all in humans. Anecdotal reports from field studies in many primate groups indicate that one feature of the behavior of dominants or territory holders is control of the behaviors of others in their group or territory, even when there is no apparent reason to do so, making another animal move away from a spot that is then not further utilized, for example. The value of this may be that it emphasizes the dominance relationship and facilitates future obedience of the controlled animal. In species showing coalitional aggression with one group attacking another group, the issue of the dominant’s control over members of its own group may take on additional and specific importance. The number of species showing coalitional aggression is increasing, and now includes several primate species, canids (wolves), meerkats, at least one bird species, several species of more primitive vertebrates, and some invertebrates (some ant, wasp, and sea anemone species).

Offensive Aggression: Behaviors and Targets

Most of the studies aimed specifically at analysis of behaviors involved in offensive aggression have been done in rodents. Adult rats can be maintained in small, mixed sex groups, whereas mice and hamsters are more difficult, as lethal attacks may be common when both sexes are present. Dominant male rats show a highly organized form of offensive attack, with bites aimed at the back of the

attacked (usually male) animal, a site in which bites are unlikely to cause debility or death. Such bites provide a means of delivering pain to subordinate males and encouraging them to leave the group, but without much risk of killing or damaging the reproductive potential of an animal that is likely in nature to be one of the dominant's own maturing male offspring. The same mechanism, a painful but nonlethal bite or blow, is additionally useful in species where the continued presence of subordinate adult males in a group adds to numbers that may be important in functions such as defense against predators; group predation tactics; or attacks on neighboring conspecific groups. It is notable that canids and primates as well as rodents appear to show a targeting of attack bites and blows. An additional adaptation reducing the dangerousness of fights is found in the evolution of protective structures for sites that are the targets of bites or blows. These structures may be especially necessary in species that are equipped with very dangerous weaponry. Thus lions, the only large cats to live in social groups, have a mane over the back of the head and the neck that is not found in other large cats.

However, the most common behavioral defense against bites or blows aimed at specific target sites on the body of the opponent may be for the defending animal to conceal or remove these targets by body manipulations or contortions. In rats, and also in mice, although targeting of attack is somewhat less stringent in this less gregarious species, behavioral protection of target sites for attack involves a number of back-defense behaviors, including upright facing of the attacker, interposing the defender's face (which is protected by long vibrissae, another structural protection for an area that would otherwise be a target of attack); and ventrum (an area that is highly vulnerable and not attacked) between the attacker's jaws and the defender's own vulnerable dorsal (back) area. The attacker counters this defense by attempting to lunge around the defender to reach its target, whereupon the defender pivots in the same direction, to continue to face the attacker. When the attack becomes very pressing, the defender may slip backwards to lie on its back, additionally rolling toward the attacker if the latter attempts to dig under for a bite. These attack and defensive behaviors occur sequentially in the actions of attacking and defending rats or mice in interacting dyads, with the form of defense typically serving to drive the specific actions involved in the attack.

The tenet that during intraspecific offensive attack damaging behaviors such as bites and blows tend to be aimed at less vulnerable sites on the opponent, with this tendency higher in social species, is important to understanding a number of factors in aggression. First, it represents an important enabling factor for the adaptive value of offensive aggression to be realized while avoiding damage to conspecific opponents. Second, it provides an

explanation for the specific form of a number of attack (and defensive) behaviors seen during intraspecific fighting. Third, it is highly compatible with findings of structural adaptations for intraspecific fighting, including manes, ruffs, antlers, horns, and the like. Fourth, it provides a means of evaluating whether a specific harm-producing action represents offensive or defensive aggression. Notably, the target site strategy applies to play fighting as well, but the targets of play fights tend to be different from those in either offensive or defensive attack.

If target sites for attack provide an explanation for the specific behaviors involved in attack and defense in some species, then these behaviors should be regarded as functional. In contrast, the more traditional ethological interpretation of many of the behaviors involved in conspecific fighting is that they represent signals to the opposing combatant. This is not to deny that there may be signal components to such behaviors: Thus piloerection, erection of hairs to make the combatant appear larger, might well be regarded as sending a (false or exaggerated) signal of the animal's size. But, a signal-only view of such behaviors requires a relatively convincing analysis that these actions are not functional in attainment or denial of access to a target site.

There is a clear and important use of target sites for offensive versus nonoffensive forms of attack to determine, in a given instance, what pattern of aggression is being demonstrated. However, in practice, target site analyses are rare, potentially leaving uncertainty about whether offensive attack is involved in a particular instance of fighting. In 'maternal aggression,' for example, attack by a lactating female on a small male intruder into her nest site appears to be offensive, although attack on a larger male intruder may involve a mixture of offensive and defensive elements. In particular, there are highly damaging forms of attack that are associated with defensive rather than offensive behavior, as well as a number of examples of abnormal aggression from recent literature, that are different than normal offense patterns (see below), suggesting that at least some of the confusions and contradictions in the literature on the neurobiology of aggression may be due to a mixture of offensive and nonoffensive attack modes in studies attempting to determine neurobiological factors in aggression.

Offensive Interspecies Fighting

Offensive aggression between different species is coming to be recognized as a relatively common event with important effects on species ecology and distributions. Many fish that live in coral reefs, for example, are highly territorial and will attack both conspecifics and nonconspecifics that intrude into their territories. Among mammalian predators, interspecific competition over

food or territories is particularly common, often with lethal results. This has been particularly well documented among larger predators on the African plains, perhaps reflecting the degree to which these predators and their behaviors are visible, and the consequent high numbers of studies involving them. Lions, leopards, hyenas, cheetahs, and wild dogs have been observed in cross-species altercations over food (prey). Many of these interactions are asymmetrical, with participants of the weaker species rapidly retreating while the victor consumes the prey. However, when larger groups of smaller/weaker predators confront smaller groups of stronger predator species, an aggressive encounter of substantial duration and potentially lethal intensity may occur.

Strategies for minimizing interspecific aggression over resources include spatial and temporal differences in habitat usage, such that the weaker participant species may be forced to completely withdraw from a given habitat, or to utilize it at a time of day or a season, in which they are less likely to encounter the stronger predator species. These ecological shifts may have effects on prey as well, in that animals selectively targeted by the weaker of two sympatric prey species may benefit greatly by the relative absence of their specific predators due to pressures from stronger predators. In theory, interspecific offensive aggression should not be inhibited by the potentially lethal impact of offensive aggression on the opponent. This is not an issue that has received a great deal of attention, but there are a number of reports of lethal wounds resulting from aggression between predator species, consonant with a view that the lethality of such fighting is not modulated by the types of mechanisms found in intraspecific offensive attack.

Defensive Behaviors

Defensive behaviors are the immediate and direct behavioral response to threats to life and bodily safety. They have evolved because of the differential survival success they provide when used successfully. For a defensive behavior to be successful, it should constitute an appropriate, that is, likely to be successful, response to both the type of threat encountered, and the situation in which it is encountered. While, as in offensive aggression, there may be substantial learning of what constitutes an eliciting stimulus, at least in more complex animals, defensive behaviors reflect evolved neurobehavioral systems providing a range of behaviors that tend to occur as unconditioned responses to threat stimuli of biological significance.

Defensive Aggression and the Defense Pattern

Flight, avoidance, freezing, defensive threat, defensive attack, and risk assessment to threatening stimuli have

been characterized in a variety of species, and these responses appear to be relatively common to most mammalian species. This reflects that higher animals face threats that are relatively consistent, involving predators and attacking conspecifics, and that appropriate and effective responses to these stimuli have a great number of parallels from one species to another.

The circumstances that promote defenses other than defensive aggression are outlined in this encyclopedia elsewhere. Briefly, these include features such as a way out or a hiding place (promoting flight or hiding, respectively) and stimulus ambiguity, which promotes active investigation of the stimulus; risk assessment. In contrast, defensive aggression is most strongly elicited to present, animate threats that are closely approaching the subject. For wild rats, defensive threat vocalizations to an approaching human will begin at about 1 meter, and defensive attack begins to occur at about .5 meters. While defensive aggression may be more likely in situations that are relatively inescapable, it is clear that the major environmental factor involved is the distance between the subject and the latter's attacker. Even while fleeing a rodent is likely to turn and attack as the pursuing predator comes within contact distance. This is functional, as the existence of an environmental escape route is irrelevant to an animal that is in the process of being overtaken by its pursuer. Notably, the actions comprising both defensive threat and defensive attack are free to occur at any prey-predator, or conspecific attacker distance. That they do not do so provides evidence for situational control of defensive aggression. Other species may show rather different threat-subject defensive distances, but again, these tend to be consistent within species and types of attacker. Thus, prey species that are large and formidable relative to their predators may utilize defensive aggression as their major defense, showing defensive threat, and even attack, at longer prey-predator distances than do animals for which defensive aggression represents a last-ditch effort.

Animate threat stimuli are more likely to elicit defensive threat and attack. From an evolutionary perspective, this is very sensible, as inanimate threats are seldom deterred by being attacked. However, an inanimate threat that delivers pain on contact may also elicit an immediate attack reaction. In laboratory rats, a group for which defensive threat/attack has largely been bred out by husbandry practices of consistently removing animals showing defensive aggression from the breeding pool, pain is perhaps the most efficient method of restoring defensive aggression to an animal's repertory. One very efficient means of doing so is to present a predator or conspecific to a confined rat while simultaneously delivering a mild shock to its tail. The result is a strongly time-bound (within 1 s of the shock) bite, but at a different body site on the opponent than is common in offensive

attack. Such defensive bites are most easily, in terms of the magnitude of tail shock that elicits them, obtained toward the opponent's snout and head, in contrast to the back targets favored in offensive attack.

This targeting appears to be consistent to both predators and attacking conspecifics, providing a view that in defensive aggression, the identity of the threat stimulus may be less important than it is in offensive aggression, where such features as the sex and pubertal status of an opponent have a major impact on the probability of attack. Another important implication of the extreme reduction in defensive threat and attack by domesticated rats, particularly to humans, is that it stands in contrast to offensive attack, which is apparently little changed from wild to laboratory rats. Findings that genetic selection against defensive attack has all but eliminated such attack in laboratory rats, in the absence of pain, but without much influence on offensive attack, strongly supports a view that the two are independently influenced by at least some genetic factors.

Differentiating Offensive and Defensive Aggression

Defensive aggression is different from offense in terms of the four cardinal features that traditionally define a behavior: Antecedent or triggering stimuli; organismic (e.g., motivational and experiential) variables; response characteristics; and outcomes. In terms of antecedent conditions, defensive aggression is a response to the threat of bodily harm or death, rather than to challenge another over resources. The motivation associated with defensive attack is fear, whereas offensive attack is reduced by fear.

Both the signals associated with defense and the actual form of defensive attack are different from those in offensive aggression. Defensive threat signals include loud vocalizations (screams, in both rats and cats) in a range likely to be audible to predators; display of weapons such as teeth or claws and body orientations and distentions that enhance the animal's apparent size; all useful in indicating the defensive capabilities of the defending animal. These are highly salient signals, impossible to ignore. Except for exaggerating the size of its body, offensive displays are different. The offensive cat walks quietly, albeit on straight, stiff legs that make it appear as tall as possible, toward the opponent. Offensive threat vocalizations tend to be quieter. In rats there is no specific vocalization associated with offense, whereas offensive cats emit a low growl rather than the scream of the defensive cat. In addition, the contorted movements of the defensive cat that is ready to attack, lying half on its back with claws of both fore and back limbs extended, have no counterpart in the offensively attacking animal.

These bodily distortions, often interpreted as displays or signals, may actually be more than displays. In addition

to indicating (and possibly exaggerating) the capabilities and determination of the defensive animal, such actions also present weapon systems in a state of readiness, constituting preparation for the species-typical fighting techniques that will be used if the display itself is not effective in deterring attack. Thus, the lying-half-on-the-back cat is in an excellent position to seize its attacker with its forepaws and hold it while it uses its hind paws (and claws) to rip at the attacker's ventrum, potentially leading to lethal disembowelment if the attacker is a conspecific.

This brings up the important distinction that defensive attack is often aimed at particularly vulnerable sites such as the eyes and snout, whereas offensive attack involves targets where damage is less lethal or crippling. The defensive animal typically does not show defensive aggression except as a terminal behavior in a series of actions such as flight and freezing that have failed. Injury or death to the opponent is irrelevant to the adaptive status of this behavior, whereas in offensive aggression where the adaptive outcome is more subtle, death or reproductive debasement of a relative is an additional consideration.

Factors Reducing Attention to Defensive Aggression

There are a number of reasons why the offense–defense distinction has been somewhat neglected in recent years. Because of selective breeding, in laboratory rats defensive attack is typically elicited only by painful contact with an attacker. When the attacker is a conspecific, this usual occurs only during the second or so following a bite, and only if the target sites for defensive attack, the face and snout of the attacker, are available to be bitten during this time. Defensive attacks are therefore very rare in aggressive encounters involving laboratory rats. Moreover, as defensive aggression in antipredator behavior can be seen only when the predator is allowed to carry out an actual attack on a prey animal, an event that is seldom allowed in most contemporary laboratories, it too rarely occurs in laboratory settings. However, experienced laboratories may utilize specific components of the defensive threat pattern, such as defensive vocalizations, as markers for the pattern. That this very limited role for defensive attack is misleading may be seen in findings that wild-trapped and first-generation laboratory-bred wild *Rattus norvegicus* do show high (and effective!) levels of defensive threat and attack to even nonpainful human contact.

For these reasons, when defensive attack does appear, following manipulations such as brain stimulation or lesions, it is often interpreted as offensive aggression, or, more commonly, as simply aggression, with no distinction made between the two forms of attack. In a classic case,

the so-called ‘septal syndrome’ is frequently interpreted as a hyperaggressive response. Rats with electrolytic lesions of the septal area will readily attack and bite when being handled, and will attack conspecifics when placed together with them in a small chamber. However, if the lesioned rats are allowed to escape the stranger rather than attacking it, they will do so.

Abnormal Aggression

More recently, a number of reports of ‘abnormal aggression’ from animals exposed to early stressors, or, following adrenalectomy, or as a result of selective breeding, have raised again the issue of forms of aggression that do not correspond to offense. What defines this abnormal aggression appears to be its lack of reliance on the features that normally control (offensive) aggression. Thus, abnormal aggression makes little distinction between legitimate targets of attack, for example, adult male conspecifics, and animals such as females and prepubertal males that are normally not attacked. Opponents displaying submission signals are also attacked. Finally, the target sites for attack in abnormal aggression are not, in rats, the back and flanks where bites are made in normal offensive aggression, but the head/snout.

These factors suggest that abnormal aggression may be more related to defensive than to offensive attack. While, at present, the case for such identity is largely inferential, it would be of great interest to evaluate this potential relationship, perhaps by more intensive comparisons of behaviors across these models, and also in terms of brain regional activation patterns, using c-Fos or other activity markers. The point is not just academic, as early stress or abuse, in particular, are substantially related to patterns of bullying and other hyperaggressive response in juveniles and later in adults. If the abnormal aggression patterns seen following early stress, or in animals of ‘short attack latency’ lines, are linked to human aggression phenomena, it is clearly important to learn whether these may be related to an offensive or a defensive aggression pattern.

This situation is further complicated by the fact that offensive and defensive forms of aggression may occur in the same animal or person, in the same agonistic bout. In fact, every example of two animals, or persons, engaging freely in an agonistic bout would be expected to involve some offensive motivations on the part of both parties. As

one of the combatants gains the upper hand, however, it is predictable that the other should experience an enhancement of fear, along with a diminution of offense. Such mixed motives in a naturalistic situation, are common; for example, sexual and aggressive motivations or defensive and appetitive motivations. What they do emphasize is the importance of adequate analysis in order to (experimentally) tease apart the mixed motives and polarize both motivations and behavior patterns in order to gain an improved understanding of when and how aggression occurs in the real world.

Glossary

Conditioned place preference – A learned preference for an environment previously paired with a hedonic stimulus.

Frustrative nonreward – Nonhedonic approach behavior despite either intermittent reward or omission (i.e., extinction) of reward.

Negative reinforcement – Increasing the likelihood of a behavior by omitting a negative affective punisher.

Positive emotions – A category of emotion that consists of appetitive prosocial emotions (e.g., happiness/joy) and consummatory sensory pleasures (e.g., gustatory pleasure).

Positive reinforcement – The ability of a positive emotional reward to increase the likelihood of the reward-eliciting behavior.

Sonogram – A frequency (y-axis) by duration (x-axis) by intensity (grayscale) visual representation of sound.

Ultrasonic vocalizations – Vocalizations with a peak frequency above the threshold of the human hearing range (20 kHz).

positive affective states are primarily related to positive prosocial interactions.

Experimental studies that elicit positive affective states generally use social positive affective stimuli (i.e., positive feedback, giving a small gift, or watching a video tape eliciting positive affective states). Positive affective states that are elicited in an experimental setting by these stimuli have been shown to increase gregariousness, optimism, and openness to new experiences. These phenomenon have been referred to by Barbara Fredrickson and colleagues as 'broaden and build'.

Consummatory Positive Affective States

Experimental studies of pleasure have primarily focused on the hedonic effects of food or thermal regulation. These studies show that the function of pleasure is to maintain behaviors that return the body to homeostasis. For example, a warm stimulus would be experienced as pleasurable by a cold individual, with the magnitude of the pleasure being proportional to the ability of the stimulus to return the body to homeostatic conditions. This emotionally driven change in sensation associated with a return to homeostasis is referred to by Michel Cabanac and colleagues as sensory alliesthesia.

Defining Positive Emotion

In humans, positive emotional states are positively valenced feeling states that are associated with the propensity toward approach and/or consummatory behavior. There are two main classes of positive emotions: appetitive positive emotional states (e.g., joy) are associated with approach behavior and pleasure is associated with consummatory behavior. The primary function of positive emotions is to elicit and maintain appetitive or consummatory behavior as well to produce positive reinforcement.

Positive Affective States in Humans

Appetitive Positive Affective States

Socializing with friends or romantic partners is the activity that most robustly elicits appetitive positive affective states. However, not all socializing is hedonic. The same studies show that interacting with supervisors or other family members is not consistently hedonic. Therefore,

Health Benefits of Positive Affective States

Positive affective states, as studied longitudinally in humans, confer resilience to depression and anxiety, and lead to an increase in overall health and a decrease in mortality from all causes. The psychological and physical health benefits of positive affective states are likely due to increases in resilience (continued global functioning despite the presence of stressors). For example, following a major life stressor, individuals exhibiting greater positive affect are less likely to develop psychological disorders such as anxiety and depression. Longitudinal studies also show that positive affective states precede the health benefit effect of positive affect. Therefore, positive affect is not simply a secondary consequence of overall good health. Conversely, individuals who have low levels of positive emotion are at greater risk of developing anxiety disorders, depression, and global health problems. Interventions that increase positive affective states have been shown to reduce levels of depression and anxiety.

Neurobiology of Positive Affective States in the Human Brain

The primary neuroanatomical underpinnings of positive emotion are associated with the ascending mesolimbic dopamine system, as described by brain imaging studies (i.e., functional magnetic resonance imaging or positron emission tomography), as well as the direct elicitation of positive affective states through drug administration or electrical brain stimulation. Brain imaging studies using recall of positive affective memories, listening to positive music, male orgasm, and positive anticipation of monetary reward have been shown to activate aspects of the ascending mesolimbic dopamine system (which includes the ventral tegmental area, nucleus accumbens, medial prefrontal and orbital frontal cortices). The euphoric effects of intravenous amphetamine have been shown to be directly related to dopamine activity in the nucleus accumbens. Direct electrical brain stimulation of the accumbens has been shown to elicit Duchenne laughter and self-report of positive affect. Patients given the opportunity to self-administer electrical stimulation to the nucleus accumbens or to an area at or near the ventral tegmental area repeatedly self-administered this stimulation and reported that the stimulation elicited a positive affective state.

The molecular underpinnings of positive affective states are still largely unknown. The endogenous molecules associated with the euphoric effects of drugs of abuse have received the most study. These consist of the endogenous opiates acting on μ -receptors (endorphins, met-enkephalin, and β -endorphin) and dopamine. μ -Opiate and dopamine levels in the mesolimbic positive affect circuit have been found to be positively correlated with the euphoric effect of exercise and amphetamine, respectively.

Intravenous administration of μ -opiate and dopamine agonists produced positive affective states in humans. μ -Opiate receptor antagonists have been shown to blunt the positive affective states elicited by exercise and alcohol. Dopamine receptor antagonists decreased positive affective states associated with psychostimulants. However, aversive stimuli also increased μ -opiate and dopamine levels in the nucleus accumbens. Therefore, the μ -opiate and dopamine systems are not completely specific to positive emotions.

Measuring Positive Affective States in Animals

In order to establish that an animal behavior reflects a positive affective state, at least two criteria must be met: (1) the behavior must serve as a positive reinforcer and (2)

in humans a homologous behavior must be associated with the self-report of a positive affective feeling state.

Is Reinforcement Sufficient for Positive Affective States?

Positive reinforcement is specific to positive affective states, whereas negative reinforcement is not. Negative reinforcement serves to reduce negative affective states, which is not the same as increasing positive emotion. Compulsive behaviors (e.g., checking or hand washing) and frustrative nonreward are examples of nonhedonic reinforcement.

Positive reinforcement as measured by conditioned place preference is a sensitive and specific index of positive emotional states in laboratory animals. Conditioned place preference can distinguish between positive and negative reinforcement. Stimuli that elicit positive affective states in humans increase conditioned place preference, whereas negative affective stimuli induce conditioned place aversion.

Operant responding alone is not a sufficient index of a positive emotional state. Rates of operant responding (i.e., bar pressing) can be increased both by positive affective stimuli (positive reinforcement) and the avoidance of aversive stimuli (negative reinforcement).

In humans, there is not a clear positive relationship between the frequency at which a behavior is performed and the level of positive affect associated with that behavior. In the study of positive affect in the everyday lives of Americans, watching television is only weakly hedonic but is engaged in more frequently than more hedonic activities such as prosocial behavior and exercise. In addition, working, cleaning, and commuting are high-frequency behaviors that are nonhedonic.

Taxonomy of Positive Affective States in Humans

The scientific study of positive affective states primarily relies on affective self-report. In these studies, the most consistent and robust elicitors of positive affect are prosocial interactions, eating, and exercise. Each of these behaviors has clear homologies in animals.

There are other behaviors that are hedonic in both humans and laboratory animals that do not occur frequently enough in everyday life to be captured by these self-report studies. Offensive aggression and predatory behavior are hedonic in laboratory animals, and are probably also hedonic in humans.

Some hedonic behaviors in humans have either not yet been adequately modeled in laboratory animals or modeled in animals. Relaxation is a major source of pleasure in humans, but has not yet been adequately modeled in laboratory animals.

Communicated Positive Affective States in Laboratory Animals

Some positive affective states are communicated by facial/vocal displays in both humans and laboratory animals; these displays can be used as unconditional indices of positive emotional states. Prosocial behavior elicits hedonic Duchenne smiling and laughter in humans. In laboratory rats, hedonic 50-kHz ultrasonic vocalizations (USVs) are a homolog of these behaviors. Hedonic food elicits hedonic oral facial behavior (e.g., lip smacking) in humans. In laboratory rats, hedonic taste reactivity responses are a homolog of these behaviors.

Hedonic 50-kHz USVs in Rats

Frequency-modulated 50-kHz USVs have been shown to reflect a positive affective state in rats. Positively reinforcing social interactions (i.e., mating and rough-and-tumble play), anticipation of food, and action of euphorogenic drugs of abuse increased number of emitted 50-kHz USVs, whereas aversive stimuli such as social defeat, frustrating nonrewarding situations, sickness-inducing doses of lithium chloride, and foot shock all decreased the number of 50-kHz USVs. The rewarding value of the stimuli eliciting positive affective states was positively correlated with the rates of 50-kHz USVs elicited by positive social, drug, and electrical brain stimulation reward. μ -Opiate and dopamine agonists, as well as electrical brain stimulation of the mesolimbic dopamine system, also increased rates of 50-kHz USVs in rats. The neuronal and pharmacological underpinnings of rat 50-kHz USVs appear to be consistent with those of human positive emotions.

Alternative nonhedonic interpretations of the emission of 50-kHz USVs are not supported by the available data. (1) 50-kHz USVs have been hypothesized to be an artifact of locomotor activity-induced thoracic compressions. However, additional studies found that only 10% of 50-kHz USVs were coincident with thoracic compressions, and 50-kHz USVs could be dissociated from locomotion. (2) 50-kHz USVs have been hypothesized to reflect a nonaffective contact call. More detailed studies found that flat 50-kHz calls appear to be a nonaffective contact call, occurring at the highest rates during nonpositive affective social interactions. However, frequency-modulated 50-kHz calls appeared to be selective for positive affective social interactions. (3) 50-kHz calls have been hypothesized to reflect a nonpositive affective wanting state. 50-kHz USVs are increased in the anticipation of delivered reward, which in humans has been shown to elicit a positive affective state. However, during extinction bursts or frustrating nonreward, such appetitive behavior decreased rates of 50-kHz calls and increased rates of aversive 22-kHz calls. Therefore, only positively

valenced appetitive behavior appears to elicit frequency-modulated 50-kHz USVs. (4) 50-kHz ultrasonic calls have been hypothesized to reflect a state of high arousal that is not specific to positive affective states. Highly arousing aversive stimuli such as predatory odor, foot shock, and bright light decrease rates of 50-kHz calls, whereas rewarding stimuli increase rates of 50-kHz calls.

Hedonic Taste Reactivity

Hedonic taste reactivity responses in rats, consisting of midline and lateral tongue protrusions and paw licking in response to oral infusions of tastants, have been shown to be homologous to positive affective states in humans. Hedonic sweet solutions (e.g., sucrose or saccharin), or salty (NaCl) solutions in salt-deprived animals, increase hedonic taste reactivity scores. Aversive solutions (e.g., quinine) and conditioned taste aversion produced by LiCl reduce rates of hedonic taste reactivity scores. Both sucrose and saccharin produce conditioned place preference, and LiCl produces conditioned place aversion in rats. μ -Opiates and cannabinoids increase positive affect in humans and increase hedonic taste reactivity responses when injected into the nucleus accumbens.

Noncommunicated Positive Affective States in Laboratory Animals

Not all positive affective states have a social communication component. The communication of positive affective states serves to both promote prosocial behavior and provide positive reinforcement in the receiver. During offensive aggression, the communication of positive affective states is inappropriate given that prosocial behavior and positive reinforcement in the attacked animal is not warranted. Exercise and predatory behavior do not necessarily involve conspecifics. Therefore, communication of a positive affective state during exercise and predation is also not warranted.

Offensive Aggression

Offensive male–male aggression serves as a positive reinforcer for the dominant animal in the conditioned place preference test, and therefore is considered to reflect a positive affective state. The rewarding and positive affective value of aggression is probably limited to only certain kinds of aggressive behaviors. Defensive male resident-intruder or maternal aggressive behavior may be motivated by negative reinforcement (i.e., avoid loss of sexual partner, offspring, and/or territory), and therefore not necessarily associated with a positive affective state. In contrast to the dominant animal, submissive animals have

been shown to exhibit diminished positive affective states and increased levels of depression and anxiety.

Predatory Behavior

Predatory behavior has also been shown to reflect a positive affective state in laboratory animals. In rats, animals that readily engage in mouse-killing behavior show conditioned place preference for environments paired with mice. In cats, electrode sites that support electrical brain stimulation-induced mouse killing also uniformly support self-stimulation.

Exercise

Rats will show place preference for environments paired with voluntary wheel-running behavior. In a similar manner as human positive affect, voluntary wheel running induces resilience to depression and increases the lifespan of the animal. It is unclear if forced exercise is hedonic in laboratory animals.

Drugs of Abuse

Rats will show place preference for drugs that robustly increase positive affect in humans. In contrast, aversive substances such as LiCl induce robust-conditioned place aversion. Therefore, the hedonic value of drugs of abuse can also be measured in laboratory animals.

Conclusions

The 50-kHz USVs and hedonic taste reactivity have been shown to reflect a positive affective state in rats.

Noncommunicated positive affective states can be measured by conditioned place preference. Because it is now possible to study positive emotional states in rats, the neuroanatomical basis and molecular mechanisms of these forms of positive affect can now be elucidated. These studies should lead to a deeper understanding of positive affect in humans and should lead to the development of novel therapeutics for the treatment of depression.

Social Competition and Conflict Resolution

O Petit, CNRS, Strasbourg University, Strasbourg, France

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Affiliative interaction – Positive social interaction between individuals such as grooming, playing, sleeping in contact.

Anxiety response – Emotional reaction caused by aggression. This response can be objectified using the measurement of different behavioral indicators. In primates, for example, rates of scratching increase after a conflict both in the aggressor and the aggressee.

Conflict – The aggressive behavior of one individual (vocalization, stare, lunge, pursuit, slap, grab, and bite) and the response of the opponent (aggressive or submissive). It does not necessarily involve physical contact.

Dominance hierarchy – The network of dominance–subordination relationships in a social group. When the hierarchy is linear, individuals can be ranked from the most dominant animal to the most subordinate one. Individuals can be qualified as high ranking or low ranking.

Dominance relationships – In a pair of individuals which know each other, one (the dominant) regularly wins conflicts with the other (the subordinate). When a subordinate meets a dominant, it expresses its lower status by either avoiding the dominant or submitting to it.

Reconciliation – Positive contact between former opponents following a conflict. Reconciliation is presumed to be a positive factor in repairing the relationships jeopardized by the conflict.

Stress response – Adaptive physiological reaction to either an internal or external stimulus. The adrenal cortex secretes glucocorticoids in response to stress. Chronic stress is the result of repeated exposure to stressful situations and has deleterious consequences, due in particular to the oversecretion of glucocorticoids.

Submission – One individual acknowledges its lower status to a higher-ranking individual by displaying behaviors such as avoidance, crouching, presentation of hindquarters, or specific facial expressions and vocalizations.

Third-party intervention – One individual intervenes in a conflict between two opponents. The intervention may be peaceful or aggressive. In the latter case, aggressive support leads to a coalition of two opponents against a third one.

In group-living animals, conflicts of interest over limited resources may lead to open contests between group members. Aggression occurs in many circumstances of daily life. While it is potentially disrupting for societies, it can also structure relationships. In the following text, the term ‘aggression’ will be used to describe the whole phenomenon, whereas ‘conflict’ will specifically refer to social interactions between animals. This article focuses on intra-group competition. When aggression occurs, conflict escalation can be prevented by various management strategies, and its deleterious effects on individuals and social relationships can be mitigated through post-conflict resolution and social dominance. Considering the physiological underpinnings of aggression can lead to a better understanding of the consequences of aggression and dominance for individuals.

Conflict Management

The outcome of conflicts depends on the balance of power between opponents. When the aggressee flees or submits, the conflict is called unidirectional or asymmetrical. When it counter-attacks, the conflict is bidirectional or symmetrical. Counter-attacking in a conflict is not very common and only occurs if there is a low risk of injury. Their escalation is usually nonadaptive, since suffering injuries would decrease the fitness of opponents. However, during challenging periods for top-ranking positions, animals can fight to the death. In this context, group members should maintain the balance of power and solve conflicts through several mechanisms. To study aggression, we therefore have to consider not only agonistic behavior such as threats and attacks, but also the response to this aggression in forms such as escape, appeasement, submission, or redirection.

Appeasement and Submission

The first solution to conflict is the use of appeasing behaviors between opponents immediately after the conflict. Appeasement can therefore be considered to signal the end of the conflict. One or both opponents can display these behaviors, which include facial displays, contact calls or positive contacts such as grooming, mounting, or playing. There is no division of roles between opponents:

the aggressor can start appeasing the aggrieved, or the opposite. Aggression can also be stopped by the submission of one individual to its opponent. Submission can include behaviors such as displaying facial expressions, fearful vocalizations, or bending down. Subordinate individuals generally address submissive signals to higher-ranking opponents.

Redirection of Aggression

In some instances, one opponent, more often the aggressor, redirects aggression by threatening or attacking a third individual, thus transferring to the latter the attention of its aggressor and of other group members. The target of the redirection is generally a lower-ranking individual. Redirection is only an efficient strategy if the previous aggrieved is certain to win the new conflict, and is especially efficient in species such as rhesus macaques where counter-aggression is scarce. In species where counter-aggression is common like Sulawesi macaques, redirecting aggression toward another group member would lead to new conflicts and would be a quite unproductive strategy.

Revenge

The target of a redirection can sometimes be a relative of the aggressor (kin-oriented redirection) which is often less powerful and more vulnerable than the latter (as observed in Japanese and pig-tailed macaques). It has been shown that in such cases, the former aggressor rarely supports its relative, mainly because such redirection occurs during polyadic interactions where it would have to face several opponents. This kind of strategy could be a means to modify the aggressor's attitude toward the aggrieved on a long-term scale. Indeed, this aggressor will avoid attacking this specific individual again in order to avoid redirected aggression toward its relatives and thus protect them. Such social manipulation has been considered as a revenge system; it has been reported in macaques, baboons, and chimpanzees. However, the revenge system in chimpanzees has been described as a case of social reciprocity, since the former aggressor intervenes in favor of its attacked relative during redirection events. Such differences in the aggressor's behavior in a revenge system could be explained by the different degree of nepotism and despotism observed within the two forms of social organization. Besides kin-oriented redirection, a generalization of a former conflict to matri-lineal level has been observed, with an aggrieved's kin attacking an aggressor's kin. In baboons, aggrieved and aggressor's relatives do not need to witness the conflict: hearing vocal threats and/or protest of kin's fight is sufficient to induce a conflict between them.

Third-Party Intervention

Long-lasting social tension may affect foraging performances, defense against other groups, and antipredator vigilance, which all require some degree of social stability to be efficient. Therefore, besides having direct effects on opponents, conflicts also indirectly influence the behavior of others. Any disturbance of the social balance is of interest to all group members. Given the potential effects of escalated aggression on other group members, individuals unrelated to both opponents seek to influence events following a conflict between two group members and can directly intervene in the conflict.

Interventions in conflicts have mostly been described in nonhuman primates, but they have been recently reported in rooks. The third party generally supports one individual (the beneficiary) against its opponent (the recipient of the intervention). The third party can reinforce its relationship with the beneficiary, or increase its dominance over the recipient of its intervention. The motivations and benefits of interveners are competitive. The most frequent form of intervention is aggressive, in which the intervener forms a coalition with one opponent: they attack the other opponent together and win more often (**Figure 1**). Rank reversals often occur after repeated coalitions between partners. In several nonhuman primate species, nonaggressive means of intervention occur. In agonistic buffering, during male–male conflicts, a young individual is used by one challenger to appease the other one. This intervention has been reported for Barbary macaques and several baboon species and is frequently an involuntary participation for the juvenile: adults use infants and juveniles' immunity for their own interests. More rarely, the approach of a high-ranking individual toward opponents can be sufficient to stop

Figure 1 Coalition in white-faced capuchins (*Cebus capucinus*) at Lomas Barbudal Reserve, Costa Rica. Photograph by G. Prats.

the conflict. In other cases, a third individual unambiguously intervenes in conflicts by appeasing one opponent using signals such as affiliative facial expressions, touching, clasping, and mounting.

In Tonkean macaques, nonaggressive interventions are more efficient than aggressive ones to prevent conflict escalation. They have been qualified as peaceful interventions. Similar behaviors have been reported in gorillas and chimpanzees. In peaceful interventions, contrary to aggressive ones, the intervener does not make a choice against one opponent; it helps one partner and preserves its relationship with the other. On some occasions, the intervention is directed to both opponents. The intervener threatens both opponents or simultaneously appeases them. Peaceful interventions appear more effective than aggressive ones in reducing social stress and avoiding conflict escalation.

PostConflict Resolution

De Waal and van Roosmalen defined reconciliation as a positive contact occurring between previous opponents immediately after a conflict. The measurement of specific postconflict attraction between former opponents is used to demonstrate the occurrence of reconciliation. By comparing the postconflict period to baseline conditions, it is possible to demonstrate that friendly contacts between opponents occur earlier following conflicts. Thanks to this method, reconciliation has been observed in many species such as dolphins, hyenas, wolves, goats, and more particularly in nonhuman primates: baboons, macaques, capuchin monkeys, chimpanzees, etc. The form of reconciliation and the probability of reconciliation differ not only between species, but even within a same genus. Some species display low rates of conciliatory tendencies while others display high rates. Reconciliation appears to covary with the degree of tolerance between group members, especially in macaques. Indeed, in species characterized by a strict hierarchy and a high preference for relatives, reconciliation is less frequently observed than in species where dominant individuals are tolerant toward subordinates and in which good relationships exist between most group members, including nonrelatives. Strong conciliatory tendencies keep competition costs low and help preserve social relationships. Behaviors used in postconflict interactions are not specific to reconciliation. Animals display behavior patterns such as clasping, grooming, mounting, or social play.

One might think that kin-related individuals or individuals with good relationships rarely fight, and that conflicts occur mostly between nonaffiliated dyads.

Rather to the contrary, preferred partners are often close together, so they are more likely to interact aggressively. As a consequence, they need to repair their relationships, which often suffer through conflicts. In many species, reconciliation is more likely after conflict between valuable partners.

Reconciliation may reduce the occurrence of further aggression, reduce anxiety caused by the conflict, and restore the damaged bond to preconflict levels. The integrated hypothesis links the quality of the opponents' relationship and the level of postconflict anxiety. In primates, scratching is a stress-related behavior, an indicator of tension that has been used as a measure of postconflict anxiety. Scratching provides information about the animals' perception and evaluation of a certain event, and is a valuable tool to study the impact of conflicts and postconflict events on the participants. Conflicts lead to increased levels of scratching in both aggressors and aggrieved individuals in several species, such as chimpanzees, long-tailed macaques, and baboons. The disturbance of the relationship with the adversary may induce anxiety. Reconciliation reduces stress-related behaviors to control levels. Thus, one of the main functions of reconciliation might be stress alleviation.

Given the possible effects of aggression on the whole group, the aggrieved's kin, aggressor's kin, and unrelated individuals are all liable to take part in the postconflict situation. In addition to dyadic conflict resolution, triadic postconflict affiliation has been described in several species. This refers to affiliation between conflict participants and uninvolved bystanders called third parties. Such contacts may involve the aggressor or the aggrieved as well, and third parties may be kin to either one of the contestants, or unrelated to them.

When a former aggrieved individual affiliates with a third party, this is considered as a consolation. It has been proposed that such consolation would occur when reconciliation is not possible, and allows stress alleviation. In general, triadic postconflict resolution is not an alternative postconflict interaction, it does not alleviate stress levels in aggrieved individuals, and even aggressors may receive such postconflict affiliative contact. For example, in long-tailed macaques, female aggressors showed selectively increased affiliative contacts with kin of the aggrieved and an increase in contacts with other group members (own kin and unrelated individuals). Such behavior might benefit individuals which provide affiliation: in this way they avoid escalation of aggression to other group members. The hypothesis of such self-protection is supported by the fact that affiliation in chimpanzees is selectively given to those opponents showing further aggression to third parties, and this behavior actually decreases the risk of receiving aggression from contestants.

Social Dominance

Group members should avoid systematically entering conflicts concerning competition for food, water, or mates. To deal with social competition, animals generally establish stable and long-term social relationships based on dominance, which is an adaptive strategy to maintain social cohesion. Such relationships are established through aggressive encounters where one opponent wins and the other loses. Such an outcome refers to real dominance. The iteration of aggressive interactions between two partners leads to a stable dominance–subordination relationship, with one partner being dominant over the other. In subsequent encounters, the subordinate avoids the dominant partner or submits. This formal dominance is then based on directional signals formally acknowledging the relative status of partners. This relationship lasts as long as the subordinate accepts it.

A high dominance status confers many advantages such as priority access to best resting places, sexual partners, or preferred food. The network of dominance relationships for all group members constitutes the social hierarchy. When the hierarchy is linear, the top-ranking animal of the group (sometimes called the alpha individual) dominates all other group members, the second higher-ranking animal dominates all group members except the first, and so on. In some species, we observe triangular relationships that stem from nontransitive relations: A dominates B, which dominates C, which dominates A. In species such as horses and social carnivores (mongooses, wolves, and wild dogs), dominance rank strongly depends on age. Similarly, in gorillas, an age-graded hierarchy is reported among males. The fully mature male is recognizable by its silver back; silverback and top-ranking individual are synonyms in this species. Many species display a dominance of males over females, but in some primates, alliances between kin-related females can alter it.

Dominance-rank inheritance is reported in species such as macaques and baboons, where females are philopatric, that is, females stay in their natal group during their whole life. Mothers support their daughters in conflicts against other group members, and thus help them to reach a hierarchical status close to their own. As a result, all members of the same matrilineal clan – all kins descending from the same female – have similar dominance – ranks. Within a matrilineal clan, young daughters are supported by their mother in conflicts with their older sisters, and they often outrank them.

The social hierarchy can be more or less steep. In some species, low-ranking individuals may easily approach higher-ranking individuals, and they may have access to limited resources. In other species, higher-ranking ones systematically displace lower-ranking animals. The latter

stay in the periphery of the group most of the time, preventing the occurrence of positive interactions between group members of contrasted dominance ranks. These different societies are observed in macaques, where some species are considered as tolerant and others as intolerant. In the former, aggression intensity remains low and conflicts are mostly bidirectional because individuals can protest and counter-attack without risk. This contrasts with the relations observed in the more intolerant macaques where biting is not rare; in such species, it is more effective to flee when attacked.

Physiological Determinants

The response of individuals within the context of aggression and social dominance depends on their ability to react to stressful situations. In rodents, higher social status and aggressiveness are associated with high testosterone levels, whereas subordination and defeat of conflicts are associated with increased adrenal corticoid production. Nevertheless, there is no typical scheme over time for the physiology of aggression and dominance. It depends on stability versus instability observed over the studied period. Stable periods are characterized by clear-cut hierarchical relationships where subordinate animals spontaneously submit to higher-ranking individuals. During unstable periods, some low-ranking individuals – often adolescent ones, and more especially young males – challenge high-ranking animals. Whereas an immediate stress response is an adaptive physiological reaction which is both useful and healthy, a chronic response may have pathological consequences.

Aggression and Hormones

The neuroendocrine regulation of aggression has been well studied in birds, rodents, and primates. Testosterone is linked to aggressive male behavior in response to reproductive challenges; increased testosterone output corresponds to periods of increased aggression during territory defense or mate guarding. Increased glucocorticoid secretion is also an adaptive stress response to challenging situations.

In rats and mice, aggression is associated with high levels of glucocorticoids in both opponents, although the increase is observed over a shorter period of time in the winner. In nonhuman primates, both contestants show an increase in heart rate after an agonistic interaction, and increased rates of scratching that are associated with sympathetic activation. Being attacked is also associated with increased concentrations of glucocorticoids. In general, high rates of aggression tend to be positively correlated with elevated testosterone concentrations in primates. Causality is implied by typical decline in rates

of aggression following castration and testosterone-induced restoration. However, testosterone secretion is neither necessary nor sufficient for aggression to occur. Testosterone seems to have a modulatory rather than an activational effect on aggression.

The challenge hypothesis states that plasma testosterone levels and aggression are positively correlated during periods of social instability or challenge. During such periods, aggressive interactions are more frequent, leading to high testosterone levels. Glucocorticoids and testosterone show significant increases during both mating and birth seasons in male red fronted lemurs. This increase has also been observed in birds. In seasonally breeding birds, circulating sex steroids fluctuate, generally with high levels during the breeding season and basal levels during other periods of the annual cycle. In many avian species, territorial behavior shows a similar seasonal pattern. In a migratory population in a common North American songbird, plasma testosterone levels in males are high in early spring, when males are aggressively establishing territories.

During the nonbreeding season, aggression is independent of testosterone and other sex steroids. Male and female spotted antbirds show high levels of territorial aggression toward same-sex intruders in the nonbreeding season and show elevated concentrations of dehydroepiandrosterone (DHEA) and low (or untraceable) concentration of testosterone and oestradiol. DHEA appears to play the same role in the aggressive behavior of hamsters and humans.

Serotonin is involved in the determinism of aggression. Male rhesus macaques with low central serotonin levels early in life show social isolation, impulsive aggression and high levels of violence. This profile exposes these individuals to increased risk of traumatic injury and early death. Moreover, low concentrations of cerebrospinal fluid levels of serotonin metabolite (5-HIAA) are associated with negative life-history patterns, characterized by social instability and extreme aggression, and are also linked to positive patterns such as high dominance rank.

Dominance and Stress

Many studies have found that in stable hierarchies, low-ranking individuals have higher stress levels (measured in heart rate or cortisol) than high-ranking individuals. Stress levels may cause changes in individuals that affect a number of aspects of their biology. This includes factors such as their immune competence, coronary health, basal hypertension, and a slow activation of the cardiovascular stress response after conflict, together with delayed recovery when stressful pressure reduces. Animals that are more socially stressed by the dominance hierarchy show signs of hyperactivity of the glucocorticoid system. The adrenal cortex secretes glucocorticoids in response to

stress and these steroids are central to the adaptations that the individual must carry out to cope with physical stressors. Glucocorticoids increase cardiovascular tone and inhibit a variety of costly anabolic processes – including digestion, growth, reproduction, and immune and inflammatory responses – until after the stressor has decreased. These functions represent high catabolic process costs. Therefore, it is not surprising that the pathological consequences of chronic stress are largely mediated by overexposure to these same steroids.

Dominance rank was found to correlate with urinary cortisol in female long-tailed macaques: high-ranking individuals had lower rates than low-ranking individuals. In addition, high-ranking females attracted more, gave more agonistic support, and were bitten less frequently than low-ranking females, but they were not attacked less frequently than low-ranking ones. Similarly, in rhesus macaques, low-ranking animals were attacked more severely, but not at higher rates than high-ranking ones. A correlation between dominance rank and aggressiveness has been reported in the females of the latter species, high-ranking females being more aggressive than low-ranking ones. Moreover, a negative correlation was found between aggressiveness and cortisol. Thus, individuals near the top of the social hierarchy differ in physiology and behaviors from those occupying lower positions. Interestingly, in baboons, subordinates that initiate fights or redirect aggression have lower cortisol levels than subordinates that do not display these behaviors. From these results, no single physiological profile can be associated with either dominance or subordination; some studies found no relation between stress levels and position in the hierarchy.

Social instability may explain variations in the interrelations between endocrine function and dominance. During periods of social stability, basal testosterone concentrations are similar in high- and low-ranking males, although the former tend to be more resistant to stress-induced suppression. Indeed, they are relatively resistant to the inhibitory effects of stress, that is, they are more prone than others to maintain and even to increase concentrations of testosterone during stress. Studies of dominant male primates in stable hierarchies have shown their adrenocortical axes to possess rapid and high secretion with the onset of stress, with prompt termination at the end. In baboons, high-ranking males tend to have low resting cortisol secretion, an ability to rapidly increase secretion during stress, and an enhanced sensitivity to the feedback regulation that terminates secretion. Under stable conditions, dominant males also show metabolic, cardiovascular, and immune profiles that are potentially less pathogenic than those of subordinates. In contrast, during periods of instability, basal testosterone levels are considerably higher in high-ranking than in low-ranking males. High rank during times of social

instability is associated with both high rates of aggression and high concentrations of basal testosterone, as proposed by the challenge hypothesis. In challenging periods or during group formation in baboons, dominant males most frequently initiate aggressive interactions and also have the highest basal testosterone levels. On the contrary, a severe decline is observed in subordinates at the same period. Similar results have been reported in rhesus macaques and squirrel monkeys. Therefore, a positive correlation emerges between rank and testosterone, although it is not apparent during stable periods. In addition, during instabilities dominant males no longer show the lowest glucocorticoid concentrations. They no longer display the most spectacular increases in cortisol concentrations during stress. Differences between dominant and subordinate males in gonadal activity during stressful situations in stable groups are associated with altered regulation of pituitary–adrenal activity. These adaptive and dormant features of adrenocortical function, characteristic of high-ranking males during periods of social stability, are lost during periods of instability. It appears unlikely that high testosterone causes dominance. The association between dominance and high testosterone concentrations appears to be primarily due to an effect of behavior on the endocrine system; one would expect a decreased correlation as the relationship become more relaxed under stable conditions.

Reproductive Correlates

From an evolutionary perspective, being dominant appears more advantageous than being subordinate, at least during stable periods. Struggling for dominance is presumed to yield higher benefits at higher costs, whereas accepting subordination probably produces lower benefits but at lower costs. But no consensus exists as to whether dominant or subordinate animals are more physiologically stressed. When considering which ranks are more stressful, we must look at the dominance style of the species. In species where higher-ranking individuals have to repeatedly and physically reassert their dominance, they are the most stressed animals, reflecting the physical demands of frequent fighting. This applies to cooperative breeders where all group members rear young, whereas dominant individuals monopolize reproduction by harassing subordinates and those with temporary periods of rank instability. In contrast, in species where social hierarchy is stable and high rank is

maintained through nonphysical pressure rather than through aggression, this profile occurs among subordinates because they are more exposed to frequent social stressors.

Experiencing low rank can lead individuals to develop alternative strategies, less conspicuous than aggressive ones. In various species of monkeys where the reproductive skew is biased in favor of the top-ranking male, subordinates can increase their reproductive success using alternative strategies such as sneaking copulations. Females have some control over the partners they mate with in species like baboons or chimpanzees. They may choose low-ranking males with whom they have preferential relationships. These males not only increase their reproductive success but they show fewer physiological indices of stress than expected from their social rank.

To summarize, no clear pattern can be drawn concerning the link between aggression, stress, dominance, and reproductive success. Dominance might have advantageous correlates as long as subordinates accept their low social status.

Glossary

Anxiolytic/anxiogenic – The stimuli (chemical, drug, environment, etc.) that decrease anxiety; anxiogenic refers to stimuli that increase anxiety.

Corticotropin-releasing factor (CRF) – A stress hormone produced by the hypothalamus and other brain regions. It binds to the cognate receptors, CRF-R1 or CRF-R2 (also known as CRF1, CRF2).

Hypothalamic–pituitary–adrenal (HPA) axis – The hypothalamic–pituitary–adrenal axis is responsible for the neuroendocrine response to stress.

Phenotype – A detectable expression of a genotype.

Selective breeding – The breeding/mating of animals showing similar traits (behavioral, physical, or physiological) to enrich offspring with the same trait.

Stress reactivity – An individual response to a stress/stimuli expressed by behavioral and endocrinological measures.

pituitary corticotropes to stimulate the release of adrenocorticotropic hormone (ACTH). ACTH, in turn, increases the synthesis and release of glucocorticoids from the adrenal gland. Glucocorticoids direct the metabolic and energetic changes that allow the body to respond to the stressful stimulus and help to terminate the HPA-axis response through a negative-feedback loop to return the body to homeostasis.

The activation of the HPA axis can result from internal or external signals, often categorized as either processive or systemic stressors. Processive stressors are those that invoke higher cognitive functions such as restraint, novelty or novel environments, and social stress. Systemic stressors are elicited by sensory stimuli such as metabolic or immunologic disturbances; examples include hypoxia, pain, inflammation, and blood loss. Experience with any of these stressors results in increased release of CRF, ACTH, and glucocorticoids within the HPA axis; a variety of major neurotransmitters (i.e., norepinephrine and epinephrine, dopamine, and serotonin (5-HT)) or other neuropeptides (vasopressin, neuropeptide Y (NPY), etc.) are also released, often from non-HPA-axis circuitry.

Strikingly, the frequency (acute vs. chronic) and familiarity of a stressor have differential effects on both the physiological response as well as activation of non-HPA-axis neuronal circuits. Acute stressors reliably elicit an HPA-axis response, but the level of response is controlled in part by the type and intensity of the stressor. Chronic stress can be predictable, as in exposure to restraint stress for multiple sessions, or unpredictable, using a varied number of stressors administered in a random fashion, and the response of the HPA axis differs depending on the predictability. A repeatedly administered or encountered stressor – such as daily restraint stress (homotypic stress) – often leads to habituation, evidenced by decreased glucocorticoid release. In contrast, if multiple stressors are administered in a random order, even if repeated over several weeks (chronic unpredictable stress), little or no habituation is observed. While the duration, controllability, and intensity of the chronic stress episode influence the outcomes, a wide variety of behavioral effects (e.g., aggression and anxiety) and physiological responses (e.g., elevated corticosteroids (CORTs), enlarged adrenal, involuted thymus, and decreased body weight) have been observed. The inability to adapt to stress has been associated with changes in

Stress

Stress is often broadly defined as a disturbance in the homeostasis or well-being of an organism caused by a physical or psychological challenge (stressor). At the physiological level, stress is characterized by the activation of the hypothalamic–pituitary–adrenal (HPA) axis that results in an increase in circulating glucocorticoids (cortisol in humans, corticosterone in rodents, etc.). The acute stress response is highly beneficial to humans and animals since it facilitates the fight-or-flight response to endangerment and a return to homeostatic conditions. However, either the inability of the body to respond adequately to stress or prolonged exposure to stress can result in adverse consequences on physical and psychological well-being.

HPA Axis and Stress

The HPA axis is the direct pathway to the release of adrenal stress hormones into the circulation. In response to stressful stimuli, the corticotropin-releasing factor (CRF) produced in the paraventricular nucleus (PVN) of the hypothalamus is released from the median eminence into the portal blood, acting on anterior

CRF and glucocorticoid secretion and can lead to increased risk for affective disorders in humans. Sustained changes in glucocorticoid secretion have also been linked to cardiovascular disease, obesity, and type II diabetes.

Basic Neural Circuitry Underlying Stress Response

While all stress ultimately results in HPA-axis activation, the type of stressor strongly influences which other neural circuitry (e.g., limbic circuitry vs. brainstem) is activated. In general, systemic stressors activate the brain areas involved in the initial sensory processing of the stimulus – especially brainstem nuclei – and are notably independent of activation of limbic circuitry. Many brainstem nuclei send direct projections to the PVN, resulting in activation of the HPA axis; cognitive awareness is not necessary to activate a stress response since systemic stressors tend to acutely threaten homeostasis.

In contrast, processive stressors generally activate the limbic circuitry, including the amygdala and hippocampus. Limbic circuits appear to play a primary role in the conditioning that leads to the memory of a stress in the absence of the actual stimuli. Through the repeated pairing of a stress-inducing stimulus with a neutral one, the stress response can be induced by the once-neutral stimulus. For example, if a rodent is shocked in an environment that otherwise is not harmful, the rodent will release stress hormones in that environment and avoid it even in the absence of the shock. Both the amygdala and the hippocampus have been shown to be involved in the consolidation of these emotional memories. Cortical activation is also involved in processive stressors, adding to the cognitive dimension. As these stress-regulatory limbic sites (cortex, hippocampus, and amygdala) lack significant direct input to PVN, they relay their information through synapses in the bed nucleus of the stria terminalis (BNST), preoptic area, and hypothalamus – providing the opportunity for integration with other information on ongoing physiological status prior to the final signal to the PVN stress neurons. It is important to note that within each class of stressor, the same circuitry is not necessarily invoked, but any mono- or multisynaptic circuitry involved eventually innervates the PVN to activate the HPA axis.

Emotionality

Emotionality in humans refers to the experience of emotions (e.g., happiness, sadness, fear, anger, and anxiety) and includes the accompanying physiological changes, such as alterations in heart rate and sweating. Emotions are forms of communication between individuals and, as

in the case of fear, can be a useful life-saving defense mechanism. However, when the extremes of emotion are exhibited for extended periods of time, they can represent a more severe pathological state. Affective (mood and anxiety) disorders represent the dysregulation of emotional states. Mood disorders, as categorized in the *Diagnostic and Statistical Manual-IV* (DSM-IV), include major depressive and bipolar disorders, while anxiety disorders include generalized anxiety, panic, phobia, and posttraumatic stress disorder (PTSD). Understanding the etiology of these affective disorders is critical for developing appropriate treatments to reestablish personal well-being.

In animals, especially rodents, emotionality usually refers to fear and anxiety; some investigators also include depression-like behavior. Although animals may not experience the same constellation of emotions as humans, fear- and anxiety-related behaviors in particular represent negative emotions that are driven by species-specific, yet evolutionarily conserved, defense mechanisms. Fear and anxiety are distinguished by the reality of the harmful stimulus: a real, imminent threat results in fear, whereas the perception of a harmful threat, not necessarily present, results in anxiety. Further distinctions between the emotional states of fear and anxiety have been elucidated pharmacologically. In rodents, benzodiazepines (anti-anxiety drugs) reduce anxiety-related behaviors such as risk assessment, but do not affect fear responses to an imminent threat or danger.

Emotionality in rodents is measured by a behavioral response to a specific change in the animal's environment. Historically, one of the most commonly used responses was the locomotor activity observed after placement in a novel, aversive environment (open-field). Locomotor stimulation or depression was often accompanied by changes in autonomic responses such as heart rate, defecation, and urination. Together, activity and defecation were used to describe rodents as more emotional (decreased activity and increased defecation) or less emotional (increased activity and decreased defecation). Although this test is still commonly used, other behavioral assays have been developed to measure anxiety (elevated plus maze (EPM), light-dark box, etc.), fear (startle, conditioned fear, etc.), or depression-like behavior (forced swim, tail suspension, etc.). However, it must be emphasized that no single test can be used to definitively measure anxiety, fear, or depression-like behavior in rodents since these emotional states are complex behaviors, subject to individual variation. Thus, animal models are often tested on a battery of behaviors to better assess an anxious, fearful, or depression-like phenotype. Pharmacological treatments that affect outcomes in these behavioral tests have been used for the validation of these behavioral assays, and these behavioral tests continue to be used for the identification and development of novel therapeutics for the treatment of affective disorders.

Brain Circuits Mediating Fear and Anxiety

Our understanding of the circuitry underlying emotional states has been advanced by the use of imaging studies in human subjects. The ability to visualize the brain regions activated by fearful or anxiety-provoking stimuli has indicated that activation of the amygdalar nuclei is critical to anxiety and fear responses. Functional imaging studies have also identified the amygdala, hippocampus, and cortex as regions involved in anxiety disorders, including PTSD and phobia.

In rodents, the neural circuitry underlying fear (using the startle response and conditioned fear/fear-potentiated startle) and anxiety have been identified by lesion and pharmacological studies. Results from these studies have identified limbic regions, in particular the amygdala and BNST, in mediating fear- or anxiety-related behaviors. Using fear-potentiated startle as a model, the general flow of information within the extended amygdala has been identified with the basolateral nucleus of the amygdala (basolateral amygdala (BLA)) acting as the input center for fear or anxiety stimuli and the central amygdala (CeA) and BNST acting as the main output regions. Fear and anxiety have also been dissociated anatomically; the BLA and the CeA mediate responses to fear-related startle stimuli, whereas the BNST appears to mediate anxiety-related responses. For example, CeA lesions block fear-potentiated startle, whereas BNST lesions do not. In contrast, anxiogenic stimuli (e.g., bright light) enhance startle – an effect that is altered by BNST lesions, but not by CeA lesions. Thus, the dissociation of fear and anxiety can be seen not only at the level of the activating brain regions but also at the subsequent downstream neural circuits.

Stress and Emotionality

Many affective disorders are precipitated and/or exaggerated by stress. Assessing the interplay between stress and emotionality is, therefore, critical to understanding the development and progression of emotional psychopathology. Does stress reactivity predict anxiety/fear reactivity? Does increased anxiety predict altered stress reactivity? The answers to these questions are complex and require an understanding of the overlapping circuitry of these processes and a wide variety of *in vivo* studies using pharmacological, behavioral, and genetic approaches. In the sections below, we attempt to provide some insights into these areas using both human and animal model systems.

Behavioral Interactions of Stress and Anxiety

A review of the literature clearly demonstrates that stress and emotionality are closely interrelated in human and

rodent behavior. In humans, early-life stress can predispose vulnerable individuals to depression and/or anxiety disorders later in childhood or adult life. Children who lose a parent or are physically or sexually abused show a much higher risk for the development of affective disorders as adults. With these early-life stressors, the HPA axis often becomes hyperactive, resulting in altered glucocorticoid release and feedback – sensitizing the individual to subsequent stressors. Similarly, chronic stress during childhood or as an adult can result in altered emotional response and increased risk in susceptible individuals for mental disorders such as generalized anxiety, major depression, and bipolar disease. In addition, a single traumatic and intensely stressful event can result in PTSD.

Dysfunction of the HPA axis is observed in a wide variety of these affective disorders. In social phobia, an elevated HPA-axis response to social stressors is observed; the HPA-axis response is often dysregulated in PTSD as well. These results suggest that stress or stress-associated factors may contribute to the development of anxiety and mood disorders; however, it is possible that the HPA-axis dysfunction may develop subsequent to the psychopathology in some cases. Finally, the contributions of genetics and environment cannot be understated as the individual differences in response to similar stressors suggests that both genetics and environment contribute dramatically to an individual's coping skills and vulnerability to affective disorders. Recent data suggest that the negative effects of early-life stress can be moderated by both subsequent caregiving environment and by genetic factors – further emphasizing the important interactions between genes and environment in determining one's sensitivity or resilience to stressful stimuli.

In animal models, the interactions of stress and anxiety-like behavior have also been investigated. Not surprisingly, even a single exposure to an acute stressor can affect anxiety-like behavior, depending on the type and duration of the stressor, time of testing, and stress-sensitivity of the rodent. A single, intense stressor such as footshock can decrease the time spent in the open arms of the EPM, increase acoustic startle, or decrease social interaction – all indicative of increased anxiety-like behavior. Animals exposed to unpredictable chronic mild stress paradigms have been widely used as models for depression-like behavior, and the effects of these chronic (usually 2–4 weeks) treatments on anxiety-like behaviors have also been investigated. While these chronic mild stress paradigms have significant effects on depression-like behaviors, they often show lesser effects on anxiety-like behavior, with great variation in results depending on the specific stress paradigm utilized. In general, while acute stress and chronic stress both produce a reliable HPA-axis response, the effects on anxiety-like behavior

can be quite varied, suggesting activation of both similar and distinct neural pathways. Finally, it should be noted that some animal models with increased or decreased anxiety-like behavior show relatively normal HPA-axis responses to stress, again suggesting that stress reactivity and anxiety-like behaviors can overlap or dissociate, depending on the stimuli, neural pathways, and genetic and environmental status of the animal.

Neurocircuitry Connecting Stress and Emotionality

The limbic regions that are activated by processive-type stress stimuli provide the connection between stress and emotionality. As described above, these processive stressors activate the amygdala, BNST, hippocampus, and cortex – all regions that also process fear- and anxiety-provoking stimuli. Neurons in the CeA and BNST project to the lateral hypothalamus, midbrain, and brainstem nuclei (e.g., ventral tegmentum, locus ceruleus, and dorsal raphe nucleus), and hypothalamic PVN, to name a few. Hence, integrated information in these limbic regions can alter HPA-axis and autonomic stress responses as well as fear- and anxiety-related behaviors. Recent studies further suggest that chronic stress can lead to dendritic remodeling in the amygdala and BNST, with resultant changes in BNST volume as well. These structural changes suggest a potential mechanism for the functional modulation of emotional behavior by chronic stress.

Stress Hormones and Emotionality

The relationship of stress hormones – especially CRF and CORT – to emotionality has been an area of significant interest due to the expression of CRF, CRF receptors, and CORT receptors in the limbic structures. As noted earlier, alterations in HPA-axis activity are clearly associated with susceptibility to various affective disorders including depression and anxiety, and CRF and CORT have been widely associated with fear- and anxiety-related behaviors as well. CRF binds to two receptor subtypes in the brain, CRF-R1 and CRF-R2, and these receptors are expressed not only in the HPA axis (e.g., in the PVN and pituitary), but also in numerous limbic regions including the amygdala and BNST, key areas involved in fear and anxiety, and brainstem nuclei such as the locus ceruleus and the dorsal raphe, key sites of interaction between the CRF and noradrenergic and serotonergic systems, respectively. A CRF-binding protein (CRF-BP) distinct from the CRF receptors is also widely expressed in the brain and pituitary where it is thought to bind CRF and reduce CRF receptor activation. Finally, the brain receptors for glucocorticoids, the low-affinity glucocorticoid receptor (GR) and the high-affinity mineralocorticoid receptor (MR), are also highly expressed in

the limbic system, making the hippocampus and amygdala particularly sensitive to circulating CORT levels. Specific roles for each receptor type/subtype have been investigated in terms of stress and emotionality responses.

CRF is generally found to be anxiogenic in tests of anxiety and fear (EPM, social interaction, fear-induced freezing, etc.), although familiarity with an environment can elicit anxiolytic behavioral responses to CRF. Studies from many groups suggest that activation of the amygdalar CRF system, particularly via CRF-R1, may contribute to the stress-evoked alterations in fear/anxiety-related behaviors. If nonselective CRF receptor antagonists are injected into the amygdala (CeA or BLA), an anxiolytic effect is observed. As mentioned previously, CRF and CRF-R1 expression in the PVN are also central to the HPA-axis modulation of stress responsivity. Hence, it is not surprising that total pharmacological blockade of brain CRF-R1 receptors can diminish both stress responses and anxiety-like behaviors.

CORT also play very important roles not only in stress, but also in fear and anxiety. However, the effects of CORT on anxiety-related behaviors are highly dependent on the levels of CORT (low levels activate only MRs, while high levels activate both MRs and GRs), the timing of CORT exposure relative to the stressor, and whether the stressor is unconditioned or conditioned (i.e., based on memory). CORT levels are elevated in rodents after exposure to the EPM, and elevated CORT levels have been correlated to risk assessment behaviors (stretch-attend postures). Interestingly, CORT administration enhances CRF gene expression in the CeA (in contrast to decreasing expression in the PVN), suggesting that CORT may increase anxiety in part by increasing CRF expression in CeA. Finally, chronic-stress-mediated changes in CORT levels may also increase CRF in the CeA and BNST, contributing to the maladaptive, higher anxiety state that may predispose to other pathophysiology.

Animal Models of Stress and Emotionality

It is generally accepted that affective disorders have a genetic component that – when combined with environmental factors – results in greater susceptibility. Identification of the risk factors, both genetic and environmental, can be a daunting task. While early-life stresses have been shown to increase risk for pathophysiology in later adolescence or adulthood, pharmacological or behavioral therapeutics/treatments have not yet been developed for these environmental challenges. Genetic linkage and genome-wide association studies have led to the identification of candidate genes for a number of affective disorders, but further testing the role of those genes is not feasible in human populations.

However, there are several types of animal models that have been used to probe the interrelationships between stress and emotionality and the potential contributions of specific genes or sets of genes to these behavioral responses. The simplest models rely on the variable expression of stress and emotionality traits in large, general populations. Using this phenotypic approach, the relationship between stress reactivity and anxiety-like behaviors has been examined. If rats are phenotypically selected for low- or high-anxiety-like behavior, no differences are seen in stress responsivity. However, if rats are selected for high or low activity in a novel environment, the high-activity rats generally show a greater stress response, but often exhibit either no change or decreased anxiety-like behavior (greater risk takers). While this phenotypic approach is very useful for behavioral correlations, it is limited in its ability to provide information with regard to common genetic mechanisms. To address this issue, the use of selective breeding in animals has allowed for the determination of (1) genetic (heritable) factors underlying the selected trait (e.g., stress or behavioral response) and (2) genetic correlations with other (nonselected) traits. For example, rat lines bred for differential locomotor response to a novel environment can be tested for HPA-axis response to restraint stress to ascertain the extent to which common genetic factors underlie both traits. Inbred rat and mouse strain studies are additional genetic models that provide useful information with regard to the genetic relationship between different behavioral traits.

While selective breeding moves closer to identifying common genetic factors underlying stress reactivity and emotionality than phenotypic studies, this technique is still not capable of identifying or testing the role of specific individual candidate genes that may be involved. Genetic engineering has provided important tools for generating animals with targeted disruption or over- or underexpression of specific genes to determine their effects on specific behaviors. While some of these methods are being used in rats, most of the genetically modified models have been created in mice.

Not surprisingly then, numerous genetically modified mouse models have been examined to address the role of specific stress-related molecules on emotionality. While one might predict that a single-gene effect would not have a large effect on quantitative traits such as anxiety or fear, many of these genetically modified mice showed changes in anxiety-like behaviors, suggesting that many genes may contribute in significant ways to emotionality. For example, the data from knock-out (KO) mice involving CRF receptors support pharmacological data indicating an important role for CRF receptors in anxiety-related behaviors. Mice lacking CRF-R1 showed less anxiety than wild-type mice, suggesting a role for CRF-R1 in mediating anxiety-like behavior. As predicted,

CRF-R1 KO mice show impaired ACTH and CORT responses to stress as well. The role of CRF-R2 is more variable, but data suggest it is important for restraining the stress (HPA-axis) response and anxiety-like behavior, as CRF-R2 KO mice appear to be more stress-sensitive. CRF-BP KO mice show increased anxiety, consistent with higher than normal levels of free active CRF. Paradoxically, CRF KO mice show a dramatically impaired stress response, but do not show altered anxiety-like behaviors, likely due to compensation by other CRF-related molecules. Finally, overexpression of CRF in mice leads to increased basal circulating glucocorticoids, characteristic of Cushing's disease, with reports of either no change or increased anxiety-like behavior, consistent with the predicted roles of CRF.

Glucocorticoid manipulations have also been shown to affect stress-, anxiety-, and fear-related behavior. Mice lacking functional brain GRs demonstrate increased basal corticosterone, but decreased anxiety. However, mice lacking GRs only in the forebrain show an altered HPA-axis response and an increase in stress-induced locomotion, but no change in anxiety-like behavior – indicating the importance of subcortical regions in modulating anxiety-related behavior. Transgenic mice with an overexpression of forebrain GRs demonstrate increased anxiety and depression-like behavior. In contrast to overexpression of GRs, transgenic mice that overexpress MRs in the forebrain exhibit decreased anxiety with normal basal HPA-axis function. While alterations in GR and MR levels would be predicted to alter HPA-axis function in stressed and basal states, the changes in anxiety-like behavior or stress-reactivity are also quite striking, likely due to the important roles of these receptors in fear/anxiety pathways as well.

As stress and the CRF system also regulate the serotonergic system, it is not surprising that many mouse models with alterations in 5-HT signaling also show altered phenotypes relevant to stress and emotionality. The neurotransmitter 5-HT is released during stress and anxiety and has been widely implicated in mood disorders due to the effectiveness of selective serotonin reuptake inhibitors (SSRIs) as antidepressant therapeutics. Among the many 5-HT receptors, 5-HT_{1A}, 5-HT_{1B}, and 5-HT_{2A} receptor subtypes have been targeted for roles in stress and anxiety responses. In contrast with pharmacological studies, the deletion of 5-HT_{1A} receptors resulted in an increase in fear and anxiety-like behavior in a number of tests, suggesting an effect of this receptor in decreasing anxiety behavior. Interestingly, using a tissue-specific, conditional 5-HT_{1A} KO mouse, deletion of this receptor in embryonic and early postnatal development – but not during adulthood – resulted in increased anxiety-like behavior, suggesting an important developmental period for the expression of 5-HT_{1A}. Consistent with the role of 5-HT_{1A} in anxiety-like behavior, the

overexpression of 5-HT1A in the brain resulted in decreased anxiety-like behavior. 5-HT1B receptor KO mice tend to show hyperactivity, with no change or a decrease in anxiety; 5-HT2A receptor-deficient mice show decreased anxiety-like behavior in the open-field, EPM, or light-dark tests, but show no alterations in fear conditioning or HPA-axis function. Finally, 5-HT transporter (5-HTT) KO mice exhibit significant increases in anxiety and stress-related HPA-axis function, consistent with the linkage of 5-HTT-gene-linked polymorphic region (5-HTTLPR) with anxiety- and depression-related personality traits. Clearly, the role of the 5-HT system in mediating anxiety, fear, and stress responses is complex, depending on specific brain circuits and thus the receptor subtypes expressed in those circuits.

Together, the results from all of these animal models support the critical roles of the CRF, CORT, and 5-HT receptor systems in the pathophysiology of anxiety disorders and depression. The specific genetic linkages that contribute to vulnerability to affective disorder remain a key area of analysis.

Emerging Areas of Interests

Genetics and environment are key factors related to stress-reactivity and the development of anxiety and mood disorders. While genetics is a key area of study in both humans and animal models at the present time, the long-term effects of environmental challenges are less well understood. Studies with human subjects and nonhuman primates have shown that early-life stress can have long-lasting psychological effects, increasing the risk for emotional disorders like depression and anxiety. In rodents, early postnatal stress caused by maternal separation can result in increased stress responses and higher anxiety in these animals as adults. Studies suggest that prenatal stress can have significant impact on the pups as well. Recent work by several groups suggests a model in which environmental conditions result in epigenetic alterations in expression of key stress-related molecules. The role of these epigenetic changes is an exciting new area of study that is key to elucidating the long-term effects of stress and anxiety across development. Finally, male/female differences in stress and emotionality should

not be ignored as sex differences are quite apparent in many affective disorders. The interactions of gonadal hormones and stress hormones during critical periods of development may impact the maturation of stress-sensitive brain areas, including the limbic-forebrain areas, affecting long-term sex differences in responses to stress and anxiety. Additional studies in all of these areas will enhance our understanding of the impact of sex, genes, and environment on our ability to cope with stress and anxiety in adaptive versus maladaptive ways and may lead to new therapeutic strategies.

Glossary

Cultural display rules – Rules learned early in life that dictate the management and modification of emotional displays depending on social circumstances.

Culture – A meaning and information system, shared by a group of individuals and communicated from one generation to the next.

Emotion – A transient, bio-psycho-social reaction designed to aid individuals in adapting to, and coping with, events that have implications for survival and well-being.

Microexpressions – A fleeting, transient facial expression of emotion that is often a form of nonverbal leakage. They are signs of concealed emotions, and are characterized by their speed, subtlety, and often fragmentary nature.

Schadenfreude – A German word referring to the pleasure one feels in the misfortunes of others.

Moreover, affect and emotion are aspects of psychology that all humans have a lifetime of access to, and a lifetime of contemplating the proper words to describe nuances of an inner physiological state or sensation. Thus, it is difficult to arrive at a consensual definition of emotion that encompasses all the possible types of emotion, and at the same time differentiates it from affect. Nevertheless, it is important to adopt a working definition of emotion so that readers can understand what part of the affective world we call emotion.

We define emotion as “transient, bio-psycho-social reactions designed to aid individuals in adapting to and coping with events that have implications for survival and well-being.” They are biological because they involve bodily responses; they are psychological because they involve specific mental processes required for elicitation and regulation of response, as well as affect; and they are social because they are often elicited in interactions, and have meaning to those interactions. (We use the word ‘social’ here in the broadest sense in relation to our evolutionary history, which includes interactions not only with other humans, but also other living beings, such as snakes, bears, wild pigs, etc.)

Emotion, therefore, is a special class of affective phenomena. They are unique, evolved, higher-order information-processing systems that allow the human to regulate and modulate all the other evolved cognitive, motivational, and motor-behavioral systems in order for the human to survive. When emotions occur, they turn-on some systems and turn-off others, so that the human is not overloaded with sensory and cognitive stimuli when dealing with events that have import and require a response. Emotions prevent internal chaos, and provide the human with a rapid, unconscious, and automatic system of processing information to facilitate goals, and a mechanism to deal with events, ultimately promoting survival. They evolved to help us cope with events and situations that have consequences for our ‘immediate’ welfare. If the human did not have emotions, we would not know when to attack, defend, flee, care for others, reject food, or approach something useful, all of which were helpful in our evolutionary histories (as they are today). Thus, emotions helped the human adapt to immediate needs in their environments, and were instrumental in our survival as a species.

Affect and Emotion

In psychological science, affect refers to the various feeling states the human, and perhaps other animals, experience. Affect plays an important role in our lives, serving as a mechanism of self-information about one’s internal states, events that occur, and our relationship with others and our environment. The human experiences a wide range of affective phenomena, such as being tired, bored, sleepy, excited, hungry, angry, afraid, sad, ashamed, proud, embarrassed, happy, or jealous. Affect motivates our behavior, directs our goals, changes our ways of thinking, and colors all of life’s experiences in meaningful, relevant, and important ways. Feeling hungry, for instance, motivates us to find food, just as feeling tired motivates us to rest.

One of the problems that plagues our understanding of the subjective experience and communication of emotion is that emotion is often equated with affect, and this should not necessarily be the case. Indeed, the universe of affective phenomena includes all feeling states, which includes emotion, but also moods, affect-related personality traits, some psychopathologies, and well-being. Our affective world also encompasses physiological need states – hunger, thirst, tiredness, sleepiness, and boredom.

How Are Emotions Elicited?

Emotions are elicited when we perceive the occurrence of an event that is important to us and requires a behavioral response. This system originally developed to deal with species-constant problems that could occur in interactions with nature or other beings, and are related to survival in a time-tested, predictable, and automatic fashion. The emotion system is hard-wired, fairly impermeable to modification by experience, and relatively unchanged throughout the life span.

When sensory information is perceived, it is converted to schemas – mental representations of the situations or events being perceived. These schemas may consist of two components – one referring to the physical characteristics of the sensory information associated with the perceived event trigger, the other referring to psychological meanings or themes associated with the event trigger. In other words, perceived schemas may describe what the events are, and/or what they mean.

Then, the created schemas are evaluated in an appraisal process, which is immediate, unbidden, opaque, unconscious, and automatic. In that process, perceived schemas must be compared to a known set of emotionally relevant schemas, that is, schemas that when matched should initiate an emotional response. These latter schemas are held in an ‘emotion-schema database.’ For example, the perception of a coiled, cylindrical object that is hissing may match the schema of a snake in the emotion-schema database, triggering the emotion of fear. The perception of the smell of feces may match the schema of contamination in the emotion-schema database, triggering the emotion of disgust.

The schemas in the emotion-schema database have been learned in our evolutionary history and are hard-wired into the emotion system, so that individuals do not need to re-learn them in their lifetime. The learning has already occurred, and one of the beauties of the emotion system is that events associated with these hard-wired schemas will trigger emotional responses with no learning, thus allowing individuals to rapidly respond to the event triggers automatically and unconsciously. Indeed, if the human had to learn about schemas for fear and then consciously think about the appropriate responses, we may not be alive today. However, because we have learned them in our evolutionary past, or because these schemas remain through a process of natural selection, we do not have to relearn them in each and every new lifetime, which is a considerable survival advantage.

If the perceived schemas do not match those in the emotion-schema database, no emotion is elicited and the individual continues to scan the environment. A match, however, initiates a group of responses, which are coordinated, integrated, and organized, and constitute what is

known as an emotion. The term ‘emotion’ is a metaphor that refers to this group of coordinated responses.

The Emotion Response System

Emotions aid in adaptation because they recruit programs that coordinate and orchestrate other evolved systems, such as perception, attention, inference, learning, memory, goal choice, motivational priorities, physiological reactions, motor behaviors, and behavioral decision making. We group these responses into four categories – cognitions, physiology, expressive behavior, and subjective experience. Their engagement allows for the simultaneous activation of certain evolved systems and deactivation of others, in order to prevent the chaos of multiple, competing systems being activated at the same time, allowing for coordinated, orchestrated responses to environmental stimuli. Thus, anger prepares the body to fight, and fear prepares for flight. To be sure, not everyone who is angry actually does fight, nor does everyone who is afraid actually flee. In these cases, anger and fear ‘prepare’ the individual to do so; engaging in such motor behaviors, however, depends on a host of other factors, both cultural and individual.

The Subjective Experience of Emotion

One of the major components of emotional responses involves affect. The subjective experience of emotion refers to the affective feeling states associated with the arousal or elicitation of emotion. These experiences are most likely heavily influenced by the physiological reactions that occur when emotions are aroused. Research has demonstrated that emotions such as anger, disgust, fear, joy, sadness, and surprise are associated with distinct physiological signatures both in the autonomic and central nervous systems. These physiological changes help prepare individuals to respond to the eliciting stimulus immediately and effectively by initiating and maintaining whole-body activity. Anger, for instance, produces vaso-dilation, pupil constriction, foaming, and piloerection, each of which prepares the individual to fight. Fear, however, produces vasoconstriction, pupil dilation, and bulging eyes, preparing the individual to flee. The same physiological signatures have been found in people of very different cultures, and thus are strongly suggestive of a biologically innate, universal program for emotional responding that is unique for each emotion.

Because these physiological changes occur, they produce sensations that are felt as part of the subjective experience of emotion. Thus, anger produces feelings of pressure and heat in a container, while disgust produces feelings of revulsion in the mouth. Fear feels cold and

constricted, sadness brings about loss of muscle tone and aching in the eyes, and joy brings about tingling. All of these sensations are experienced precisely because of the physiological changes that occur when emotions are aroused.

Emotions also recruit a host of cognitive processes that support the action-preparedness of the individual. Two types of basic-level cognitive processes are associated with this arousal. One is the perceptual/attentional system, which maximizes attention to the elicitor and minimizes attention to distractors. The other is the gating of higher mental processes, which limits the novelty of the response and aids in the accessing of memories and other knowledge stores helpful in determining the appropriate subsequent behavioral response. This is why when one is angry, it is easier to think about aggressive thoughts, and to remember previous anger-eliciting episodes. One's senses are heightened to perceive anger in others. All of these cognitive reactions are part and parcel of emotional responses, and contribute to emotional experiences.

Because each emotion recruits a different physiological and cognitive response, each emotion is associated with a unique subjective experience; thus, anger feels qualitatively different than disgust or fear or jealousy. Sadness feels different than shame or guilt. Even positive emotions such as pride, amusement, awe, gratitude, excitement, relief, wonder, or *schadenfreude* feel different from each other. Moreover, each of these emotions is elicited by different types of events, turns-on different physiological and cognitive responses, and leads to different potential behavioral outcomes.

Like all affective responses, the subjective experience of emotion serves a function. Feelings of anger, joy, jealousy, or disappointment tell us important information about our internal states, and whether we are cognitively or physiologically prepared to run, fight, jump with joy, or just sit and recuperate. Subjective feelings tell us about our relationships with others or the environment. The thrill of victory and the agony of defeat would not occur if competition and its associated outcomes were not important to us, just as are many other matters, such as birth, battle, seduction, and just plain getting along. In addition, our subjective experiences motivate our future behavior. Success breeds success, or more pointedly, the joy associated with success leads one to want more, just as the disgust that occurs when tasting spoilt milk assures that we do not want to drink it again in the future.

It is useful to distinguish among the affective component of emotion, conscious awareness of it, and the labeling of it. Although affect is aroused as part of the emotion response system, sometimes individuals are not consciously aware that an emotion has been elicited, and that their bodies and minds are reacting. Thus, it is possible to have an emotion but not be aware of it. Even when one is consciously aware of one's feelings, one may

label them in a variety of ways, or attribute their causes to different things. Because emotions and their response components are universal, there are great degrees of similarity around the world in how emotional reactions are labeled and interpreted. However, both labeling and the causal attributions about emotions can be dependent on cultural and individual differences. Thus, it is also entirely possible for anger to be elicited in two people with very different backgrounds, and for one to label and interpret their reactions as anger, and for the other to label and interpret reactions differently, even though the reactions themselves are quite similar.

The Communication of Emotion

Darwin suggested that expressive behaviors associated with emotion are the residual actions of more complete behavioral responses. Facial and vocal expressions are part of those actions, and occur in combination with other bodily responses – postural, gestural, skeletal muscle movements, and physiological responses. This perspective suggests that different emotions are associated with specific, unique facial configurations, and that each facial configuration occurs because it complements the behavioral response associated with the aroused emotion. Thus, we express anger in our faces by furrowing the brow and tightening the lips with teeth displayed because these actions are part of an attack response; we express disgust with an open mouth, nose-wrinkle, and tongue-protrusion as part of a vomiting response. Facial expressions are part of the coordinated response involving multiple systems.

There is strong evidence for the universality of facial expressions of seven emotions. One such line of evidence comes from judgment studies, in which observers in different cultures are shown various facial expressions and are asked to judge which emotion is being portrayed. Observers around the world universally recognize the facial expressions of anger, contempt, disgust, fear, joy, sadness, and surprise across different stimulus sets, investigators, expressor ethnicities and sex, and response formats.

Even stronger evidence, however, comes from production studies, in which emotions are elicited and the resulting facial behaviors are measured. The most well known of these is Ekman's classic study of Americans and Japanese college students. However since then, there have been many other studies that measured facial behaviors that occurred in reaction to emotionally evocative situations, and reported that the facial configurations originally posited by Darwin, and verified and somewhat modified by Ekman, actually occur. These studies have involved a variety of emotion-elicitation methodologies, and participants from many different countries and cultures,

Figure 1 The seven universal facial expressions of emotion.

demonstrating the universality of facial expressions of emotion. Examples of the universal facial expressions of emotion are depicted in Figure 1.

Moreover, the available evidence strongly suggests an evolved, biological basis of universal facial expressions of emotion. The universal facial expressions among the human have been observed by ethologists in nonhuman primates for years. Most recently, methods to measure the facial expressions of nonhuman primates have been developed, and studies show that nonhuman primates have the same facial musculature for emotion signaling as does the human, and that the same expressions occur in the same types of emotionally evocative situations as with the human. In addition, congenitally blind individuals spontaneously produce the same facial expressions as sighted individuals when emotion is aroused, and their expressions are more concordant with their kin than with strangers. Interestingly, congenitally blind individuals have difficulty posing expressions voluntarily when asked to do so; but when emotions are aroused spontaneously, they produce the same facial muscle movements as do sighted individuals. Similarly, facial expressions of emotion are more concordant among monozygotic twin pairs than dizygotic twins. Each of these lines of evidence points to an evolved, biological source of universal facial expressions of emotion that does not have to be learned or recreated in ontogeny, because the learning and selection has already occurred in our phylogeny.

Although an evolutionary perspective suggests that vocal expressions of emotion are also universal, the evidence for the universality of vocal expressions of emotion is equivocal. There is some evidence to suggest that vocal expressions associated with anger, fear, and joy may be reliable and universal. Anger produces voices with harsher, louder sounds, and with an edge to them; fear produces higher pitches, and joy produces enthusiastic and excited sounds. Evidence for the universality of

vocal expressions of disgust, sadness, and surprise is weaker, but suggests that disgust is associated with yuck sounds, sadness with softer, labored sounds with longer pauses, and surprise with higher pitches and inhalations. It is no wonder that the face and voice are tied together, as there are some connections between the neural control of the facial musculature and the vocal chords. That is why one can hear another person smiling while talking on the phone, or why it is easier to speak in lower, harsher tones when one's brows are lowered.

Because emotions evolved in order to aid the human by preparing us to engage in some action, the responses associated with emotion – physiology, expressive behavior, cognitions, and subjective experience – need to be organized and coordinated. This notion is referred to as ‘response system coherence,’ and has garnered empirical support over the last decade, especially in studies that use facial expressions as markers to signal when an emotion is occurring; that is, facial expressions of specific emotions are correlated with feelings of the same emotion, but not other emotions; thus, facial expressions of anger are correlated with the feelings of anger but not other emotions. Likewise, facial expressions of disgust, fear, joy, or sadness are associated with the subjective experiences of disgust, fear, joy, or sadness, respectively, but not with other emotions. These linkages are universal across cultures.

Cultural Influences on Universal Facial Expressions of Emotion

There are cultural differences in how universal facial expressions of emotion are displayed. Many years ago, psychologist Paul Ekman and his colleague Wallace Friesen coined the term ‘cultural display rules’ to describe the rules that people learn, from early in their childhood and throughout their lives, to manage and modify their

emotional expressions based on social circumstances. These rules are cultural norms that provide guidelines for what is appropriate to display and what is not, depending on the context.

Display rules can act to moderate expressions in many ways. When experiencing emotion, for instance, individuals can express emotions as they feel them with no modification. However, they can also amplify their expressions, displaying more than they truly feel (e.g., laughing at your boss's bad jokes); deamplify them, displaying less than they truly feel (downplaying your anger toward your children's misbehavior); neutralize them, showing nothing when in reality something is felt (the poker face); qualify them, showing emotions in combinations with other emotions or signals that comment on the original feeling (smiling at the same time showing that one is miserable); or mask them (smiling instead of showing one is miserable). Display rules, therefore, allow for a considerable range of individual and cultural variation.

In the first study to demonstrate the existence of cultural display rules conducted almost 40 years ago, American and Japanese participants viewed highly stressful films, initially alone and then in the presence of a higher-status experimenter. When alone, both the Americans and Japanese displayed the same facial

expressions of disgust, anger, fear, and sadness to the films, highlighting the universal nature of the expressions. In the presence of the experimenter, however, cultural differences emerged. While the Americans generally continued to display their negative feelings, the Japanese were much more likely to smile to hide their feelings. Interestingly, these were the very same participants who, just moments before in the first condition of the experiment displayed the very same expressions as did the Americans. These differences in expression were interpreted to have occurred because of a Japanese display rule to mask their negative feelings with smiles in the presence of a higher-status individual. Figure 2 provides examples from this experiment. The two photos to the left show the Americans and Japanese displaying the same expressions of disgust when alone; the two photos on the right, however, depict their expressions when with the experimenter.

Another example of cultural display rules comes from a study of medalists of the Olympic Games. Athletes all around the world at this level of competition are under intense pressure to 'be a good loser' or 'be a good winner'; that is, they learn display rules of managing their emotional reactions after winning or losing matches. Figure 3 depicts three expressions shown in sequence by an athlete

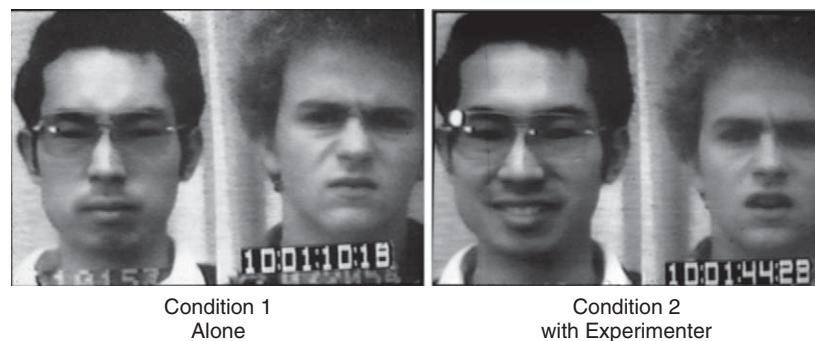

Figure 2 Examples of cultural display rules.

who just won the gold medal at the 2004 Athens Olympic Games. The first photograph was taken precisely when the match was over and the outcome was known. Here you can see a broad, strong expression of intense joy from having just won the gold medal. In fact, when observers around the world were shown this photograph and asked to make judgments about it, most people judged this person to be happy and to have won the match.

A few seconds later, however, the athlete displayed the second photograph, which shows him controlling his expression by rolling his lips in and pressing them together as he is smiling. Interestingly, when observers around the world are shown this photograph, most people judged this person to not be happy, and to have lost the match.

A few seconds after that, the athlete was unable to control his joy, and the smile once again burst onto his face in the third photograph. Once again, most observers around the world judged him to be happy, and to have won the match.

These photos are interesting because they highlight the temporally dynamic nature of facial expressions of emotion. Universal facial expressions of emotion were displayed immediately at the end of the match, when outcomes were known. These expressions were universal, and there were no cultural differences in them. A few seconds later, however, cultural influences kick in, and expressions are modified according to culturally learned rules. Thus, facial expressions of emotion are both universal and culturally dependent. This example also highlights why we think cultural differences are so pervasive; when emotionally evocative events occur, we often focus our attention on the event, and not on the expressions of the people involved in the event. When we turn our attention to the people involved even a few

seconds later, however, cultural display rules may be kicking in, and what we see are culturally modulated expressions; that is, we may have missed biologically based, universal expressions that occur immediately, automatically, and unconsciously, because we often do not look at people when they occur.

Macro versus Microexpressions

When individuals experience an emotion and there is no reason to modify or conceal their feelings, the facial expressions that occur have certain characteristics. They are likely to have smooth onsets and offsets, last between 0.5 and 4 s, and be symmetrically displayed on the face (with the exception of contempt, which is depicted by a unilateral or one-sided tightening of the lip corners, giving the impression of a smirk). These kinds of expressions occur in normal discourse, are easily seen, and form the basis of emotional sharing that occurs among friends, colleagues, and many interactants. These are known as ‘macro-expressions.’

There is a special case of facial expressions of emotion, however, called ‘microexpressions.’ The major characteristic of these microexpressions is their speed; they can occur as quickly as for 1/15th or even 1/30th of a second. Because they are so fast, it is easy to miss them. Indeed, if you blink you will not see them.

Microexpressions are signs of concealed emotions, that is, when the expresser does not wish for his true feelings to be known to others (or him or herself). They were first observed by psychologist Paul Ekman 40 years ago, who analyzed footage of depressed inpatients who were lying to obtain a weekend pass in order to commit suicide. When asked if the patient had any plans to hurt herself,

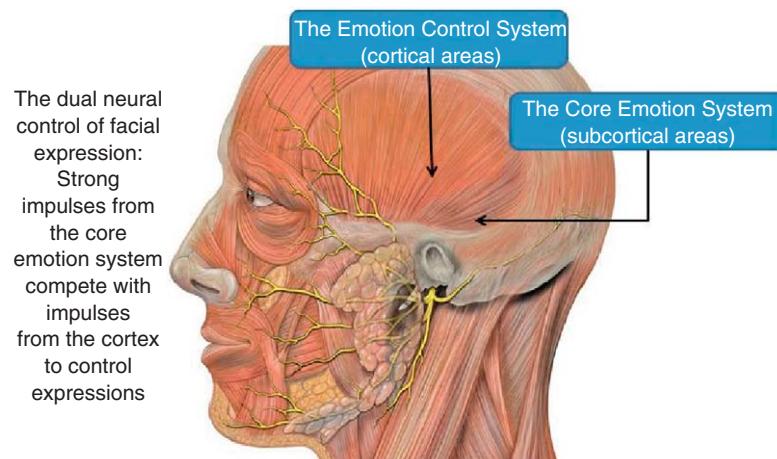

Figure 4 Why do microexpressions occur? By Patrick J. Lynch and C. CarlJaffe, MD. Reprinted by permission (c) Paul Ekman Group 2008.

the patient displayed a microexpression of sadness when she replied "no." Since then, Ekman and his colleagues have created valid and reliable methods of assessing the ability to read microexpressions, as well as training tools to improve people's ability to read them. Research has also demonstrated that microexpressions are often (but not always) a reliable sign of deception.

Microexpressions of emotion occur because of the dual neural control of facial expressions of emotion. The processing centers of emotion are widely believed to exist in certain subcortical areas. When emotions are elicited, neural impulses emanating from these areas trigger the emotion response system, turning on the physiological, cognitive, and expressive systems. Direct impulses from these areas to the facial nerve tell the face to fire the facial muscles in the configurations associated with the emotion aroused. At the same time, however, display rules and other culturally learned norms are widely believed to be stored in the cortex, and the cortical areas of the brain control voluntary behavior. Thus, if an individual experiences an intense emotion but at the same time is in a context in which he or she does not wish to display his or her feelings, the facial nerve will receive dual, competing impulses – one from the subcortical areas saying to fire, the other from the cortex saying to neutralize the expression (Figure 4). The result is what is known as emotional or nonverbal 'leakage' in the form of a microexpression.

Glossary

Genetic drift – Changes in the frequency of alleles in a population which are due to chance events or stochastic effects.

Heritability – Proportion of the interindividual variation observed in a phenotypic trait that is due to additive genetic variance.

Natural selection – A process of sorting phenotypic variants on the basis of their differential ability to survive and reproduce. Natural selection works as soon as

- (1) there is phenotypic variation in a population,
- (2) this variation is correlated with fitness differences, and
- (3) is heritable. The response to selection is observed in the resulting change in allelic frequency occurring in the population between two consecutive generations.

Phylogeny – The connections between all groups of living organisms as understood by ancestor/descendant relationships.

Sexual selection – A particular case of natural selection in which sorting of phenotypic variants depends on their ability to secure access to gametes of the opposing sex.

The evolutionary approach to behavior is concerned with the ultimate causes of behavior, that is, its evolutionary origin and adaptive function. As any observable trait, the behavior of an organism is, to some extent, the final product of an evolutionary process, during which both natural selection and genetic drift may have exerted some influence. However, because genetic drift is essentially a random process, only natural selection can promote a better fit between an organism's features and its environment.

Although adaptation is a central concept in evolutionary biology, its significance remains somewhat ambiguous. Strictly speaking, the term 'adaptation' refers to the endproduct of an episode of natural selection acting on a trait – at which stage there is no more additive genetic variance on the trait in question. Under the assumption of environmental stability, stabilizing selection is then supposed to maintain the trait at its optimal value, through eliminating deleterious mutations. However, the term adaptation is also used to refer to

natural selection in progress. In that sense, any trait for which certain values confer higher phenotypic fitness (i.e., a superior ability to survive and reproduce) can be regarded as 'adaptive.' The distinction is important as the two acceptations of the term 'adaptation' generate contrasting research programs.

The Cost–Benefit Approach to Behavior

One way to test hypotheses about the current adaptive value of a behavioral trait is to examine the current benefits and costs associated with the trait. Consider the 'broken-wing' display, a form of distraction display used by nesting waders and plovers and some dove species to attract the attention of an approaching ground predator away from the nest or young. Typically, incubating or brooding birds walk away from the nest with one wing hanging low and dragging on the ground, thus appearing to be an injured, easy prey for a predator. Through doing their best to distract the predator's attention from their progeny, the parents expose themselves to the risk of being wounded or killed. To decide whether the broken-wing display is adaptive, one has to establish whether the costs of attracting the predator's attention are outweighed by the benefits in terms of survival of the eggs or young. Such a question is typical of the cost–benefit approach by which behavioral ecologists assess to what extent costly traits can be favored by natural selection. In the case of the broken-wing display, one would have to measure the frequency with which the display is used in the face of an approaching danger, its efficiency in actually driving out the predator away from the progeny, and the frequency with which adults performing the display are predated upon or injured by the predator. The same logic has, for instance, been applied to food hoarding. Various bird and mammal species hoard food that they retrieve and consume after a certain period of time. The evolutionary logic of hoarding behavior is that it increases food availability during periods of food scarcity. In the Eurasian red squirrel (*Sciurus vulgaris*), for instance, it has been observed that females that spent more time caching seeds had higher survival and tended to wean more young in their lifetime than those that spent less time recovering hoards, suggesting that food hoarding is an adaptive foraging strategy.

Optimization

A more refined version of the cost–benefit approach consists in the use of optimization modeling to assess the adaptive value of behavior. The behavior of an animal is then described as a sequence of decisions, without explicit assumptions about the cognitive abilities involved in the decision-making process. Basically, the approach considers that any animal regularly faces several alternatives of which one must be favored or chosen. For instance, an animal may have to decide where to establish its breeding site among different possible locations, choose a reproductive partner from several potential mates, or decide whether to attack a prey or not upon encountering it. The logic of the use of optimization models in investigating animal behavior is based on an analogy with human economics. Animals, through their decision, maximize a certain value, more or less closely linked to phenotypic fitness. This axiom implies that natural selection acted in the past to design the decision rules used by animals in such a way that they now behave efficiently in terms of maximizing survival and reproductive output. However, resorting to optimization models to study animal behavior does not imply that animals are considered to be perfectly adapted to their current environment. Simply, the tenants of the optimization approach consider that the gap between what the animal maximizes through its decision and the value the animal should maximize if it were perfectly adapted to the environment is not too large.

Classically, optimization models include three main components: decision assumptions, currency assumptions, and constraint assumptions. Consider the case of an animal foraging for prey. The decision assumptions deal with the nature of the problem the animal is facing. For instance, the predator may have the opportunity to consume several prey types (be generalist) or focus on a single type of prey (being specialist). Or the forager may have to decide how much time it should spend in one particular patch before leaving for another one. The currency assumptions define which criteria must be used to compare among themselves the outcomes of different alternatives. Ideally, one should be able to measure the fitness consequences of the decision made by the animal in terms of lifetime reproductive success (LRS). However, this is often not an achievable goal in practice, and one has to consider a proxy for fitness such as the net rate of energy obtained over a given time period, or the ability to survive over a certain period of time. The constraint assumptions include all the factors that affect the relationship between the currency and the decision variables. These may include both intrinsic constraints (e.g., those related to the cognitive abilities of animals or their tolerance to various external factors such as temperature and humidity) and extrinsic ones (e.g., duration of daylight for a diurnal forager). Based on the different assumptions, a

model is developed which allows one to predict which option confers the greater fitness to the animal. The performance of the animal (observed in the field, or, preferentially, in a controlled environment) is then compared to the predictions issued from the model. Any discrepancy between the observed and predicted performances leads to a reconsideration of the assumptions, and, eventually, the formulation of new predictions. Through this process, the researcher can progressively identify the major factors influencing the behavior under scrutiny.

Optimization models have been widely and successfully used in behavioral ecology, especially in the field of foraging behavior. A large amount of empirical evidence, encompassing a large array of species, shows, for instance, that animals often tend to behave optimally (i.e., maximize their long-term food intake) when selecting prey, or during patch exploitation.

Game Theory

A different situation emerges when the costs and benefits associated with any behavioral option depend on the frequency with which it is used at the population level. Consider, for instance, the case of N foragers that have to make a choice of exploiting two food patches a and b , in which there is continuous input of food at rates k_a and k_b (defining the profitability of each patch), respectively. Let us further consider that each food item appears at the food patch and then disappears if not consumed, and that each forager has the same ability to catch a food item (a case of equal competitive abilities). Clearly, all possible distributions of the N foragers over the two patches are not equivalent in terms of individual gains. If all foragers gather in patch a , then all the prey in patch b will disappear without being eaten, and vice versa. Now consider that N_a and N_b foragers exploit patch a and patch b , respectively. The average gain of any individual foraging during a time T is $P_a = (k_a T)/N_a$ in patch a , and $P_b = (k_b T)/N_b$ in patch b . There is only one distribution at which no individual can increase its gain through switching between patches. This equilibrium distribution can be found by solving the equation $P_a = P_b$, which gives $N_a/N_b = k_a/k_b$. For the distribution to be stable, the ratio of foragers at each patch must match the ratio of profitabilities of the two patches, a rule known as the ‘input matching rule.’ More complex solutions exist when foragers differ in competitive ability, or when the relative payoffs change across patches.

Behavioral ecologists rely on game theory (a branch of economic theory) to deal with similar situations of frequency-dependent selection. Game theory has particularly been applied to the study of social behavior. Central to its application is the concept of evolutionary stable strategy (ESS). A strategy is an ESS if, when adopted by a large majority of individuals in a population,

it cannot be invaded by any rare alternative strategy. An important aspect of ESS is that it represents a competitive optimum that differs from what can be named a simple optimum, when benefits are not frequency dependent. Whereas the simple optimum provides the highest possible fitness gain, the competitive optimum is only a point of equilibrium and is not the point at which individual fitness is at its highest. A simple game, known as the producer–scrounger game, provides a perfect illustration of the phenomenon. It refers to a situation where individuals in a group, foraging for food that is patchily distributed, have a choice between two strategies. They either can search for their own food, and ignore what other individuals around them are doing (the producer strategy), or they can monitor the behavior of their conspecifics and join any individual who has discovered a food patch to share its content (the scrounger strategy). The payoff of each strategy is frequency dependent. When the majority of individuals play the producer strategy, it pays more to play the scrounger one and vice versa. Obviously, on the one hand, the scrounger strategy cannot be a stable strategy, because if no one looks for food all animals will end up dying of starvation. On the other hand, the producer strategy is not a stable strategy either, because when played by all individuals in a population it is particularly vulnerable to invasion by a few rare mutants playing the scrounger strategy. **Figure 1** shows the payoffs of the two strategies as a function of the number of scroungers, and the equilibrium point at which the benefit of a scrounger is equal to that of a producer. Predictions from this model have been verified in a large number of experiments, often using small passerine birds feeding in small flocks. As can be seen on the graph, at the equilibrium point, each individual receives a

lower payoff than if all individuals were playing the producer strategy. This is because natural selection does not act at the level of the group, but at that of the individual. Natural selection can only favor behavioral strategies which are evolutionary stable.

Phenotypic Engineering

The study of adaptive design (i.e., the estimation of the relationship between phenotype and fitness) in natural populations is constrained by the distribution of phenotypes available for selection to act upon. Strictly speaking, if a behavioral trait represents an adaptation, its heritability should be null (because the alleles coding for the optimal value of the trait have been fixed in the population), and, consequently, its expression should vary very little among individuals (beyond the variation attributable to environmental effects). It is then often impossible to use natural variation to ask questions about adaptive design because such variation is weak or does not even exist. It is, however, possible to create artificial variation to assess whether the mean value of a particular trait observed in the population corresponds effectively to an optimum. Through artificially broadening the distribution of the trait, phenotypic engineering provides a way to increase the statistical power of detecting relationships between traits and fitness.

Phenotypic engineering has been used, for example, to understand what limits the intensity of aggression in territorial species. In many species, the ability to survive and reproduce critically depends on the possession of a territory. Once they hold territory, individuals must regularly fight-off intruders to maintain their ownership. It is, however, difficult to evaluate to what extent the observed

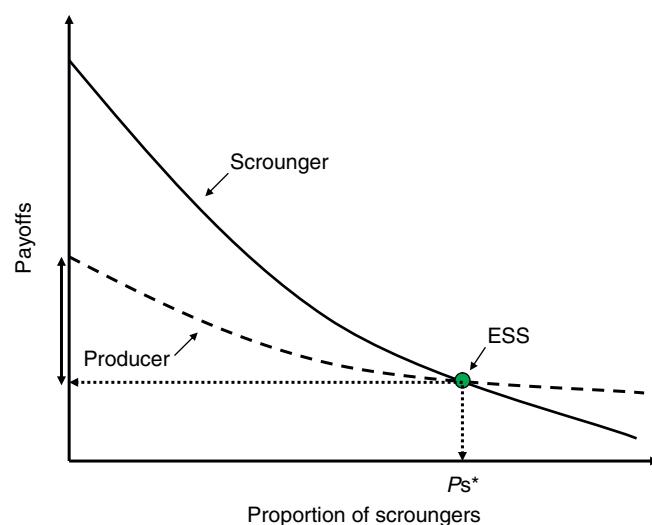

Figure 1 The payoffs of the producer and scrounger strategies as a function of the proportion of scroungers in the population. At the ESS, the payoffs of the two strategies are equal. Note, however, that at this stage, individuals do worse than if the producer strategy was played by all of them (see the bidirectional arrow on the left-hand side of the graph).

levels of aggressiveness have been shaped by natural selection. One way to tackle the question is to artificially increase the amount of territorial defence through manipulating the hormonal profile of individuals. For instance, increasing the level of testosterone (the hormone implicated in the regulation of aggressiveness) did increase territorial defence in male mountain spiny lizards (*Sceloporus jarroo*). However, increasing testosterone level reduced survival, essentially through increasing energy expenditure, while standard metabolic rate remained unaffected. Thus, survival costs may limit the level of aggressiveness in mountain spiny lizards.

Phenotypic engineering is also popular among researchers working on sexual selection. Ever since Darwin, the role of female choice in the evolution of male ornaments has been controversial. According to some models, the extravagance of some male traits such as the peacock tail could result from the existence of open-ended preferences for larger values of the trait in females. At some point in evolution, a stable equilibrium must be reached at which the costs of having an extravagant ornament are compensated by the increased attractiveness of their bearers. However, it is expected that females would prefer males with larger ornaments if only they were present in the population. Several studies have checked the validity of this prediction through manipulating the size of ornaments in males, extending the range of values available to females beyond that offered by natural variation. One famous study concerns widow birds (*Euplectes progne*) – a polygynous bird species characterized by extensive sexual size and color dimorphism. In particular, males have a very long tail (measuring up to 50 cm) that is used during displays. The researchers increased or decreased the tail length of males, while control males simply had their tails cut and restored. Males with experimentally elongated tails attracted more females in their territories than both males that had their tails shortened and control ones, thus demonstrating the preference of females for males with larger ornaments. However, experimental manipulation of tail length in other species suggests that increased tail length is likely to reduce flight manoeuvrability as well as impose fitness costs. Tail length observed in nature may then often be a feature under stabilizing selection.

The Comparative Approach

Another way to assess to what extent behavioral traits can be regarded as adaptations is to rely on the comparative approach. Making comparisons between species to identify behavioral adaptations is a recurrent approach in the study of animal behavior. For instance, the famous ethologist and Nobel prize winner Niko Tinbergen and his colleagues adopted a comparative approach to study the

adaptive function of eggshell removal in several species of gulls. Black-headed gulls (*Larus ridibundus*) produce eggs with a cryptic external color that make them inconspicuous in an environment made of sand and vegetation, whereas once the eggs have hatched, the white interior of the eggshell contrasts markedly with the background. However, soon after hatching, the parents carefully remove pieces of eggshell and deposit them at some distance from the nest. This particular behavior is not observed in the closely related black-legged kittiwake (*Rissa tridactyla*): whereas the black-headed gull nests on the ground in the vegetation, nests of the black-legged kittiwake are placed on cliff ledges; this makes a big difference in terms of exposure of eggs and young to predators. Ground predators can easily access the nests of black-headed gulls but cannot reach those of kittiwakes. Hence, the assumption that the removal of eggshell observed in black-headed gulls is an antipredator adaptation. Through a series of experiments, Tinbergen and his colleagues checked that the presence of eggshell close to the nest of a black-headed gull did indeed increase its chance of being predated. However, it was not enough to prove that eggshell removal does constitute an adaptation. Further evidence comes from the observation that the behavior is systematically present in ground-nesting gull species and absent in cliff-nesting ones.

Comparison between species is indeed a powerful tool to assess whether a behavioral trait is an adaptation. However, two main reasons can explain why a similar behavior is present in two distinct species. The behavior may have been inherited from a common ancestor (a case of homology) or the similarity can correspond to evolutionary convergence (a case of analogy). In the latter case, the two species facing the same problem come about with the same solution over evolutionary times, independently of each other. It is then crucial, in order to identify behavioral adaptations, to distinguish between analogy and homology. To that end, behavioral ecologists rely on statistical methods taking phylogenetic relationships between species into account. The evolution of jumping performance in Tropidurinae lizards provides a good example to illustrate the use of the comparative method. In Brazil, eight species belonging to this subfamily have colonized two contrasting habitats. One is a semiarid area characterized by a sandy substrate, while the other is a savannah-like habitat with dense vegetation and rocky outcrops. Because locomotion on sand imposes high energetic costs, one would expect that lizard species in the first habitat have a lower tendency to jump and have a lower level of jumping performance than lizards in the second one. Phylogenetic analyses confirm this prediction, through demonstrating a large difference in jumping capacity between sister species from the two habitats. Thus, the observed differences in jumping performance appear to be independent of

phylogeny, and, most probably, reflect behavioral adaptations to contrasted habitat pressures.

Genetic Tools to Study Behavior Adaptation and Evolution

Natural selection is most often a slow, gradual process. Studies quantifying selection in the wild generally report weak, albeit significant, selection coefficients acting on phenotypic traits. In addition, the pace of evolution strongly depends on generation time, such that evolutionary changes in behavior are difficult to detect in the wild, especially in long-lived species. Another problem lies with the difficulty in quantifying behavior, in contrast with, for instance, morphological traits. However, sudden environmental changes may provide opportunities to observe natural selection acting on behavior over short periods of time. For example, recent studies have shown that the adaptation of migratory behavior in birds in response to climate change involves changes in the genetic composition of populations. However, antagonistic correlations between a particular behavior and other life-history traits may slow down adaptive evolution and make it difficult to document in the wild. For a long time, then, behavioral ecologists have ignored genetic analyses in their approach to behavioral adaptation. The situation has changed, though, and genetic tools are increasingly used to answer questions about the adaptive significance and evolution of behavioral traits.

Artificial Selection

One simple way to reveal the existence of genetic variation in natural populations on which natural selection can act is to perform artificial selection experiments. The method has been used widely to assess to what extent a given behavior can be shaped by natural selection. Death-feigning, for instance, is characterized by a state of immobility in response to external stimuli. This antipredator behavior is observed in both vertebrate and invertebrate species. Through performing two-way artificial selection for the duration of death-feigning in the red flour beetle (*Tribolium castaneum*) across 10 generations, researchers obtained two strains characterized by either long-duration or short-duration death-feigning, thus demonstrating heritable variation of death-feigning behavior. In addition, individuals from the short-duration strain were more vulnerable to predation by a female Adanson Jumper spider (*Hasarius adansoni*) than those from the long-duration strain. Taken together, these results strongly suggest that death-feigning behavior may have evolved under natural selection.

Artificial selection might also be useful to visualize correlated or indirect selection on behavior. The

phenomenon may arise from the existence of genetic correlations between different behavioral characters, or between behavioral characters and other traits, or because two traits compete for the same resources during development. For instance, it has been shown that artificial selection for the ability to cope with limited nutritional conditions results in reduced learning ability in the fruit fly *Drosophila melanogaster*. Reduced learning ability appears, in that case, to be a correlated response, whereas higher survival, faster development, and reduced adult size were the direct responses to selection.

Genetic Dissection of Behavior

One major question in behavioral ecology is to understand how genetic diversity and alternative strategies can be maintained in natural populations. Genetic dissection of behavior complements nicely phenotypic approaches based on density- and frequency-dependent selection or environmental variation, although its use remains so far limited to a few model organisms. For instance, it has been shown that both the solitary versus gregarious polymorphism in the nematode *Caenorhabditis elegans* and the rover versus sitter polymorphism in *D. melanogaster* (two polymorphisms that influence how the animals forage in the wild) depend on allelic differences at a single gene. Furthermore, it has been shown that the foraging polymorphism in *D. melanogaster* is maintained by both negative frequency-dependent selection and density-dependent selection. When food is scarce, the fitness of each strategy is inversely proportional to its frequency, whereas when food is abundant, the sitter strategy shows higher fitness. This contributes to explain why natural populations of *D. melanogaster* generally consist of 70% sitters and 30% rovers. In *C. elegans*, the solitary strategy has a higher fitness than the gregarious one when food is clumped. However, no difference in fitness is observed when food has a patchy distribution. Thus, variation in the distribution of food may contribute to maintain the polymorphism in nature.

Reconstructing Recent Evolutionary Changes

Quantitative genetics can be a particularly useful tool to document past evolutionary changes, as shown by a study of the behavior of the waterflea *Daphnia* in relation to changes in predation pressure. This study took advantage of a peculiar characteristic of waterfleas: they produce long-lived (>100 years) dormant propagules, under the form of a stratified egg-bank accumulating in the lacustrine sediments. This gives the possibility to reconstruct recent evolutionary changes in behavior through a quantitative genetic analysis of resurrected populations. The study compared the rate of evolutionary rates of change in an adaptive antipredator behavior (e.g., orientation to

light, related to diel vertical migration) with those in selectively neutral markers (DNA microsatellites). The study population had experienced variable and well-documented levels of fish predation over the last 30 years. Genetic changes in orientation to light correlated with episodes of high predation pressure by fish. In addition, genetic differentiation for the studied behavioral trait was significantly higher than that observed for neutral molecular markers. Taken together, these results provide strong evidence that evolutionary changes in orientation to light were driven by natural selection.

The Role of Behavior in Evolution

Despite ample evidence that natural selection can shape behavioral traits, the role of behavior in evolution is still debated. As a matter of fact, behavior can be both subject to selection and a major agent of selection. It has thus been argued that animals would not necessarily be passive in the presence of selective pressures. According to this constructivist approach, animals, though their ability to select and perturb their environment, could minimize exposure to new selective pressures. Ultimately, behavioral change could prevent the operation of natural selection following perturbation of the environment. However, the relevance of this hypothesis remains elusive, as it has seldom been tested rigorously. One noticeable exception, however, concerns a study of predator-induced behavior shifts in *Anolis* lizards. This field-experimental study consisted in comparing changes in antipredator and natural selection on morphological traits in a small lizard species *Anolis sagrei*, on several small islands in the Bahamas, following the experimental introduction of the larger, predatory lizard *Leiocephalus carinatus*. Populations of comparable small islands where the predator had not been introduced were used as controls. Because sprinting ability is largely influenced by body size and relative limb length, it was expected that larger and long-legged individuals should be favored by selection on islands where the predator had been introduced. On the other hand, rapid behavioral adjustments may allow *A. sagrei* individuals to find refuge in arboreal vegetation, and then escape from the mainly terrestrial *L. carinatus*. Indeed, the study convincingly demonstrated rapid changes in antipredator behavior in *A. sagrei* following the introduction of the predator species. After 6 months, only 12% of *A. sagrei* individuals were seen on the ground on islands where the predator had been introduced as compared to 34% on control islands, a statistically significant difference. In addition, perch-

height did also increase over 6 months in the populations exposed to predation. However, patterns of natural selection on body size and limb length differed significantly between experimental and control islands. Natural selection significantly favored larger and long-legged individuals on experimental islands, whereas no consistent pattern was observed on control islands. This particularly valuable experiment shows that although behavioral shifts can occur following environmental perturbation, they are not necessarily sufficient to counter or cancel natural selection.

Glossary

Altruism – In biology, altruism is defined on the basis of the outcome of interactions expressed in terms of the effect on the fitness of the individuals involved. An altruistic act, seen in isolation, is detrimental to the actor and beneficial to the recipient.

Biological market model – It belongs to the partner-choice models. This paradigm stresses the selective effect of partner choice in cooperative interactions and of the effect of changes in supply and demand on the exchange rates of goods or services that are traded between cooperating agents. Agents often belong to distinct classes of traders, such as plants and pollinators or breeders and helpers.

Collective actions – The production of a public good by means of cooperation by several, usually many, agents. The problem of collective actions is that the contribution of individual agents is difficult to control, as is the exploitation of the public good that results from the collective action. An example is the construction and exploitation of a communal irrigation system.

Cooperation – The term cooperation stands both for interactions that are simultaneously beneficial to all its participants and for the behavior of the participants in such interactions.

Cooperative investment – An investment, in another agent, that aims at obtaining a net benefit from the interaction with that agent, but bears the risk of resulting in a net loss.

Cultural evolution – Evolution resulting from selection of traits that are culturally transmitted, as opposed to those genetically transmitted. Group selection is much more prominent under cultural selection than under natural selection.

Group selection – A trait is group selected if the fitness of the members of the group depends on the success of the group in competition with other groups (of the same species). Group selection is generally a much weaker force than individual selection. The term ‘multilevel selection’ is used to describe the combined effect of selection at the individual level, the group level, and eventual further levels.

Kin selection – An explanation for the evolution of altruism among closely related individuals proposed by W. D. Hamilton on the basis of an idea originating from J. B. Haldane. A trait is kin selected when it penetrates in

future generations as a result of investments in the improvement of the reproductive success of close relatives, rather than as a result of investments of the actors in their own reproduction.

Mutualism – Used by ecologists to describe series of discrete cooperative interactions between members of different species. Outside ecology sometimes used for intraspecific interactions to describe mutually beneficial interactions, as opposed to altruistic interactions.

Partner-choice models – Models explaining the evolution and/or stability of evolution that concentrate on the effect of partner preference upon the outcome of cooperative interactions. These models resemble models of sexual selection, but apply to cooperation rather than reproductive behavior.

Partner-control models – Models explaining the evolution and/or stability of evolution that concentrate on the problem of controlling the investment of the partner(s).

Public goods – Goods that can be accessed by a, usually large, pool of actors (also known as common-pool resources). Examples include public infrastructure, fish in the ocean, and the global climate. Public goods can give rise to social dilemmas, because individual agents can exploit the public good in their private interest and thereby lower the value of the public good for all other members of the pool. The best-known description of the public-goods problem is known as the tragedy-of-the-commons: the overgrazing of communal meadows caused by farmers adding cows after the carrying capacity of the meadow has been reached.

Reciprocal altruism – An explanation proposed by R. Trivers for the evolution of altruism among unrelated agents. The idea is that, by taking turns, a pair of unrelated individuals can gain a net benefit from a series of altruistic acts as long as (1) they take turns in playing the roles of altruist and beneficiary and (2) the benefit of receiving altruism is, on average, higher than the cost of performing an altruistic act.

Sexual selection – A trait is under sexual selection, as opposed to natural selection, when it enhances individual fitness through its effect on the access to sexual partners. The access to sexual partners largely depends on the success of competition with same-sex competitors, either in direct competition or in indirect competition as a result of the preferences of the other

sex for certain characteristics. Examples of sexually selected traits include the peacock's tail and antlers.

Social dilemmas – Social dilemmas are situations in which the interests of individual agents collide with the interest of the community to which the agents belong. Each agent is better off following a selfish strategy, but when all agents use such a strategy everybody is worse off than when all agents follow a strategy that maximizes the total payoff. Social dilemmas are often split into two categories, depending on whether the dilemma is caused by the production or the exploitation of a common resource.

Symbiosis – Used by ecologists to describe long-lasting, mutually beneficial relationships between members of different species.

history, replicator chemistry, etc.). Each discipline uses its own terminology and, even more confusing, different disciplines use the same terms but for different phenomena. The word mutualism, for example, is used by anthropologists, behavioral ecologists, ethologists, and economists for interactions that lead to an immediate net benefit to the agents involved, but stands for cooperation between members of different species in community and ecosystems ecology, as opposed to ‘cooperation,’ which refers to within-species interactions.

Taking an evolutionary perspective implies that definitions should refer to the actions of agents rather than outcomes of interactions, since natural selection acts on the former rather than the latter. To give a simple example: hunting lionesses may show the same cooperative behavior during several hunts independent of the outcome of each hunt. Natural selection has resulted in the evolution of cooperative behavior in lions, while this behavior led to net benefits to individuals showing it, averaged over individuals and long series of such interactions. Both successful and unsuccessful attempts have determined which form of cooperative behavior was finally selected. Cooperative hunting has evolved in lions, because on average the returns have been higher than the investments for those individuals that took the risk to invest time and energy in hunting with others.

In this article, specific jargon will be avoided by using generic terms, for example, ‘cooperative investment’ instead of ‘altruism’ or ‘cooperation.’ Altruism is the term traditionally used in evolutionary biology to describe interactions that, seen in isolation, are costly to the actor and beneficial to the receiver. How such behavior can evolve in spite of being detrimental to the actor is the enigma that has kept evolutionary biologists busy for decades. Cooperation is used for both an interaction in which all participants gain a net benefit and the behavior of those participants in such an interaction. The crucial characteristic of both altruism and cooperation is that actors take the risk to invest in other individuals with no guarantee of returns high enough to reap a net benefit. The investment risk becomes higher the lower the degree of control of the actor over the receiver is and the longer it takes to receive compensation.

Multiple Forms of Cooperation: Different Ways to Cut the Cake

The first dichotomy to be made is that between natural forms of cooperation, which result largely from natural selection, and human forms of cooperation, which are often under cultural selection. This dichotomy is reminiscent of splitting a bimodal frequency distribution rather than distinguishing two mutually exclusive categories, as is the case for most other classifications used in

Cooperation: A Crucial Element in the Evolution of Life

Loosely defined, cooperation is an interaction between entities that results in a net benefit to each of them. The entities, henceforth called ‘agents,’ can be molecules, cells, individuals, groups, firms, nations, and so forth. Defined along the same lines, an agent is called ‘altruistic’ if an interaction results in a net loss to himself and a net benefit to his partner. These are functional definitions as used in biology and economics in which no prior assumptions are made about the mechanisms and motives underlying the agents’ behavior. Functionally, altruism boils down to taking the risk of investing in a partner without having the guarantee of obtaining net returns. The evolution through natural selection of evermore complex agents, such as molecules, chromosomes, cells, multicellular organisms, and groups, would not have been possible without cooperation among agents forming the preceding layer. A major scientific challenge is to understand the mechanisms that lead to the origin and maintenance of cooperation in each layer of complexity. Most forms of cooperation are only possible due to mechanisms that help to surmount the inherent instability that characterizes most forms of cooperation. More often than not, one or more agents have the option to reap immediate benefits by not cooperating, which they may prefer over future benefits produced by cooperation, even if these are likely to be higher.

Confusing Semantics

Cooperation is studied in many different major disciplines and subdisciplines (biology, anthropology, economics, political sciences, psychology, sociology,

this article. The evolutionary mechanism that is diagnostic for the split is group selection, which tends to be a weak force under natural selection and a strong one under cultural selection. Natural selection can act at multiple levels, such as single genes, individuals (i.e., packages of genes), groups, populations, and species. The individual level is generally considered to be the most important by far. However, the rules of the game are considerably different under cultural selection, which acts on information multiplied by communication rather than genetic information multiplied by sexual reproduction. Under group-selection, the fitness, or utility gain in economic terms, of an individual depends more strongly on the fate of the group to which the individual belongs, relative to other groups competing over the same resources, than on the individual's own success in competition with other individuals within the group. Selection can take place at multiple levels simultaneously, however, and both natural and cultural selection can act in tandem.

Historically, the enigma of the evolution of altruism has played a pivotal role in putting evolutionary biology back on a sure footing with selection at the individual level prevailing over group selection. Darwin's original insights were largely correct in this respect, but later generations of biologists have had a tendency of explaining the evolution of altruism rather sloppily – using concepts like group selection and deme selection in an intuitive manner. The general public probably understood natural selection as a force acting at the level of species in those days and this vision is still reflected in the popular press, at times, even today. A sharp critique of group selection by G. C. Williams in a book published in 1966 has been an eye-opener for many an evolutionary biologist and has helped to develop the new discipline of sociobiology, which was later relabeled as behavioral ecology. As so often the pendulum of science had a tendency to overshoot and the almost dogmatic rejection of group selection that followed has hampered the recognition of the impact of this form of selection under certain circumstances.

Natural Forms of Cooperation

The traditional way of classifying phenomena in biology is to describe observable phenomena. This implies that interactions are in most cases classified as cooperative on the basis of outcome and the easiest way to describe cooperation between individuals is to use the jargon of ecology. Mutualism and symbiosis are two forms of interaction between members belonging to different species. The main difference is in the duration: mutualistic relationships consists of one or more discrete interactions that are short relative to the life span of the species involved, while symbiotic interactions last a major part or even the entire life span of the individuals involved. Examples of

the former include ant–aphid interactions, pollination, and seed-dispersal networks. Lichens, a combination of fungi and algae, and mycorrhiza, which consist of tissue formed by plant roots and fungi, are two examples of symbiosis. Mutualism and symbiosis, taken together, represent the lion's share of natural forms of cooperation. A third category is formed by cooperation among members of the same species. Within this category, the most important form is probably cooperation between closely related individuals, with examples ranging from parents and offspring and colony members in eusocial insects to biofilms formed by bacterial clones.

A relatively small category contains various forms of cooperation among conspecifics in which relatedness plays no role. The label 'cooperation among unrelated conspecifics' will be used as a shorthand here. It makes no difference from a theoretical point of view whether an interaction takes place between members of different species or between unrelated members of the same species, at least as long as individual selection is assumed. Hence, the term 'cooperation' used in a theoretical context often applies both to mutualisms between members of different species and cooperation between unrelated conspecifics.

There are important forms of cooperation that take place at the subindividual level and without which life as we know it would not exist. To name a few examples: the cooperation between replicator molecules that resulted in chromosomes and genomes, the symbiosis between unicellular organisms that gave rise to the eukaryotic cell, the cooperation between cells that preceded the evolution of multicellular organisms, etc. However, these forms of subindividual cooperation fall beyond the scope of this article.

Uniquely Human Forms of Cooperation

Humans show many forms of cooperation the equivalent of which can also be found among nonhuman organisms, for example, cooperative hunting, cooperative breeding, and the direct exchange of resources between unrelated individuals. However, humans also engage in other forms of cooperation that are unheard of outside our species. One is the simultaneous cooperative investment by large numbers of unrelated individuals, called collective actions – for example, building an irrigation system, raiding a neighboring tribe or organizing a strike. Closely related are the interactions of large numbers of individuals that have an interest in a communally used resource, known as a common good – such as an irrigation system, once it is constructed by collective action, fish stocks in a lake, and unpolluted air. The common label used for interactions involving communal actions and common goods, social dilemmas, hints at the highly unstable nature of these forms of cooperation, discussed

in more detail below in the section titled ‘Cooperation models.’ The fact that humans can solve at least some social dilemmas of this kind sets our species apart from all other species. The ability to solve social dilemmas is, of course, closely linked to several other defining characteristics of the human species, notably language and other cognitive highlights, such as planning deeply into the future and theorizing about processes in the minds of others.

Cooperation by a sizeable number of unrelated individuals is rare among nonhuman organisms. Animal aggregations might be seen as an example of such cooperation. A safety-in-numbers strategy is found in many species. Considerable risk-reduction occurs due to the dilution effect that results from the proximity to other potential prey. Staying together poses a coordination problem but lacks the risky-investment element of cooperation, however, because being near a conspecific inevitably leads to a dilution effect. Cooperation between entities consisting of multiple agents that in turn cooperate at a lower level, thus forming a hierarchical structure of cooperating entities – such as found in armies, government coalitions, and nation-states – is perhaps not uniquely human either, but certainly much more common among humans than anywhere else. A nonhuman example is the formation of associations by groups of different species. Such ‘polyspecific associations’ are common in forest-living primates and usually serve to augment the protection against predation without increasing the food competition as much as would be the case when monospecific groups of the same size would have formed. As in the case of aggregations, the groups of different species coordinate rather than cooperate. At least one group has to invest by diverting from its most profitable foraging pattern; but that investment carries no risk, because the returns are instantaneous.

Cooperation Theory

No Conflict of Interest

Not all forms of cooperation and altruism require mechanisms to solve conflicts of interest. Often enough, an individual can profit from the presence or the actions of another organism without having any influence, positive or negative, on that organism. Cattle egrets profiting from large herbivores that flush insects from the grass by their movements form an example of such ‘byproduct altruism.’ A closely related concept is ‘pseudoreciprocity’: the members of one species have been selected to provide a resource, for example, shelter, that is used by members of another species, for example, ants, which in turn provide a benefit, protection against herbivores, to the plant as a byproduct of their presence.

Conflicts of Interest

Virtually all forms of cooperation imply some degree of conflict of interest between the agents involved, most frequently about the height of the investment and the division of the gains due to cooperation. The degree of conflict varies considerably from case to case. Individual interests can become diametrically opposed after two partners obtain an indivisible resource at a high price. Male baboons forming a coalition against a high-ranking male to obtain access to a receptive female provide an example. The male pulling the short straw may face the wrath of the high-ranking male alone, while his partner consorts the female away from the scene. The potential for conflict is virtually absent when individual interests coincide, and no options for free-riding or exploitation of the partner exists. Think of a rowboat on a lake with two rowers each handling one oar. As long as they agree about a common goal and that goal can be reached following a straight line, they will have to pull equally hard. Endless variation in the degree of conflict of interest also exists in forms of cooperation with multiple partners. A famous example of a strong conflict of interest between individual agents and the rest of the community is known as the tragedy-of-the-commons. A commons is a communal meadow on which multiple farmers can graze their cows. There is little cause for conflict as long as the number of cows remains below the carrying capacity of the meadow. However, any cow added to the herd above the carrying capacity puts its owner on collision course with the other farmers. The owner is the only one to profit from the extra cow, but the costs of overgrazing are carried by all.

Partner Control, Trust, and Partner Choice

The most prominent problem agents need to solve, notably when the conflict of interest is strong, is to make sure not to be exploited by the partner(s). Most models of cooperation concentrate on this problem of partner control. The opposite side of that coin comprises gaining trust. When mistrust reigns but cooperation is profitable, agents have an interest in gaining the other’s trust as well as in judging correctly when the other can be trusted. However, attempting to understand cooperation by only concentrating on the problem of partner control is a bit like trying to understand mating markets by only paying attention to the interaction within couples. Another important aspect, therefore, is partner choice: selection of partner(s) from multiple candidates, switching from less profitable to more profitable partners, and selectively ending relationships with the least profitable of multiple partners.

Cooperation Models

The past half a century has seen an endless stream of theoretical papers on cooperation. Some proposed radically new models, but most suggested refinements of existing models. One way of classifying these models in different families is using a number of dichotomies: the agents are closely related or not; the agents interact only once or repeatedly; two or more than two agents are involved, and stress is laid on partner control or on partner choice. The scope of this article allows only a sketch of the outlines.

The best strategy of an agent confronted with the dilemma between maximizing benefit from cooperation and minimizing the costs of being exploited depends, in a dynamic way, on the strategies played by the other agents involved. The most effective tool for analyzing such situations is game theory: a mathematical branch of economics developed during World War II by J. von Neumann and O. Morgenstern and reinvented a few decades later by the evolutionary biologist J. Maynard-Smith.

Related Agents: Kin Selection

W.D. Hamilton's seminal paper of 1964 went a long way in explaining altruism and cooperation among closely related individuals. He introduced the concept of 'inclusive fitness' of an inheritable trait – in this case, the propensity to act altruistically toward familiar individuals. This is the sum of direct fitness (the chance that the trait is inherited by an offspring) and indirect fitness (the chance that the trait penetrates into future generations via a relative). Genetic information coding for a trait is considered to be identical when both sets of information are copies of genetic material carried by a common ancestor, hence the term identical by descent.

Hamilton proposed the inequality ' $rb > c$ ' to describe the conditions under which agents could increase their inclusive fitness by assisting a relative. The benefit to the recipient (b) and the cost of an act to the altruist (c) are expressed in terms of the increase and decrease, respectively, of fitness due to an act of altruism. The coefficient of relatedness (r) between two agents can be calculated using the formula $r = P(0.5)^L$ in which P is the number of pathways, which depends on the number of common relatives, and L is the number of generation links. For example, cousins have two grandparents in common, so there are two pathways ($P=2$), one via grandparent A and one via grandparent B. It takes four steps, or generation links, to go from one cousin to the other (cousin A-parent A-grandparent A-parent B-cousin B), so $L=4$. Hence, the coefficient r for cousins is $2(0.5)^4=0.125$. An agent could, therefore, augment his

inclusive fitness by helping his cousin if the benefit to the cousin is at least 8 times the cost of the agent's altruistic act. In other words, if the act would prevent the agent from producing a single offspring, the cousin should be able to produce eight extra offspring as an immediate result of the agent's altruistic act. This is an extreme example to illustrate why this form of altruism quickly becomes unlikely with increasing genealogical distance. However, the costs of altruistic acts are rarely that high. An individual that has no chance to breed in a certain year has relatively little to lose by helping relatives. For example, in many bird and mammal species young adults, with little chance to find a breeding slot, act as helpers raising the next batch of offspring from their parents. This explanation, which has become known as the 'habitat saturation' hypothesis for cooperative breeding, also applies to some human societies.

Kin selection implies kin discrimination and, thus, mechanisms of kin recognition. Often enough, these mechanisms will be based on rules of thumb that work in most cases, such as for birds feeding chicks as long as these are in the nest built or chosen by themselves. However, using rules of thumb make actors vulnerable to exploitation, for example, by cuckoos. In that case, we talk about (brood) parasitism by the cuckoo rather than altruism by the host. In principle, the evolution of altruism can be promoted in the absence of genealogical kinship as long as the altruistic trait is invariably connected with a perceptible marker – a so-called 'green beard' and altruism is aimed at carriers of green beards only. This theoretically interesting concept is probably hard to find in nature, but does exist, for example, in some flocculating yeasts.

Two Unrelated Agents

The discussion of the sixties of the last century that led to the demise of group selection in favor of individual selection centered on the question of explaining altruism. The hard nut to crack, assuming individual selection, was explaining how altruists escaped exploitation by free-loaders and otherwise selfishly acting individuals. Successful exploitation would result in higher fitness of selfish individuals, relative to altruistic ones, and thus lead to the extinction of altruism. The pivotal question asked was: 'How can altruistic behavior lead to net benefits in interactions with unrelated individuals?' Starting from this question one almost naturally arrives at the search of mechanisms of partner control in dyadic interactions. In the heat of the debate another crucial question was overlooked: 'How are dyads of cooperating individuals formed in the first place?'

The first to offer a plausible scenario for the evolution of altruism toward unrelated individuals was R. Trivers in 1971. He pointed out that two agents could both gain a net

benefit if they would engage in a series of interactions in which they would take turns in playing the role of altruist and beneficiary, if the costs of acting altruistically would be on average lower than the benefits received. The stumbling block of Trivers' 'reciprocal altruism (RA)' is, of course, that each agent may be tempted to reap short-term benefits at any time by breaking off the series after benefiting from an altruistic act. Following a suggestion by W. D. Hamilton, Trivers proposed to analyze this problem by using the 'Iterated Prisoners' Dilemma (IPD) as a paradigm. The IPD is the repeated version of a famous one-shot matrix game with the payoff distribution depicted in **Figure 1(a)**. The one-shot version has one Nash-equilibrium in which both players defect. The choice combination D–D is a Nash equilibrium, because both players are better of playing D, independent of the choice of the other player. However, the repeated version with an unpredictable number of rounds has no Evolutionary Stable Strategy (ESS; the equivalent of the Nash-equilibrium in evolutionary game theory) and it is, therefore, much less straightforward to find winning strategies. In 1981, Axelrod and Hamilton published the outcome of a round robin computer tournament in which they had different strategies playing against each other and which brought the winning strategy,

'TIT-FOR-TAT' (TFT), to fame. A TFT player always starts by choosing C and then copies its partner's choice in the previous round. Two TFT players will, therefore, always play C, as long as none of them makes a mistake or is unable to fulfill the requirements needed to play C. TFT is not an ESS, in spite of being the winner of the tournament, but so simple that agents with limited or no cognitive abilities can plausibly play it. A population of TFT players could be invaded by several other strategies, among which players always cooperate (ALL-C), but the resulting populations can always be invaded by other strategies in turn.

Strictly speaking, the IPD with its simultaneous choice by the two players cannot be a model of reciprocal altruism in which the players as per definition take turns in choosing an option. However, the flavor of the two is the same, and the IPD can be adapted to suit the assumptions of RA.

The IPD can by no means be used as the universal paradigm for all instances of cooperation involving two agents. There may be a conflict of interest, but the potential to exploit the partner is not always that strong. Many more matrix games have, therefore, been proposed as paradigms for cooperation, of which a few are discussed here. Described here are the one-shot versions; however, all games can also be played in an iterated fashion.

		<i>Player 2</i>	
		COOPERATE	DEFECT
Player 1	COOPERATE	1, 1	-1, 2
	DEFECT	2, -1	0, 0

		<i>Driver 2</i>	
		SHOVEL	DEFECT
Driver 1	SHOVEL	1, 1	0, 2
	DEFECT	2, 0	-1, -1

		<i>Husband</i>	
		BALLET	SOCER
Wife	BALLET	3, 2	1, 1
	SOCER	0, 0	2, 3

		<i>Hunter 2</i>	
		STAG	HARE
Hunter 1	STAG	3, 3	0, 1
	HARE	1, 0	1, 1

Figure 1 (a) The one-shot Prisoner's dilemma. Both players choose one of two options simultaneously and without communication. Each cell contains the pair of payoffs resulting from a pair of strategic choices made by the two players. Left: payoff of player 1; right payoff of player 2. (b) The Snow Drift game. (c) The Battle-of-the-Sexes. (d) The Stag Hunt.

A matrix game that resembles the PD, but differs in one crucial aspect is the 'Snow Drift' game. The story is as follows: two drivers approach a snowdrift that blocks their road from opposite directions. They have two options, stay in their car (or make a U-turn) or shovel the snow out of the way. As in the PD, it is best to defect when the other cooperates, that is, shovels; however, in contrast to the PD, it is better to shovel when the other defects, that is, stays in the car. The snow-shoveling story is used to stress the cooperative aspects, but the game is in fact the same as the 'Game of Chicken,' well known to economists and fans of James Dean in his role in the classic movie *Rebel Without a Cause*. Evolutionary biologists know the same game as the 'Hawk–Dove game,' so far as in the latter game the costs of escalation are higher than the value of the resource at stake. The game's ESS, well known from analyses under its name Hawk–Dove game, is a mixed strategy, meaning that one choice is made with a chance p and the other with a chance $1 - p$, whereby p depends on the relative costs and benefits of the two possible actions.

Sometimes, a cooperative dilemma boils down to a coordination problem rather than a conflict of interest. An example is given by a game called the 'Battle-of-the-Sexes' (**Figure 1(c)**). The story is that of a husband and wife that like to spend the evening together, but the wife would rather be doing that by going to a ballet performance together, while the husband would like to see his wife accompany him to a soccer match. The payoff matrix, depicted in **Figure 1(c)**, reveals that the game

has two Nash-equilibria (both BALLET and both SOCCER), but that does not mean it has a clear solution. A solution in this game is easily found, however, if one of the two players has the opportunity to choose first (technically turning the matrix game into a game in extensive form). For example, if the ballet starts an hour later than the soccer match, the wife can stick it out and wait and the husband has no rational choice other than staying with her till it is too late to go to the soccer match.

Yet another useful paradigm is known as the ‘Stag Hunt’ (**Figure 1(d)**). The story – which goes back to Rousseau – is one of two people going on a deer hunt, which can only succeed if they work together. Both hunters are tempted to go after a passing hare, however. A hare is worth less than half a deer, but can be bagged by a single hunter. Once one of the hunters goes after a hare, the chances of slaying the stag become quite dim. The game has two Nash-equilibria (both STAG and both HARE), but here one of those clearly yields a higher payoff than the other. This turns the problem not only into one of coordination, but also into one of trust. When the two players trust each other sufficiently, they can coordinate and stay on the deer hunt.

All such games serve as analytic models meant to reflect the bare-bones characteristics of naturally occurring cooperative interactions. Several of these games can also be used as experimental games to compare different classes of players and so forth. In ‘experimental economics,’ for example, different games are used to study the effect of gender, personality, cultural norms, and several other factors on human strategic behavior. In most such experiments, subjects play with anonymous partners via computer screens. One large study used two games – the ultimatum and the dictator game – to reveal the effect of different cultural norms in 15, mostly preindustrial, societies. In the ‘Ultimatum game,’ one player – the proposer – can decide to give a certain sum of money to the responder, for example, any amount between 0 and 10 euros in steps of €1. The responder can, in turn, decide to accept or reject the offer. If he accepts, he can keep the money offered to him and the proposer keeps the rest. If the responder rejects, both get nothing. Rational proposers, belonging to the illusive species *Homo economicus*, would offer €1, because rational responders would never choose lower payoff over higher payoff. However, real humans reacts rather differently and may reject offers of €4 while showing strong indignation. The ‘Dictator game’ resembles the Ultimatum game, but the responder is replaced by a player in a passive role with no option to punish the proposer by rejecting the offer. In theory, a proposer could get away with an offer of zero, keeping 10, but in practice most people make higher offers. However, the offers are usually lower than in the Ultimatum game, showing the effect of fear for direct punishment.

These games and several others, such as the Stag Hunt, can be used to measure a personality trait called trust. Trust is central to many cooperative interactions that could not take place when the agents would not trust each other at all. This trait is studied more specifically using the ‘Trust’ game. One of the many varieties goes as follows: player 1 has the choice between giving €4 to player 2 (trust) or keeping €2 and giving €2 away (no trust). Player 2 can then show greed, resulting in €4 for himself and only €1 for player 1, or altruism, which leads to a payoff of €3 each.

Partner-control mechanisms

Changing a partner’s behavior to one’s benefit can be advantageous, notably when future encounters with the same partner under the same circumstances are likely. A simple form of punishing a partner is by refusing further interaction, but obviously this leads to a loss of future benefit from cooperation by the actor too. Force can be used to change the partner’s behavior in an ongoing interaction. Such harassment may not only change the momentary, but also the future, behavior of the partner. Force can also be used after a dissatisfying interaction particularly to specifically alter the future behavior of the partner. This strategy is sometimes labeled punishment, but this term is also used in several other ways. A related term is sanction, which is most frequently used in the context of mutualisms in which a single, usually large, member of one species, for example, a tree interacts with multiple, usually small, members of another species, such as bacteria of the Rhizobium group. Sanctioning by the large partner is fatal for the small one. This strong form of partner choice does not change the partner’s behavior within the lifetime of that partner, but changes the behavior of a population of partners in evolutionary time by its selective effect.

Risk reduction in two-player IPDs

Partner control is the archetypical problem of agents confronted with IPD-like situations. Certain strategies can be used, however, to keep the agent out of an IPD (parceling) or reduce the risk of being short-changed (raising-the-stakes). A parceling agent makes such small investments in each round that the payoff distribution per round is no longer that of a two-payer PD. Individuals can also arrive at a state in which they exchange larger investments per round by starting small and slowly building-up trust.

Multiple Agents, Dyadic Interactions

A different class of models is used to investigate the effect of outside options, notably the possibility of partner choice and switching, on the interaction within dyads of

cooperating agents. The ‘biological markets’ approach has a lot in common with sexual selection theory: what happens between potential cooperation partners depends on the options each of them has to reach their goals by forming other dyads, just as what happens in reproducing couples largely depends on the male-to-female ratio on the mating market. The partner-switching option leads to potential partners being played-off against each other, which in turn can lead to bidding wars. Biological market theory aims at explaining two phenomena: traits selected as a result of partner choice at an evolutionary timescale and explaining the dynamics of cooperation in reaction to changes in supply and demand within the lifetime of agents. Partner choice does not exclude that dyadic partner-control models apply once dyads are formed, but the payoff matrix of, say a two-player IPD, looks rather different when players have only two options, COOPERATE or DEFECT, or when each players can turn to other partners as well.

The option of partner choice and partner switching have been added to several existing partner-control models as well. Yet other models define the constraints within which agents can interact with others by using ‘spatial models,’ such as single-layered or multiple-layered grids, or social networks.

The partner choice option also opens up a different opportunity for agents to control their partners. Agents can threaten to damage the reputation of their partner by revealing their uncooperative behavior to third parties. Obviously, sophisticated communication systems, such as human language, are needed to make reputation-based mechanisms work. Related to this concept is ‘indirect reciprocity’ – the idea that prior to making a choice, agents can learn about potential partners by observing their interactions with others. The latter option is also open to agents without access to language and has, indeed, been observed in the cleaner fish-client fish mutualism.

Multiple Agents Cooperating Simultaneously

Humans frequently forms large cooperating groups that consist of unrelated or only distantly related individuals. These forms of cooperation are inherently unstable, hence the common label social dilemmas. In 1968, Hardin drew attention to this phenomenon by presenting a verbal model, the tragedy-of-the-commons. Theoretical models of social dilemmas are often based on the ‘n-players Prisoners’ Dilemma (NPD).’ A large number of games with the fundamental structure of the NPD have been used in experimental economics, usually under the label Public Goods games.

Mechanisms used to solve human social dilemmas

Social dilemmas are so typically human that it is legitimate to ask whether we are equipped with specific mechanisms that help us to cope with such situations. This would imply that we would differ in crucial ways from nonhuman agents that do not succeed in cooperating under NPD-like circumstances. Traits could either have evolved under natural selection, for example, neuroendocrinological reactions after being short-changed, or evolved under cultural selection, for example, mechanisms that help to ostracize free-riders. Cultural evolution gained considerable momentum after the evolution of language. Our language skills, as such, may also have evolved as a result of natural selection in individuals that found themselves frequently confronted with social dilemmas, of course. Indeed, it is not unlikely that several feedback loops have simultaneously driven the evolution of language and the evolution of social dilemma-related skills under both natural and cultural selection.

A large number of mechanisms have been mentioned in this context, several of which are also known to occur in nonhuman agents and probably have roots deep in our phylogeny. The first set assures that we recognize specific agents and attribute the consequences of their actions to them, at least those that concern ourselves. Crucial skills include individual recognition and deciphering the intentions of others. Our ability to form a picture of what others are thinking (possessing a theory-of-mind) is indispensable in this context. A second set determines our attitude toward a specific individual by combining memories from past interactions with momentary information. Most frequently mentioned are selective adjustments of the titers of neurotransmitters and neurohormones, such as oxytocin, vasopressin, serotonin, and dopamine. These change the likelihood that we trust a person, feel disgusted by an act, value a possible benefit of cooperation, etc.. Research on the effect of these substances provides inroads to the study of the genetic basis of cooperative behavior.

Human societies brim with a large variety of institutions that, in one way or the other, stabilize NPDs and this solves social dilemmas: police, justice systems, governments, laws, religions, etc. Their main function is to police the behavior of agents involved in social dilemmas and correct their selfish behavior by punishment. Punishment does not necessarily need to come from an institution external to the cooperating group, however. Experiments have shown that human agents have a strong tendency to strong reciprocity, that is, to punish free-loaders and other selfishly acting agents within their group even at a cost to themselves. Some players in experimental games have even been found

to punish those that fail to punish free-riders. In order to determine whether or not another agent is acting selfishly, his behavior needs to be compared to some norm. These norms of cooperative behavior can differ considerably from society to society and thus appear to be socially learned to a substantial degree. A further strong mechanism to stabilize cooperation within a group is a conflict with an out-group. Experimental work shows that we have a strong tendency to trust members of our own group more than members of another group, even if the criterion for group membership is arbitrarily determined by the experimenter and groups are formed by a random process. This tendency for ‘parochial altruism’ is seen as the basis for a less fortunate form of human cooperation: warfare.

Cooperation Models and Empirical Observations

Both, the idea that reciprocal altruism can explain altruistic behavior among unrelated agents and that the IPD catches the essence of cooperation, gave rise to an enormous literature, notably in the theoretical domain. However, after three decades of frantic activity a good part of the cooperation community has come to the awkward conclusion that the theoretical emperor had no empirical clothes. Few, if any, examples of reciprocal altruism under natural conditions exist and few situations that resemble a two-person IPD also show cooperation through strategies like TIT-FOR-TAT or similar. Many such situations may exist, but if they do the agents apparently play an ALWAYS DEFECT strategy. Reciprocal altruism and IPD-like situations can be created under laboratory conditions, but only by taking away the option of partner choice and by reducing strategic options by using a highly artificial apparatus.

More realistic models, which were often inspired by empirical observation in the first place, fare much better. Both parceling and raising-the-stakes can be seen in nature and many examples of biological markets have been reported. The n-player models that specifically apply to human societies have, however, been developed by a healthy interaction between theoretical advances and empirical study.

Glossary

Amniotic fluid – The watery fluid in the amnion, in which the embryo and, later, the fetus are suspended.

Canopy – The cover formed by the leafy upper branches of the trees in a forest.

Catecholamines – Any of a group of amines produced by the brain and by the adrenal glands which includes epinephrine, norepinephrine, and dopamine.

Catecholamines have important physiological effects as neurotransmitters and hormones in situations of stress but are also known to modulate attention, memory processes and social behavior.

Endorphins – Endogenous opioid polypeptides produced by the central nervous system in vertebrates during strenuous exercise, excitement, pain, and orgasm. They resemble the opiates in their abilities to produce analgesia and a sense of well-being. Endorphins work as natural pain relievers and are known to be involved in social attachment.

Lagomorphs – Any member of the order Lagomorpha, comprising the hares, rabbits, and pikas, resembling the rodents but having two pairs of upper incisors.

Oxytocin – A mammalian hormone that also acts as a neurotransmitter in the brain and best known for its roles in female reproduction: it is released in large amounts after distension of the cervix and vagina during labor, and after stimulation of the nipples, facilitating birth and breastfeeding, respectively. Recent studies have begun to investigate the role of oxytocin in various behaviors, including social recognition, bonding, anxiety, trust, and maternal behavior.

Parental investment – In evolutionary biology, parental investment is any parental expenditure (time, energy, etc.) that benefits one offspring at a cost to parents' ability to invest in other components of fitness.

Components of fitness include the well-being of existing offspring, parents' future reproduction.

Prolactin – A polypeptide hormone produced by the anterior pituitary gland in mammals. Increased serum concentrations of prolactin during pregnancy cause enlargement of the mammary glands, increase the production of milk, and facilitate the onset of maternal behavior in some species. Sucking by the young on the nipple then promotes further prolactin release, maintaining the ability to lactate.

Prosimians – Species belonging or pertaining to the primate suborder Prosimii, characterized by nocturnal habits, a long face with a moist snout, prominent whiskers, large mobile ears, and large, slightly sideways-facing eyes, comprising the lemur, loris, potto, bush baby, and aye-aye.

Somatosensory system – A diverse sensory system comprising the receptors and processing centers to produce the sensory modalities such as touch, temperature, proprioception (body position), and nociception (pain). The sensory receptors cover the skin and epithelia, skeletal muscles, bones and joints, internal organs including the uterus, and the cardiovascular system.

Suids – Any member of the family Suidae, hooved mammals, order Artiodactyla, including the wild and domestic pigs. Suids are stout animals with small eyes and coarse, sometimes sparse, hair. All have muzzles ending in a rounded cartilage disk used to dig for food and some species have tusks.

Behaviors associated with the birth and care of young are essential for the survival of mammals. For the mother, they represent a means of investing in her reproductive fitness; for the young, it is a question of individual survival, as the mother is the only source of food, at least in the early stages of development. In some cases, the father may assist the female in care of the young but among mammalian species it is more an exception than a rule. The pattern of mother–young interactions varies according to the developmental status of the neonate and the litter size, and mammals differ in the extent to which physiological factors contribute to the postpartum expression of their caring behavior. However, in all species that have been studied so far (with the exception of some primates), maternal behavior has retained its close relationship to the endocrine and neuroendocrine processes that govern reproduction. Its appearance is synchronized with the end of pregnancy when the profound changes induced in the neuroendocrine balance regulate the synchronized onset of parturition, lactation, and parental behavior. Hormones act on the reproductive tract to initiate parturition, and the combination of hormonal and somatosensory stimuli activate brain structures involved in the initiation of

maternal care and bonding. Males are not stimulated hormonally to exhibit parental behavior; nevertheless, in the species concerned, they exhibit such behavior either at the birth of their young (rodents) or later (canids).

Characteristics of Mammalian Parental Care

Variety of Parental Behaviors

The variety of forms of parental care depends very much on the maturity of the young at birth. Mammalian neonates are subdivided into three classes: altricial (immature), precocial (fully developed), and intermediate species. These primary parameters interact with other factors, including postnatal growth rate, litter size, and social structure to determine the nature of care provided.

Species with altricial young

Altricial young are very immature at birth; they are blind, deaf, and have limited locomotor ability. Because they are born without fur, they are also unable to regulate their body temperature. Parental care usually consists of a nesting pattern after the mother has selected a site in which she may build a nest and gives birth to numerous young. This can be underground, as in many rodents and in rabbits, at ground level, as among carnivores, or in the canopy, as in squirrels and prosimians. The nest is then the central element around which maternal care is organized (Figure 1). Mothers nurse their young in the nest and stimulate them to urinate or defecate by licking their anogenital area. In many species, they retrieve them to the nest. Marsupials are an extreme case in this group as their young are very altricial and carried by their mother. At birth, the embryonic young crawl into the mother's pouch until they emerge as fully developed, mobile animals.

Species with precocial young

A second major pattern is characterized by species giving birth to one or two precocial young (most ungulates). These newborns have fully functional hearing and vision, rapid locomotive development, and the ability to achieve thermoregulation. The young are able to stand up and engage in sucking by approaching the mother within minutes of being born (Figure 2). Mothers engage in a pattern of parental behavior that is called leading-following. Species of this type are usually herd animals, the mother leading the offspring which follow her as she moves with the conspecifics of the group (sheep, horse, etc.). In a few species, however, this pattern includes a brief postpartum period where the newborn is hidden (goat, deer, etc.). During this hiding phase, the mother returns periodically to feed her offspring. This system serves to protect the young from predators at times when the mother is foraging and while the young is still too weak to escape from predators.

Species with intermediate young

The third major pattern is expressed by many primates including the human, as well as by suids. In these species the young are intermediate at birth (semialtricial or semi-precocial). Hearing and vision are functional, but neonates have limited locomotor and thermoregulatory autonomy. The number of young among primates is small (mostly singletons, twins in tamarins, etc.) and they are carried by their mother for thermal comfort and transportation. Human mothers carry their infants in their arms, but among subhuman primates the infants must cling to the mother's fur and often ride on her back,

Figure 2 Maternal behavior in the ewe. (a) Two ewes licking indiscriminately two lambs immediately after parturition; cleaning of the neonate and consumption of amniotic fluids are typical traits of maternal motivation. (b) Mother sniffing her neonate while it is suckling in parallel-inverse position; olfactory recognition of the young by its dam leads to acceptance at udder. (c) Ewe displaying aggressive behavior (butting) toward an alien young. (d) Lamb suckling its own mother in parallel-inverse position while an alien young is suckling from behind; suckling from behind prevents olfactory identification by the ewe and reduces rejection behavior. side, or chest. In suids such as pigs, the mother gives birth to large litters which remain in a den or a nest for the first 2 weeks.

Maternal Behavior

Social isolation

Females show a tendency to isolate themselves from their social group just before giving birth, a behavior well described in ungulates. In these animals, nonmaternal females show very strong behavioral responses when isolated from conspecifics indicative of agitation and stress. Around parturition, such distress reactions disappear. Isolation is an important preliminary step in the formation of the mother–young bond as it protects the offspring from disturbances by congeners and predators, and facilitates early interactions. However, not all species seek isolation at the approach of parturition. African buffalos or the wildebeest, for example, give birth within the herd – a behavioral adaptation which may have been shaped by the communal defense against predators observed in the former species, and the tendency of the latter to congregate in huge herds during their annual migration.

Parental aggression

The physiological changes associated with pregnancy, parturition, and lactation bring about profound changes in the aggressive behavior of the female and these have to be considered as intrinsic components of the behavioral profile of motherhood. Aggression toward adult conspecifics, especially males, is a common feature in various rodents. The vulnerability of young to predators has shaped various behaviors considered to be antipredator strategies in adults. In suids, mothers are very reactive to the squeals of piglets. In case of danger, the young gather around the mother who may defend them with success. Domestic sheep have been observed to remain undisturbed in the presence of foxes but can repel ravens, and it is reported that mountain ewes are much less protective of their young than the large mountain goats with their lethal horns. In some species, active defense of the young is displayed by other members of the group as well. In African buffalo, an entire herd of adults may react to a calf's distress call, and the muskoxen are known for their successful use of social defense against wolves.

Nest building

The main characteristic of mammals that give birth to altricial young is to provide shelter and thermal protection to their offspring. In rats and hamsters, burrowing increases in the pregnant female but nest building is initiated at the very end of pregnancy (Figure 1). Carnivores also use nest sites, usually in the form of a den. But the most striking example of nest building is no doubt displayed by rabbits. A few days before giving birth,

the female digs several shallow burrows and collects straw and grass. The day before parturition, she selects one of the burrows and lines it with hair pulled from her own body, a behavioral feature unique in mammals, which results in an elaborate structure. Weakening of the ventral hair follicles precedes the initiation of nest building only by a short time. Among ungulates the wild sow, which gives birth to semiprecocial young, builds a nest of grass and small branches in an undisturbed place away from other adults. Even though domestic sows kept under intensive rearing conditions do not have the opportunity to perform such activities in their farrowing pens, free-ranging females display prepartum behavior similar to that of their wild counterparts. Although goats do not build a nest, they do select a site for kidding, a behavioral trait that is not as common in sheep.

Postpartum behavior

Cleaning of the neonate and consumption of amniotic fluids and placenta is one of the first behaviors displayed by most mammals. In sheep and goats, attraction to amniotic fluids and fetal membranes begins during the last stage of parturition, but complete consumption of the placenta is occasional. In ewes and less clearly in cows, the birth fluids are normally repulsive but become temporarily attractive around parturition (Figure 2). This attraction highlights the primary importance of olfaction for the establishment of maternal behavior. Suppression of olfactory cues coming from amniotic fluids leads to an absence of licking, refusal to nurse, and aggressive behavior in primiparous ewes. In contrast, species giving birth to altricial young lick their offspring and systematically ingest the placentas before engaging in nursing. Placentophagia can also be displayed by males as in biparental hamsters. Placentophagia and amniotic fluid ingestion serves several functions such as facilitating expulsion of the next fetuses, having an analgesic effect, regulating lactation, and, in species which build a nest, maintaining the birth-site clean and minimizing bacterial infection.

During grooming, many species of mammals emit characteristic vocalizations of low amplitude and frequency. These vocalizations are mainly emitted around parturition and, later on, during nursing. In precocial species, these calls are very attractive to neonates and have soothing properties. Parturient mothers are also very reactive to calls emitted by their young. In altricial rodents, ultrasonic vocalizations emitted by pups are potent activators of retrieving behavior in the mother. In ruminants, grooming and mother–young vocalizations contribute to early bonding enabling the dam to learn the odor and the voice of her offspring.

Nursing is undoubtedly the most common pattern of maternal behavior in mammals. Irrespective of the species, it usually occurs within an hour or two of parturition.

In altricial species, the first nursing may even take place before the whole litter is delivered. While nursing, mothers adopt a typical posture: female rats arch their back (**Figure 1**), ewes adopt a parallel-inverse position with their young (**Figure 2**), and sows lie on their side. The nursing posture is triggered by the young while exploring the abdomen of the mother. Locating and reaching the udder or the nipple depends on various sensory cues provided by the mother (odors, temperature, and texture of the body). In the first stage of their development, young are allowed to suckle at any time and for as long as they wish. Later on, the mother restricts the frequency and duration of the nursing episode, generally by walking away from the offspring if it attempts to suckle.

Parental Investment and Recognition of Young

The evolutionary-genetic consequence of reproduction is the direct transmission of the parents' allele to the next generation. Individuals which produce a relatively large number of surviving, reproductively capable young thereby pass on more of their genetic material than do individuals with lower reproductive success. Effective reproduction entails considerably more than fertilization, gestation, and birth. Neonates are entirely dependent upon the care and resources provided by their mother (as well as paternal care in some species). Care of the offspring is associated with substantial cost to the mother, including the expenditure of metabolic energy for milk production and thermal regulation, and the increased risk of predation resulting from the presence of conspicuous neonates and limited mobility. Because the mother's resources and reproductive life span are limited, postnatal investment in developing young through weaning ultimately reduces her opportunity to produce additional offspring. Therefore, it follows that natural selection should favor the evolution of mechanisms to ensure that the caregivers' own offspring are the beneficiaries of such parental investment. When parents' own young are likely to intermingle with unrelated neonates – as commonly occurs in a variety of gregarious mammals – mothers rapidly develop the ability to recognize their individual offspring (e.g., ruminants; **Figure 2**). In this context, parents that respond indiscriminately to their own and alien young jeopardize their own reproductive success, since their offspring are deprived of necessary resources, which are wasted on unrelated young. In contrast, when young are born in isolation from other neonates and remain in a den or a nest (most rodents and lagomorphs), there is little need for the mother to recognize her offspring during that stage of development. Rather, by providing care to all neonates present in the den or the nest, the mother effectively restricts her investment to her own offspring alone. Functionally, this parental strategy is equivalent to

one based on discrimination between parents' own and alien young since mothers are usually very territorial and will defend the entrance to their nest or den against all intruders making the presence of alien young in it very unlikely.

Regulation of Parental Behavior

Endocrine and Somatosensory Factors

Hormones associated with late pregnancy and parturition that act on brain receptors account for the rapid activation of maternal responsiveness seen at parturition; these include the steroid hormones estradiol and progesterone which are synthesized by the ovaries and released into the circulatory system, as well as the protein hormones prolactin and oxytocin which are released within the brain and from cells or nerve terminals within the pituitary gland during parturition (**Figure 3**). Other neuropeptides and neurotransmitters, such as β -endorphins and catecholamines, also show important variations at parturition and have both direct and interactive effects on maternal behavior. It is the mechanical stimulation of the genital tract (uterus, cervix, vagina, etc.) caused by the expulsion of the fetus that ensures the immediate onset of maternal behavior.

Estradiol and progesterone

As a rule, late pregnancy and parturition are characterized by a sharp decrease in plasma progesterone levels, followed by an increase in estradiol. This shift in the estradiol/progesterone ratio occurs in most mammals and plays a critical role in the hormonal induction of maternal behavior (**Figure 3**). In virgin rats, a progesterone and estradiol treatment for 12 days, followed by progesterone withdrawal, induces maternal response after exposure to pups. Estradiol is essential to stimulate maternal care and progesterone has two functions. First, a prolonged exposure to progesterone primes the female to respond to the rise of estradiol occurring prior to parturition. Second, the decline in progesterone secretion synchronizes the onset of maternal behavior with parturition. In rabbits, steroids influence the expression of nest building. After surgical removal of the ovaries, females given estradiol benzoate plus progesterone display digging while those given only estradiol benzoate do not. This treatment also induces straw-carrying, but only after progesterone withdrawal. On the other hand, progesterone withdrawal in estradiol benzoate/progesterone-treated females induces hair-pulling in no more than 40% of the animals. Additional factors are required to promote the loosening of fur and the participation of androgens is reported. In mice, nest building is under the influence both of high progesterone and low estradiol levels. In contrast to rats, rabbits, and mice, nest building

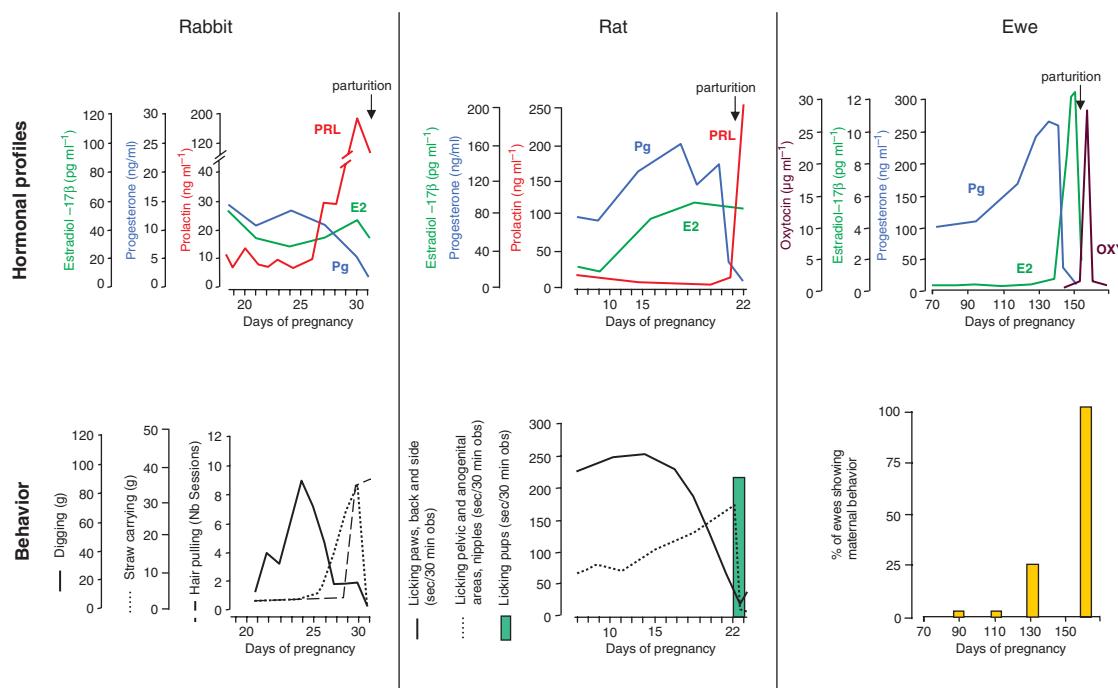

Figure 3 Changes in the plasma concentration of various hormones during pregnancy in the rabbit doe, the female rat, and the ewe (upper panel) and their concomitant maternal responsiveness (lower panel). The elements represented for each species are: (a) for the rabbit doe: digging, straw carrying, and hair pulling; (b) for the female rat: licking paws, back and side (noncritical regions for maternal care), licking pelvic region, anogenital area, and nipples (critical regions), and licking pups; (c) for the ewe acceptance of young. In rabbits, digging is stimulated by estradiol and progesterone, while straw carrying and hair pulling is under the control of prolactin. In the rat, the decline in progesterone and the increase in estradiol levels lead to a shift in licking behavior; maternal responsiveness is enhanced by vaginocervical stimulation, while maintenance of parental care is under the control of prolactin. In the ewe, maternal behavior (licking, low-pitched bleats, and nursing) is triggered by changes in progesterone/estradiol ratio, vaginocervical stimulation, and the concomitant release of oxytocin.

in hamsters begins in mid-pregnancy when levels of both steroids are elevated but they are not sufficient to induce maternal responses to pups. Likewise, in sheep, steroids alone are not sufficient to induce maternal responsiveness: high doses of oestradiol are required in nonpregnant females and only a few characteristics of parental care are displayed. In nonhuman primates, results are rather contradictory: evidence against a role for estradiol or progesterone has been reported in a number of species. In gorillas, no significant association was found between prepartum urinary steroid levels and maternal behavior. Similarly, in rhesus macaques, whether mothers were accepting or abusive was found to be unrelated to estradiol and progesterone plasma levels. In contrast, sex steroid profiles and maternal behavior at parturition are positively correlated in red-bellied tamarins and pigtail macaques. In common marmosets, operant studies have provided evidence indicating a close relation between circulating levels of estradiol and progesterone and motivation to have access to infant stimuli. In the human, although few correlations between steroids and maternal feeling were described during pregnancy, mothers who exhibit a smaller pre-to-postpartum decline in the estradiol/progesterone ratio are found to express greater

feelings of attachment to their infants during the 4 weeks following childbirth.

For some species (sheep, hamster, etc.), ovarian steroids are not able, in themselves, to stimulate maternal care, while for others (rat) they facilitate its onset but without triggering the immediate response normally shown at parturition. Therefore, steroids have a priming effect allowing other factors to trigger such behavior. These factors include additional hormones, such as prolactin and oxytocin, and somatosensory stimulation that are associated with parturition.

Somatosensory stimulation of the genital tract

Expulsion of the fetus also facilitates the onset of maternal behavior through somatosensory stimulation of the genital tract. This can be demonstrated experimentally with local mechanical stimulation. In rats, nonpregnant, intact, multiparous females receiving vaginal stimulation show immediate maternal behavior. However, this effect is synergistic with that of steroids as vaginal stimulation is ineffective in females that had their ovaries removed surgically. It is in sheep that vaginal stimulation plays a dominant role. In nonpregnant, steroid-primed females, not only does it increase the number of ewes displaying

maternal care but vaginal stimulation induces the full complement of maternal responsiveness, licking, low-pitched bleats, acceptance at the udder, and even attraction toward amniotic fluids. Similar to rats, vaginal stimulation without a steroid pretreatment is not effective. Inversely, epidural anesthesia prior to parturition inhibits parental care in primiparous ewes. In rhesus monkeys, cesarean delivery impairs acceptance of the neonate. However, vaginal stimulation is not a prerequisite for maternal care since, in the cesarean-sectioned mother, swabbing the newborn with amniotic fluids and vaginal secretions leads progressively to its acceptance. In the human, the impact of cesarean delivery or epidural anesthesia is poorly documented and whether such procedures disturb the initial mother–infant interactions or, on the contrary, are beneficial as a result of the reduced pain remains a question of debate.

Prolactin

Robust demonstrations of prolactin effects on maternal care have been reported in rodents and lagomorphs. In rats, suppression of endogenous prolactin delays the expression of maternal behavior by days – affecting mainly retrieving and crouching; these effects are restored by a concurrent administration of prolactin. Prolactin can cross the blood–brain barrier and exerts an influence on parental care via the medial preoptic area (MPOA). In mice, prolactin further enhances the levels of maternal behavior shown by virgin females, and prolactin-receptor knockout mice show major deficits in the onset of maternal behavior. In rabbits, prolactin modulates the expression of nest building. It specifically induces straw-carrying and hair-plucking, while at the same time inhibiting digging. Prolactin, together with estradiol and progesterone, also stimulates the emission of an olfactory signal from the nipple, ‘the nipple-search pheromone’ that allows the pup to locate it. In contrast, prolactin is not essential for maternal care in sheep.

Oxytocin

The neural mechanisms by which vaginal stimulation initiates the onset of maternal responsiveness primarily involve activation of oxytocin release within the brain. In rats and sheep, whereas oxytocin is a key factor for the onset of maternal behavior at parturition, it does not seem to play a major role in the maintenance of parental care once fully established. Administration of oxytocin within the brain facilitates the onset of maternal behavior in female rats and sheep, but is only effective in estradiol-pretreated animals. Inversely, administration of an oxytocin antagonist disrupts the onset of maternal behavior in steroid-primed or naturally parturient female rats. Steroids exert positive

effects on maternal behavior via central oxytocin by stimulating the synthesis of the neuropeptide and its receptors. One site of oxytocin synthesis, the paraventricular nucleus of the hypothalamus (PVN), and several sites of oxytocin release during parturition – including the MPOA, the ventral tegmental area (VTA), the nucleus accumbens (NAcc), and the olfactory bulb (OB) – seem responsible for triggering maternal behavior. Microinjections of an oxytocin receptor antagonist into these regions disrupt the onset of maternal behavior at parturition while microinjections of oxytocin in estradiol-primed females stimulate it. The effective action of oxytocin is the result of a positive feedback effect on PVN oxytocin-producing neurons which, in turn, stimulates the coordinated release of oxytocin into multiple target sites. In the human, oxytocin may be of importance during the neonatal period since levels of oxytocin are related to the mother’s level of calmness, interest in social interaction, and duration of breast-feeding.

Opioids

Three major endogenous opioid systems in the brain (β -endorphin, enkephalins, and dynorphins) coexist with three classes of opioid receptors (μ , δ , and κ). This makes opioid regulation of maternal behavior extremely complex. Different effects are observed based on the type of receptors, the brain regions, and the species. β -endorphin acting on μ -receptors in the MPOA inhibits the onset of active maternal responses in rats, while a nonspecific agonist, morphine, infusion in the VTA stimulates them. In addition, opioids binding to μ -receptors disrupt ongoing maternal care: pup grouping and retrieval are impaired in lactating females. The periaqueductal gray (PAG) is another site for an inhibitory action of opioids on maternal behavior. Finally, dynorphin levels increase in the lumbar spinal cord during late pregnancy, and by acting on κ - and δ -receptors in the spinal cord they produce an analgesic effect which might reduce the pain associated with parturition. Ingestion of amniotic fluids by parturient rats enhances this late-pregnancy-induced analgesia without disrupting maternal behavior. With respect to other species, there is evidence for a positive role of opioids in maternal behavior in sheep, while research on primates has provided evidence for both stimulatory and inhibitory effects.

Given the complexity of maternal behavior, it is not surprising that the underlying neural circuitry, where hormones act to induce the onset of maternal behavior, involves structures at all levels of the nervous system, some being primary, and others being an interface with this primary system.

Neural Control

Onset of Maternal Care

In rats, there are at least two antagonistic neural systems governing the expression of maternal behavior (Figure 4). One is excitatory and deals with the activation of maternal responses toward pups; the other is inhibitory and regulates avoidance and aversive responses to pups or pup-related stimuli. The excitatory system primarily includes the MPOA and ventral part of the bed nucleus of the stria terminalis (vBNST). Lesions of these regions or knife-cuts transecting their lateral projections abolish maternal behavior completely. Hormones that activate maternal behavior act on the MPOA. Implants of estradiol, prolactin, or oxytocin into the MPOA facilitate maternal responding. The MPOA and vBNST exert an influence on maternal behavior by interacting with the VTA and the NAcc. Activation of the MPOA stimulates the dopaminergic system originating from neurons in the VTA, resulting in dopamine release within the NAcc. Dopamine depresses NAcc activity which releases the ventral pallidum from NAcc inhibition. Disinhibition of the ventral pallidum would promote the processing of

pup-related stimuli by other brain regions so that appropriate maternal responsiveness occurs.

The MPOA/vBNST receive inputs from other parts of the brain, in particular from the olfactory and limbic systems which exert inhibitory influences on the functions of the MPOA/vBNST. Specifically, a major input to the MPOA comes from the medial amygdala (MeA) which, in turn, receives inputs from the OB and from the anterior and ventromedial nuclei of the hypothalamus (AHN/VMN). These two hypothalamic nuclei project massively to the PAG in the midbrain which regulates fear-related behavior. In virgin female rats, which do not show maternal responsiveness, pup odors would activate a MeA-AHN/VMN-PAG circuit and lead to escape responses. Since AHN, VMN, and PAG have neural projections to MPOA/vBST when these three areas are highly active, they also directly inhibit the MPOA/vBST. Around parturition, elements of this whole inhibitory circuit are depressed permitting hormonal events of late pregnancy and parturition to act on the MPOA/vBNST and to trigger the onset of maternal behavior.

In sheep, parts of the excitatory neural system have been characterized (Figure 2). Inactivation of the MPOA

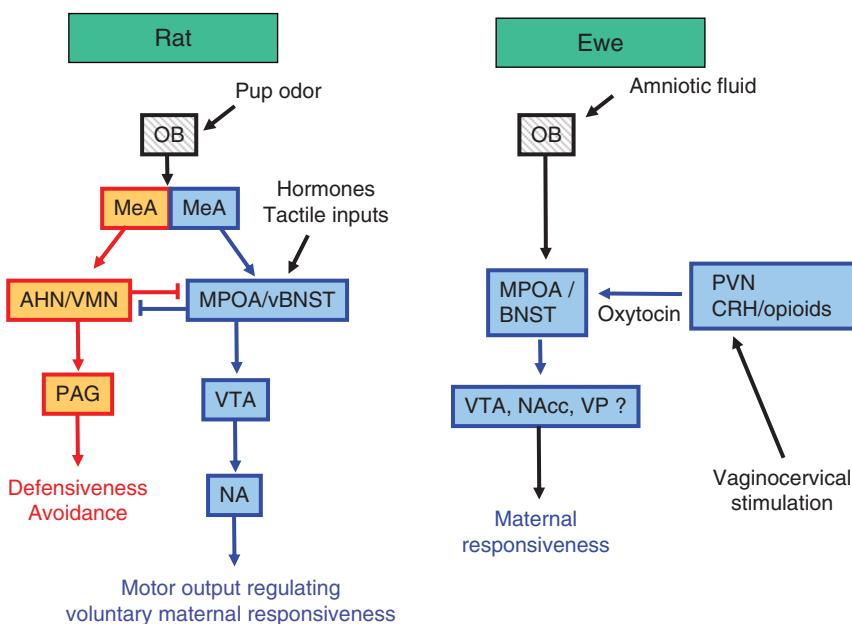

Figure 4 Composite neural model of the regulation of maternal behavior in the rat and in the ewe. Projecting lines ending in arrows signify excitatory connections and those ending in a vertical bar indicate inhibitory connections. In the rat, appropriate maternal responses occur when the medial preoptic area (MPOA)/ventral bed nucleus of the stria terminalis (vBNST) system is dominant over the anterior and the ventromedial nuclei of the hypothalamus (AHN/VMN). These latter nuclei project to the periaqueductal grey (PAG). The MeA/AHN/VMN/PAG system promotes fear responses and avoidance of pups (red circuit). Olfactory stimuli together with hormonal and tactile inputs activate the MPOA/vBST which consequently exerts a positive influence on maternal responsiveness (blue circuit) by interacting with the ventral tegmental area (VTA) and the nucleus accumbens (NA). In the ewe, the control of maternal responsiveness is mainly hypothalamic (paraventricular nucleus: PVN, MPOA, and BNST) and is triggered by vaginocervical stimulation. This stimulation activates mainly the oxytocinergic system of the PVN. Activation of the olfactory bulb by amniotic fluid is a requisite for the initial approach of the neonate in primipara and may act via the MPOA/vBST complex. Involvement of the VTA, NA, and VP is hypothetical.

at parturition impairs maternal motivation and little expression of maternal care is observed. In addition, inactivation of the BNST results in poor motivation to approach the young. It is hypothesized that at parturition, VCS activates oxytocin neurons in the PVN. This would coordinate the release of oxytocin in a number of brain regions and more specifically in the MPOA/BNST. From these two structures, brain regions that still remain to be identified may be activated to promote maternal acceptance behavior. Based upon findings in rats, the VTA, the NAcc, and its major efferent projections – the ventral pallidum – are good candidates for participation in a maternal neural network.

Onset of Recognition of the Young

Mothers of precocial species acquire the ability to recognize their own young soon after birth and refuse to nurse alien offspring (maternal selectivity). In sheep and goats, such discrimination is established within 2–4 h after parturition and relies on olfaction. The neural substrates controlling olfactory memory process have been extensively studied in sheep and differ from the brain regions regulating maternal responsiveness (Figure 5). Recognition of the young is mediated by the main OB in which coding of the familiar lamb odor is established. Norepinephrinergic inputs from the locus ceruleus to the OB are, in part, responsible for the formation of this

memory. Increase in norepinephrine release at parturition, with the help of oxytocin, causes the activation of OB cells permitting potentiation of the glutamate system by the retrograde messenger, nitric oxide. This results in an enhanced cellular activity in response to own-lamb odors. In this way, this output is decoded by subsequent olfactory processing regions. Among them, the cortical and medial nuclei of the amygdala play a preeminent role. Inactivation of either of these nuclei prevents mothers from learning to discriminate their own, from an alien, lamb. The basal forebrain cholinergic system is also activated at parturition and its lesion impairs the formation of olfactory lamb recognition.

Maternal Experience

Previous maternal experience is a requisite for optimal expression of maternal behavior at parturition in most mammals. Maternal responsiveness improves, and aggression declines, with increasing parity. Studies in rodents and sheep suggest that previous parity alters the underlying neural mechanisms making them more responsive to physiological factors at subsequent births. For instance, the number of estrogen receptors in olfactory cortices is higher in multiparous, than in primiparous, mice and ewes. In sheep, maternal experience enhances the expression of oxytocin receptor messenger RNA (mRNA) and the number of estrogen

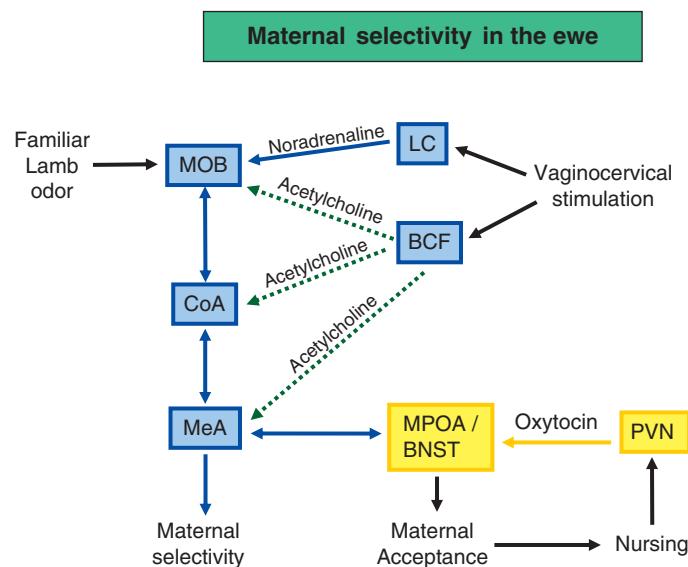

Figure 5 Neural model of the regulation of maternal selectivity at parturition in the ewe. Changes in the main olfactory bulb (MOB) reactivity toward lamb odor is triggered by vaginocervical stimulation via the noradrenergic system of the locus ceruleus (LC) and, presumably, the cholinergic system of the basal forebrain (BCF). Maternal selectivity is under the control of the cortical and medial nuclei of the amygdala (CoA, MeA, etc.) which receive input from the OB. The MeA interacts with the neural pathways involved in maternal acceptance – the medial preoptic area (MPOA), the bed nucleus of the stria terminalis (BNST) and the paraventricular nucleus of the hypothalamus (PVN). The hypothalamic oxytocinergic system is stimulated by nursing which, in turn, maintains maternal acceptance. Blue depicts the neural network involved in maternal selectivity; yellow represents the neural network involved in maternal acceptance.

receptors in the PVN. At parturition, the release of oxytocin, norepinephrine, acetylcholine, and glutamate in the OB is higher in multiparous, than in primiparous, ewes. In rats, experience-based changes are reported in glial function both in the hippocampus and the MPOA. Higher numbers of glial fibrillary acid protein-positive cells are observed in the MPOA following experience with pups in multiparous, than in primiparous, rats. Pregnancy and motherhood alter other forms of neural plasticity. Hippocampus dendritic morphology is also changed when experiencing parturition. Adult neurogenesis in the hippocampus is decreased at parturition in primiparous and multiparous mothers in comparison to nulliparous female rats. In contrast, increased olfactory neurogenesis is observed in dams during pregnancy and the early postpartum period. Other parts of the maternal neural circuit, such as the BNST and the NAcc, are also sites of increased cell proliferation induced by pup exposure. Thus, maternal experience induces changes in neurotransmitter release, receptors synthesis, neural morphology, and neurogenesis that could mediate the enhanced maternal responsiveness to hormones and neonate stimulation.

Conclusion

The study of parental care has provided one of the best opportunities to investigate how molecular and cellular changes in specific neural circuits influence behavior. The system is indeed complex, with multiple hormones and several neural systems involved, with marked differences between species in the type of maternal care, as well as in the neuroendocrine and neurobiological bases. Adding to this complexity, experiential factors influence maternal care not only through the dam's own previous experience as a mother, but also through her own experience of being mothered as an infant. For instance, infant rats who received more touch and licking stimulation from the mother in the nest show a higher level of pup-licking as adults with their own offspring, in comparison with less stimulated infants. Similar early maternal stimulation in the nest also produces a dampening of the offspring's emotional reactivity to novelty and stress when they become adult. In species in which mothers develop individual recognition of their offspring, as in sheep, similar mechanisms used to promote attachment of the young female to her mother seem to be reactivated when she gives birth and exhibits recognition and attachment to her offspring. This transfer of biological effects of early experience to later maternal responsiveness and behavior may be especially evident when considering species in which the parent is intimately involved in the socializing process of offspring, as in primates. In vervet monkeys, there is substantial evidence that the style of mothering

exhibited by adult daughters is similar to the style of mothering shown by their mothers. Vervet monkey mothers who engage in a high level of mother-ventral contact have daughters who also show high mother-infant contact. Abusive patterns of maternal care span generations as well and the incidence of abuse varies across matrilines in pigtail macaques, and studies have shown that the manner in which the infant was mothered did exert an effect on their adult mothering behavior. Among the human, it is commonly assumed that there are often intergenerational similarities in maternal behavior.

Based on our understanding of experiential effects on the brain in other animals, it is also possible that children who have been neglected or abused have experienced neurological changes which result in altered affective, perceptual, and cognitive function during development. Such changes are more than likely to affect how they perceive and respond maternally to their own offspring, how they approach maternal-care responsibilities initially, and how they are able to learn or modify maternal-care practices. One major theoretical issue, then, is to understand why this aspect of brain function which is critical for species survival is so malleable.

Mating Behavior

Glossary

Courtship – It is a behavioral process whereby an individual attracts and courts partners of the same species to convince them to mate. Courtship is species specific and often stereotyped. Courtship can also refer to the period of time during which this behavior is displayed.

Display – It is a particular pattern of behavior used as a means of attracting attention and communicating sexual and/or social status.

Gamete – It is a cell containing only one set of chromosomes (haploid) which is capable of fusing with another gamete of the opposite sex to produce a fertilized egg that contains two sets of chromosomes (diploid) that will produce a new individual. Only two types of gametes exist: the small mobile spermatozoa made by the male and the large oocyte made by the female.

Sexual selection – It is the process that gives a reproductive advantage to some individuals over others of the same sex. Sexual selection is the result of competition between individuals of the same sex (intrasexual competition) and of mate choice (intersexual competition) and is a major force driving evolution of reproductive traits often to extremes, for example, the long tail of the peacock. The theory was first proposed by Charles Darwin in 1871 (*The Descent of Man and Selection in Relation to Sex*, John Murray, London).

Reproduction is a functional necessity for survival. It is also a central focus for natural selection and directly leads to the evolution of species. Most life forms reproduce sexually. In all cases, this is done through two specific cells, the gametes. One, the spermatozoa, is small, mobile, and produced in abundant numbers; the other, the oocyte, is large and produced in much smaller numbers. Generally, gametes are produced by different individuals: males produce spermatozoa and females produce oocytes. The male and female gametes, in most cases, do not come into contact by chance but because males and females meet when in appropriate physiological and behavioral conditions. Thus, the object of sexual behavior is to bring male and female gametes together via a mating ritual, so that fertilization can occur. This requires coordination between the maturation of both female and male gametes

and sexual behavior so that sexual partners meet and copulate at the appropriate time. However, in most species, the chance to reproduce and therefore to participate in the evolutionary process are not identical for all individuals. It also depends on other ecological and social factors that lead to specific choices of mating partners and to the evolution of a wide range of highly distinct mating systems. This article reviews how sexual behavior is organized and how a mate is chosen. It addresses the factors modulating the expression of this behavior: the sensorimotor and hormonal controls responsible for its coordination with the maturation of gametes and the mating systems that facilitate reproduction. In this article, sexual behavior and mating behavior are used synonymously.

Organization of Sexual Behavior and Courtship Displays

In all species, sexual behavior comprises a sequence of specific events: first, there is an attraction phase, then a precopulatory phase and finally mating itself. The first two phases of sexual behavior provide the opportunity to test partners for attractiveness and to select among potential partners.

Attraction Phase

To engage in sexual behavior, partners in the appropriate physiological state have to first find and then attract each other. This problem is obviously not the same for all species, for example, a solitary male elephant living long distances from a potential mate compared to a snake emerging out of the nest with lots of others. It also differs with the anatomy of each species and the environment in which they live. In birds, auditory and visual cues are predominant. Sexually active males often have plumage with bright colors or specific ornament ([Figure 1](#)) or they call loudly with specific songs, and some build elaborate and highly decorated bowers. Several amphibians use auditory cues to attract a mate. Sexual partners in many mammalian and reptilian species emit specific chemical compounds known as pheromones that indicate their reproductive states. Pheromones can be produced by special glands or as a by-product of metabolism and are present in urine, feces, vaginal fluid, and skin. The strong smell of the male elephant in musth, that is, during its

Figure 1 A male peacock displaying. Photo C. Eyquem, copyright Licence Art Libre.

period of sexual excitement for example, comes from pheromones secreted by the temporal glands. A few of these compounds have been identified, for example, dimethyl sulfide in hamsters and androstenol in pigs.

The Precopulatory Phase: Courtship Behavior

In the second stage, attracted partners engage in specific patterns of courtship behavior intended to lead the other partner to mate. These behaviors often have to overcome underlying aggressive or defensive patterns of survival behavior. This is done through complex and often stereotyped patterns of motor behavior that constitute the courtship display. The courtship display is species specific, but with similarities in closely related species. In bovids, males court females with an approach from the side accompanied either by movement of the head on the back of the partner or by a rapid pawing movement of a foreleg together with specific vocalizations ([Figure 2](#)). Courtship displays can last for several hours or even days and they may be quite spectacular as in many birds. They are organized as a precise sequence in which each step is the stimulus that induces the next. A well-known example is the courtship of the stickleback first described by Niko Tinbergen: the sight of a mature female elicits a zigzag dance from the male which in turn

elicits a presentation posture until the female releases her eggs and the male his sperm. Disturbing one step prevents expression of the following behavior.

Copulation

In most fish, fertilization is external so that copulation is not necessary and the last phase of sexual behavior simply consists in the emission of eggs and sperm in a specific location such as a nest. External fertilization is also the norm in most species of frogs and toads. But in these species, it involves the male holding the female in a specific pose called amplexus during which the male releases sperm over the female's eggs as they are laid. In other vertebrates, fertilization is internal, that is, it occurs inside the female body cavity. The male deposits sperm directly into the female either by simple contact with the genital opening as in birds, with a 'cloacal kiss' or via an intromitting organ. The release of sperm in some species occurs as soon as intromission is achieved; this is typical in ungulates whereas in other species, for example, the rat, prolonged stimulation through multiple intromissions is normal. Ejaculation is often accompanied by specific male postures and it is normally followed by a refractory period during which sexual activity is decreased.

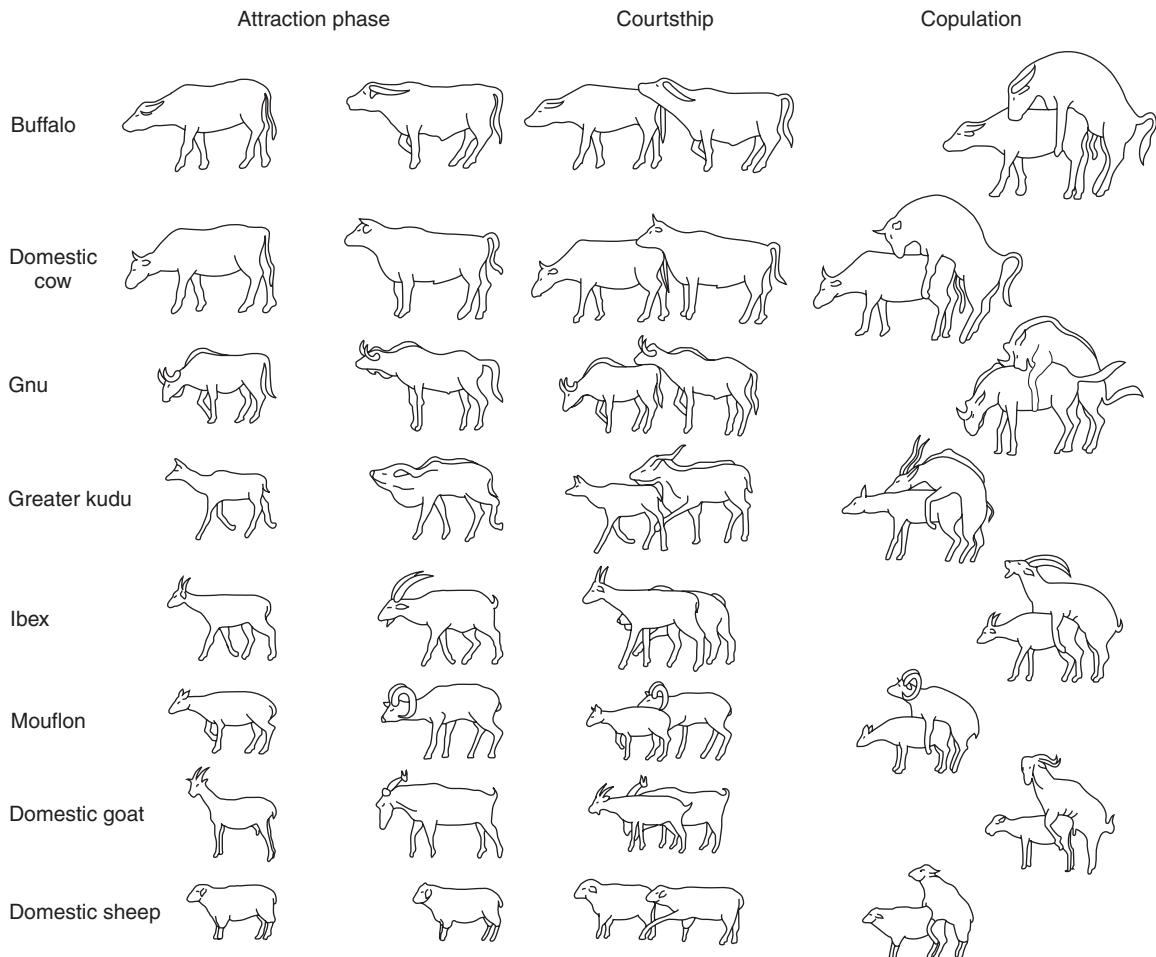

Figure 2 Patterns of mating behavior in different bovidae. Postures during mating are similar in all bovid species. When searching for females during the attraction phase, males hold their head horizontally with the neck extended. When courting, males approach the females from the rear and the side with either a placement of the head on the back of the female (e.g., buffalo, domestic cow, and gnu) or an outward rotation of the head at the side of the female accompanied by a rapid pawing of the foreleg (e.g., kudu, ibex, mouflon, sheep, and goat). Mating itself is accompanied by a downward movement of the male's head on the back of the female (e.g., buffalo, domestic cow, gnu, and kudu) or a jerking of the head backward (e.g., ibex, mouflon, sheep, and goat). Adapted from Rouger (1974) thèse de doctorat d'état, Université de Rennes.

Mate Choice

Reproduction requires a major investment of parental resources, especially in females who have to produce large eggs and nurture the progeny. Thus, although males generally have the most obvious role in sexual interactions, females have a critical role because they are mostly responsible for partner choice. Females choose their mates using multiple criteria that range from morphological traits, position in a dominance hierarchy, size of a territory, and quality of a gift to the nature of paternal behavior, to mention a few. In most vertebrates, females prefer the largest and strongest male controlling the best or largest territory. When as in the pipefish, the male has the greater parental investment, the situation is reversed. He is the choosy gender and will prefer the largest and most highly ornamented female that will compete to gain

access to him. In some species, such as the sage grouse, female choice is based on the intensity and quality of the courtship display. In others, females choose according to the form or intensity of a specific signal: the color of feathers in birds, the intensity of a call in frogs, or the size of antlers in red deer.

The characteristics of the mate that is chosen evolve because of the higher reproductive success of preferred males. It is considered a central process in sexual selection and leads directly to sexual dimorphism. Seeking the factors that drive this evolution has been the object of many studies and theories over the last 50 years. It has been proposed that these preferred characteristics are either directly or indirectly a sign of reproductive fitness that is that the male is strong, healthy, and is carrying genes that ensure the viability and reproductive success of the offspring. In some cases, the choice of a mate can be modified

by information acquired during a critical period in early life. This phenomenon was discovered by Konrad Lorenz in ducks and geese; he named it 'imprinting.' In adulthood, these birds will prefer the first moving object they saw in early life as a mating partner. Recently, imprinting has also been observed in goats and sheep reared from birth by a mother of the other species. At puberty, males and females preferred partners of the foster species to their own species. This preference reversed in females but was maintained in males during the 4 years of the experiment. This may explain why, in these species, males raised from birth in unisexual groups had an increased preference for partners of the same sex.

Hormonal Determinants of Sexual Behavior

Fertilization is only possible if maturation of the gametes and the expression of sexual behavior coincide with each other and between sexes. In most vertebrates, this coordination is achieved by the actions of reproductive hormones. Knowledge of a relationship between gonads and the expression of sexual behavior is ancient: castration has been practiced since antiquity. But the first confirmation of the role of the gonads in sexual behavior was in 1849 by Arnold Berthold. He discovered that roosters castrated as chicks did not grow a comb, never crowed in the mornings, and never mated. But they would do all these things if at the time of castration their own testis or that of another chick was reimplanted in the abdomen.

Males

In all species, ablation of testes is immediately followed by reduced sexual behavior that will eventually cease

altogether. The copulatory phase of sexual behavior is the first to stop, followed by the cessation of courtship behavior and then the cessation of the attraction phase of sexual behavior. The rate at which sexual behavior decreases is variable among species. In laboratory rodents, sexual behavior completely stopped by the end of 2 weeks after castration. In dogs, goats, and also humans some degree of sexual behavior can still be present several years after castration. The effect of castration on sexual behavior is also variable within species and several factors can slow the postcastration decline in sexual behavior. For instance, previous sexual experience, repeated exposure to sexual stimulation, and a highly stimulating sexual partner will all slow down the postcastration decrease in sexual behavior.

In most species, it is possible to restore male sexual behavior by treating castrated males for several weeks with testosterone, the major testicular hormone which is also responsible for the production of male gametes. This effect is dose dependent up to a plateau at which male sexual behavior reaches its precastration level (Figure 3). Larger quantities of testosterone will have no additional effect on male sexual behavior. The normal blood concentration of testosterone in a healthy male is always above this threshold. This explains why in most studies authors found no relationship between blood testosterone concentrations and sexual behavior. As demonstrated in laboratory rodents, genetic variation in the sensitivity to testosterone may explain part of the variability in the response. In some species, the role of testosterone is more subtle. For example, in the red-sided garter snake, the expression of sexual behavior is triggered by an increase in temperature but it depends on the presence of testosterone during the previous summer.

In the 1970s and the 1980s, scientists discovered that testosterone was not always directly active and that its

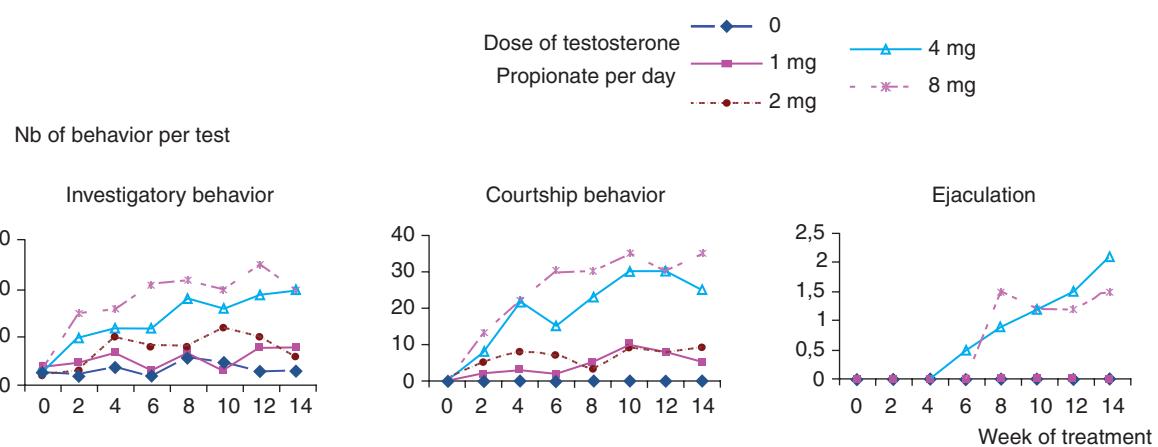

Figure 3 The effect of different doses of testosterone propionate on ram mating behaviors. The frequency of display of different behaviors increases with dose and duration of testosterone up to a plateau reached after 10 weeks at 4 and 8 mg day⁻¹. The testosterone threshold is lowest for investigatory behavior and highest for copulatory behavior. Adapted from D'Occhio MJ and Brooks DE (1982) Threshold of plasma testosterone required for normal mating activity in male sheep. *Hormones and Behavior* 16: 383–394.

action depended on prior conversion to biologically active metabolites in the target tissue. In general, 5α -dihydrotestosterone (DHT) is the active metabolite in the reproductive tract, whereas in the central nervous system (CNS) the active metabolite is 17β -estradiol. Thus, in the male rat and in the ram, 17β -estradiol is the active metabolite that induces male sexual behavior. However, in rat, some 5α -DHT is required to maintain penile sensitivity. In mice, 5α -DHT induces sexual behavior in some strains but not in others. In other species, the active metabolite depends on patterns of behavior. In the ring dove, courtship is composed of a bowing display, followed by chasing and nest soliciting. The first two behaviors are androgen dependent while nest-soliciting behavior is estrogen dependent.

In all cases, it is important to remember that hormones do not really trigger the onset of behavior but increase the likelihood that it will be expressed in presence of the appropriate sexual stimulus.

Females

As in males, ablation of gonads in females prevents the expression of sexual behavior. However whereas in the male, sexual activity can be displayed continuously during the breeding season, in most female mammals, the

expression of sexual behavior also called ‘estrous behavior,’ is restricted to a brief period around ovulation. In most species, ovulation is triggered by an increase in estradiol secretion by the ovary. This hormone is also important for the induction of estrous behavior. For a long time, apes and humans were thought to be exceptions because females may copulate at all times. Further studies have shown, however, that initiation of female sexual activity is more frequent just before ovulation in apes and humans.

In species like the cat, the pig, and the Japanese quail, exposure to estradiol alone is enough to induce estrous behavior. However, in many species, the behavior induced by estradiol alone is incomplete and castrated females need further exposure to progesterone, another ovarian hormone to present a behavior similar to that of an intact female. The exact time at which progesterone must be present differs among the species. In rodents that have short ovulatory cycles of 4 or 5 days, progesterone is required after a period of estradiol priming. In contrast, in sheep that have an estrous cycle of 17 days, estrous behavior is usually displayed only if the female has been exposed to progesterone for several days before the pre-ovulatory rise in estradiol (**Figure 4**). The quantity of estradiol needed differs between species ($0.5 \mu\text{g kg}^{-1}$ in sheep, $20 \mu\text{g kg}^{-1}$ in rat) but is always 100 times lower

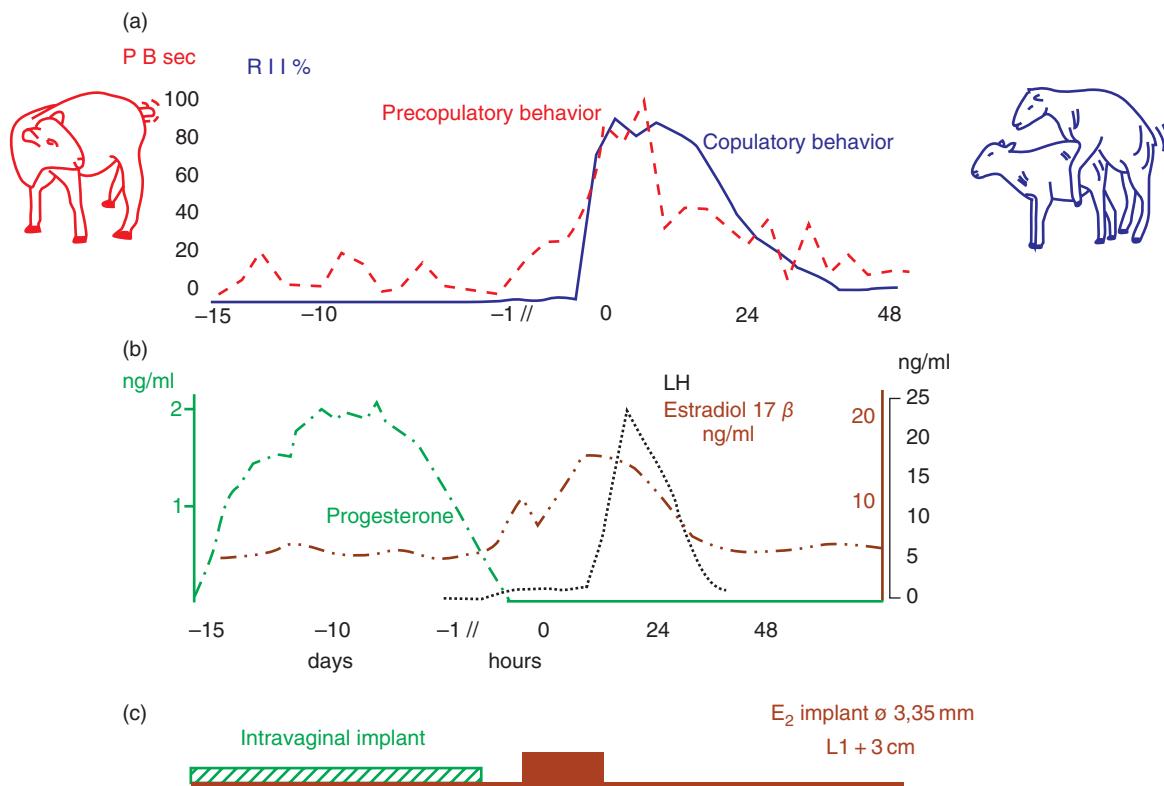

Figure 4 Behavioral (a) and endocrine (b) changes during estrus in intact ewes or ewes ovariectomized and treated with progesterone and estradiol (c). The intensity of precopulatory behavior (PB) estimated by the time ewes spent in contact with the ram in a choice test, is high for approximately 12 h. Copulatory behavior, measured as the percentage of male approaches that produce immobilization in the females (receptivity index (RI)), appears suddenly 8–10 h after estradiol increases and lasts for 24–26 h.

than the quantity of progesterone needed. Interestingly, the same type of estradiol action exists in the parthenogenetic desert-grassland whiptail lizard which contains only females that reproduce alone without males and, in which, female sexual behavior is expressed when the female is ready to ovulate but male sexual behavior is expressed at other times.

In most mammals, the progesterone produced after ovulation and during pregnancy also has an inhibitory action on sexual behavior.

In both males and females, the expression of sexual behavior can also be modulated by a number of peptides, the main ones being the gonadotropin-releasing hormone (GnRH) that also triggers ovulation and oxytocin, involved in parturition, lactation, and bonding with the sexual partner or the offspring. In amphibians, vasotocin has an important stimulatory role for sexual behavior.

Sexual Differentiation of Sexual Behavior

The type of sexual behavior expressed by males and females is generally quite different although in some species such as cattle or goats, male-pattern behavior can be part of normal estrous behavior. By treating females with androgen, it is possible in most species to induce the expression of part of the male repertoire of sexual behavior. But except in a few species, such as the ferret, it is very difficult to induce female patterns of sexual behavior in males.

Experiments in rodents have shown that differentiation in the ability to express male- or female-type sexual behavior is determined by the pattern and type of exposure to reproductive steroids in prenatal and neonatal life. If male rats are castrated at birth, as adults they can exhibit female sexual behavior following appropriate steroid treatment; they also have a reduced ability to express male sexual behavior. On the contrary, if testosterone is given to female rats between birth and day 10, the animals in adulthood will express male sexual behavior but not female sexual behavior. The testosterone, normally secreted by the testes of the male fetus or neonate, is said to have masculinized and defeminized the brain, both of which are distinct processes. An androgenized female rat will prefer an estrous female as a partner, whereas a male castrated during the critical period will prefer a male partner. This organizational action of the reproductive steroid hormones applies to most mammals although the time of the critical period and the degree of differentiation differs among species. For example, estradiol given in adulthood to male pigs, castrated at any time up to puberty, will retain the ability to express the immobile stance typical of female pigs in estrus. In this species, the critical period for brain sexualization extends to well after birth but the basic mechanism remains the same. The same phenomenon exists in birds but the deprivation

of hormones directs them to a male phenotype. In humans, sexual differentiation of the genital tract and the secondary sexual characteristics are well established but there is limited evidence showing that early exposure to reproductive steroid hormones has any effect on patterns of motor behavior during sexual activity or on the type of sexual partner that is preferred.

Sites and Mechanisms of Hormonal Action

Steroids can affect sexual behavior in acting directly on the CNS or indirectly by their action on peripheral target tissues.

Peripheral targets

Many of the visual, acoustic, and chemical signals involved in sexual behavior are steroid dependent. The bright color of sexually active male fish or birds or the colored sexual skin in monkeys are steroid dependent as also are the odor of the elephant in musth and the odor of the rat in estrus. In many cases, the sensitivity to the signals emitted by the partner is also steroid dependent. In the rat, ejaculation depends on the repeated stimulation of the penis which is covered by small spines. The density of spines on the penis is dependent on 5α -DHT and this explains why treatment of castrated male rats with only estradiol is not sufficient to restore complete sexual behavior. Androgens are also necessary for the correct development of the skeletal and smooth muscles specifically involved in sexual behavior, for example, the bulbocavernosus muscle in the penis.

Central targets

Steroids act on the CNS by first binding to specific receptors. Studies in mammals, birds, and reptiles have all found steroid-binding sites in the same areas: the preoptic-hypothalamic continuum, limbic structures such as the amygdala and the septum, and some mesencephalic structures. Experiments with localized lesion or the implantation of microquantities of crystalline steroids have shown that in all species studied, the medial preoptic area and the ventromedial hypothalamus are the most important targets of steroid action, respectively, for male and female sexual behavior. Steroids exert their action through the local modulation of the concentrations of neurotransmitters or neuromodulators by altering their concentration, turnover, or activity. Most neurotransmitters have been implicated in the central mechanisms that determine sexual behavior, but the precise action of sex steroids depends on the type of receptor, gender, endocrine conditions, and the particular type of behavior. Dopamine, for example, is important for the reward value of sexual behavior and is generally considered as stimulatory for sexual behavior, but in females its effect

may be either stimulatory or inhibitory depending on estradiol status and the phase of the mating sequence.

The CNS is also the site of the early organizational actions of gonadal steroids but the precise sites and mechanisms involved remain unclear. During this period, gonadal steroids have been shown to change the number and size of neurons, the density of synaptic connections, and the concentration of neurotransmitters in specific areas of the CNS, resulting, for example, in larger sexually differentiated nuclei in the hypothalamus of the male rat. The relationship between these anatomical changes and the patterns of sexual behavior induced by early steroid treatment still remain unclear despite some claims that structures implicated in homosexual behavior have been identified.

Mating Systems

In a species, the chances of an individual participating in reproduction are rarely identical. This is a direct result of competition among individuals of the same sex for access to partners and to the choice of partners. In most species, males compete and females choose. Together with the amount of parental care required and other social and ecological constraints, these phenomena lead to distinct mating systems across species, even among closely related ones. In addition, several types of mating systems are sometimes observed in the same species.

Monogamy

There are different definitions of monogamy. Here we consider an individual as monogamous if he/she mates with only one partner. This mating system is the rule in 90% of bird species but it is rare among mammals where its incidence is only 3%. It is especially common in species where all females are fertile at the same time or where the help of the male is needed to rear the offspring. It can be permanent – the partners forming a couple that lasts for life as in the snow bunting and in gibbons where males defend access to their territory and partner against other males. In other species, monogamy lasts for only one breeding period. Recent studies using DNA analysis have shown that many species considered as monogamous are not so exclusive; a significant proportion of the offspring results from extra-pair matings.

Polygamy

A system is said to be polygamous when an individual mates with more than one partner. ‘Polygyny’ is the term that describes a system in which the male has multiple partners, whereas ‘polyandry’ describes a system in which the female has multiple partners.

Polygyny

This is the most common system in mammals. Males monopolize permanently or temporarily several females grouped in a harem and prevent approaches by other males using aggressive behaviors. This is the case in bighorn sheep, gorillas, and bats. Sometimes, males do not defend the females themselves but the resources that females need to feed and rear their young. This is the case in cichlid fish, in the pipit, and the topi. In some species, the territory defended is a display area called a ‘lek’ from where females can choose their partner. This is observed in the black grouse, the hammer-headed bat, and the Uganda kob. In other species such as the Belding ground squirrel and the wood frog, receptive females are widely spread or they are all sexually receptive at the same time. Males compete to be the first one to mate; it is a mating system known as ‘scramble competition polygyny’.

In polygynous species, sexual dimorphism is very marked. The males are usually much bigger than females. Polygynous males also have larger testes than monogamous males, allowing greater sperm competition.

Polyandry

Polyandrous mating systems are very rare. One example is the Galapagos hawk where one female mates for several breeding seasons with up to eight males. Another example is the sand piper. In this species, the female produces a clutch of only four eggs and it has been suggested that polyandry allows the female to overcome this limitation.

Multimale multifemale groups

In this mating system, both males and females mate with multiple partners. This is reported in macaques, chimpanzees, domestic sheep, and some carnivores such as hyenas.

Alternative Breeding Tactics

Individuals excluded from reproduction by stronger competitors in the dominant mating system of the species may use alternative tactics to participate in reproduction. This is the case for several species of fishes. One way to achieve it is to look like and behave like the partner of the other sex. In the Mozambique tilapia, for example, the dominant male (also named the ‘bourgeois’ male) defends his territory and spawning pits. The subordinate male or ‘sneaker’ male is much smaller than the dominant male and behaves like a female enabling him to approach the nest and release his sperm. Another tactic is to stay close to the dominant male to take advantage of the fact that the dominant male cannot defend his territory and mate at the same time. This is the case in bighorn sheep, elephant seals, and green tree frogs. Subordinate males may also help the dominant male either to defend the territory or to take care of the eggs. In the rock blenny, the larger male, who is often the oldest, defends the nest with the help of smaller satellite males;

since the latter have access to the nest, they can occasionally fertilize eggs. These alternative tactics can be fixed for life, sequential or reversible depending on ecological conditions and the size of the population.

The sociosexual interactions in these mating systems can in turn affect the endocrinology of reproduction and, as a consequence, mating behavior. For example, in many species exposure to an active male stimulates ovarian cycles in the female hastening the onset of puberty or the breeding season. The influence can also be inhibitory as in an overcrowded group of mice or a marmoset family.

Conclusion

Mating is essential for the survival of species that reproduce sexually which is the case in most animal species. It is under tight hormonal control, which has been conserved through evolution. Furthermore, because the chance of participation is not identical among individuals, mating is also a major factor in species evolution. Through this uneven participation, the genotype of species can evolve. The fine-tuning of when, where, and with whom mating occurs is in turn modulated by the interactions between sexual partners themselves that modulate the endocrinology and behavior of the partners.

Glossary

Beacon – A conspicuous object that stands directly at the final goal location or at an itinerary reorientation point (transitory goal) along the route to the final goal.

Egocentric (or autocentric) – This applies to a place coding expressed in a frame of reference that is bound to the animal's current position, usually, but not necessarily, in terms of polar coordinates (i.e., direction and distance). The reference direction is then provided by the animal's body axis.

Exocentric (or allocentric) – This applies to a place coding expressed in an environment-bound frame of reference, usually as a content-addressable eidetic memory by which an animal can remember the location of a particular place it previously visited in the form of the image that can be perceived from this place, rather than in the form of Cartesian or polar coordinates.

Gradient – A vector indicating the direction in which a given parameter, continuously varying in space, varies with the maximal magnitude and the value of this maximal magnitude. The global area where this vector is constant or varies smoothly is referred to as a gradient field, and the local value of the parameter in question corresponds to the field potential.

Homing – This applies to a navigation process by which an animal returns to its home or some other specific goal (e.g., nest, burrow, or loft) as fast and straight as possible.

Landmark – A conspicuous object constituting an elementary component of an environment-bound frame of reference. Contrary to a beacon, it does not stand directly at a goal location.

Location-based information – A static, site-dependent information provided by the apparent configuration of the landmarks as perceived from the current place.

Route-based information – A dynamic, site-independent information provided by the kinesthetic systems and/or the optical flow about the movements performed.

orientation questions such as: In which direction should I move? Should I turn left or right? What is the shortest path to my home? As this type of questions certainly emerged early in life history, the ways animals nowadays orient themselves in their environment have evolved for an extremely long time in parallel in different taxa. *Sensu stricto*, orientation is just an angle measured with respect to a reference direction. Body orientation can be expressed relatively to the home or the previous movement direction, as well as to gravity, the geomagnetic field, or to some cardinal direction. The position of an animal in space is therefore fully defined by both its location (that is, the place it occupies) and the orientation of its body in the vertical and horizontal planes. For the sake of simplicity, we consider here only movements in a two-dimensional space, so that an animal's position is specified by two Cartesian coordinates and one single orientation value. Orientation behaviors then correspond simply to the behaviors that control the body orientation during movement so as to reach some specific goal.

There is a large diversity of orientation behaviors. The simplest ones involve elementary orientation mechanisms. They consist of getting-there procedures, which mainly specify the motor actions to perform in response to internal and/or external stimuli. Classical examples are provided by bacteria reaching high-nutrient-concentration places, first-year migratory birds reaching their wintering areas based on genetically coded vectorial information, or male moths moving upstream female-emitted pheromone plumes. Others, referred to as navigation behaviors, are more complex as they require some spatial representation. They are based on knowing-where processes, which enable animals to memorize the locations of their goals by using location-based or route-based information (see below). Hence, elementary orientation mechanisms make it possible to reach a new, unknown goal, whereas navigation processes are used to return to known, memorized goals. Although these two types of orientation behavior seem to be fundamentally different, it should be kept in mind that, as evolution is based on tinkering rather than on engineering, numerous animal species evolve original orientation solutions that in some way mix getting-there and knowing-where components.

Contrary to the satellite-based global positioning system (GPS), which now enables human beings to navigate worldwide with high accuracy levels, animal navigation systems are characterized by some working

Introduction

The behavior of most animals, at least during the early stages of their life, involves some movement of their body through the environment, and therefore results in

scale versus accuracy trade-off: those working at a large scale make it possible to only reach a more or less large area surrounding the goal location, whereas those that make it possible to pinpoint the goal can work only at a short scale, when the animal is relatively close to it. Consequently, animals that navigate over long distances have to successively rely on different, spatially nested navigation processes. For example, consider an albatross coming back to its nest after having foraged for a while (some several thousands of kilometers) at sea. It will have to rely on large-scale navigational processes through unfamiliar environment (the open ocean) until it can see its familiar breeding area (a specific island), then to shift toward a medium-scale, more accurate, navigational process to reach its nest area (a hillside or a cliff), and finally to shift toward a particularly accurate, small-scale navigation process to pinpoint the nest location. For numerous species that do not exhibit such very large movements, at least two pertinent scales – small and medium – have to be considered.

Orientation and navigation processes are fed by various sources of information. Environmental information is provided either continuously as stimuli smoothly varying in space (gradient fields) or discretely as punctual objects (beacons and landmarks). In contrast, other navigational systems, such as path integration, provide a vectorial coding of the goal location based on site-independent information. Once these various possibilities have been examined separately, it will be shown how they can be conceptually unified in a consistent theoretical framework.

Orientating in Physical or Chemical Gradient Fields

Numerous organisms and cells are able to orient themselves in a stimulation gradient field, that is, an environment presenting a physical or chemical factor to which they are sensitive and whose intensity varies more or less monotonically in space. Two types of elementary orientation mechanisms have been identified: taxis and differential-klino (DK) kinesis (other forms of kineses are space-use mechanisms not involved in spatial orientation). Taxis concerns species that can directly sense the gradient direction, for example, by comparing the values of the field potential (i.e., the stimulus intensity) measured by several accurate receptors distributed on the whole body. In contrast, DK kinesis concerns species that orientate indirectly with respect to the gradient direction (i.e., without sensing it) by controlling their local path sinuosity as a function of the variations of field potential perceived during

movement: a movement in the wrong direction, perceived as a decrease in the field potential (assuming an attractive stimulus), will lead the animal to locally lower the persistence in moving in that direction, and vice versa. This sinuosity regulation can take several forms. Bacteria orientating in a chemical gradient field rely on the most basic form: at each step, they choose a moving direction at random, and then move a distance whose magnitude is positively related with the rate of change in chemical concentration perceived. This simple trial-and-error mechanism enables bacteria to efficiently reach the areas presenting the highest concentration of some useful nutrient. It is usually misleadingly referred to as ‘chemotaxis.’

An interesting extension of this type of mechanism applies to animals, such as homing pigeons, procelariiform seabirds, and sea turtles, which are able to home through large-scale unfamiliar environments, presumably using two (or more) intersecting gradient fields. It might simply consist in locally decreasing or increasing the homing-path sinuosity depending on whether the current field potentials become closer to or further from the values that have been memorized at home. In this context, the memory of the goal location in terms of field potentials corresponds to the only knowing-where component in this otherwise getting-there-orientation process. It is usually assumed, however, that most species that have to home through large unfamiliar environments rely on a more sophisticated process involving additional knowing-where components. Indeed, they should, when moving around their home, memorize four key parameters enabling them to map the gradient fields (assumed to be more or less regular over large spatial scales beyond familiar areas): the two gradient directions with respect to a biological compass and the two gradient strengths. They may then compute a homing component for each gradient field, whose vectorial combination would enable them to infer the home direction with respect to their compass. Several biological compasses have been identified in birds (and other taxa such as hymenoptera): birds are able to learn the apparent movement of the sun azimuth (and associated changes in the skylight polarization pattern) with respect to an internal clock, as well as the rotation center of the star pattern, and so can use a sun compass by day and a celestial compass by night. They also rely on a compass based on the inclination of the geomagnetic field when the sky is overcast. In contrast, the nature of the gradient fields used to assess the current and home locations is still subject to debate. It may involve some geomagnetic parameters, such as the total intensity or the inclination, and the relative proportion of some atmospheric gas traces, which may be estimated by the olfactory system. Sea turtles may use a similar gradient map and compass navigation system to migrate between their foraging and breeding areas.

Place (or Eidetic) Navigation

At the other end of the scales, place navigation is a process that enables an animal to pinpoint a (hidden) goal location using the spatial layout of the nearby surrounding landmarks: the animal will return to this place by comparing the apparent landmark configuration memorized from the goal with the one perceived from its current location. The landmarks hence provide the basis for an exocentric, site-dependent representation of both the goal location and the animal's current location. Obviously, only landmarks that are sufficiently close to be submitted to a detectable apparent movement when the animal is moving are useful to build such representations. Indeed, if remote landmarks can provide directional cues, that is, serve as a kind of compass, they cannot provide reliable locational cues because their apparent configuration remains quite similar, whatever the animal's location. Consequently, close goal locations may be memorized, independently from each other, using a common set of landmarks, but distant goal locations have to be memorized each with respect to a specific set of nearby landmarks. It is also worth noting that only coarse-grain objects, which outline the geometric shape of the environment, should act as landmarks. In turn, objects generating high spatial frequencies should be filtered out because they provide unreliable spatial information as their locations are potentially fleeting. This filtering out is also likely to dramatically reduce the cognitive burden that bears on the exocentric localization system.

The place-navigation process used by mammals appears very flexible, notably thanks to some limbic neurons – hippocampal place cells and postsubiculum head-direction cells – that encode the animal's position (i.e., both location and orientation) with respect to the surrounding landmarks. After an exploratory phase, during which the animal learns how the apparent landmark configuration is locally altered when it moves around by jointly processing location-based information and route-based information, any place (including the goal) will be given an exocentric, content-addressable representation. Reaching the goal then involves a double change in frame of reference, from egocentric sensory inputs through exocentric localization and navigation computation to egocentric motor outputs. Birds appear to rely on a similar place-navigation system. Both mammals and birds have been shown to pay more attention to the global geometric shape of the environment, as provided by the whole landmark configuration, than to the individual characteristics of landmarks that can be used to identify them. A major difference, however, comes from that birds can use a sun- or magnetic-compass-based reference direction, whereas mammals have to extract a site-dependent reference direction by processing landmark-

based information. The ways other vertebrate taxa perform place navigation remain poorly known.

In turn, hymenoptera (bees, wasps, and ants) rely on a simpler but more rigid navigation process, which short-cuts the twofold change in frame of reference. They are indeed assumed to memorize the goal location by storing the bearings and angular sizes of landmarks in a (sun or magnetic) compass-oriented snapshot taken at the goal. Although it constitutes an exocentric, landmark-based representation of the goal location, such a snapshot is just a low-resolution, compass-referenced copy of the egocentric view (retinal image) perceived from the goal. Hymenoptera can then return to the goal by moving so as to progressively reduce the discrepancy, in terms of retinotopic coordinates, between the current retinal image and the memorized snapshot. As their image-matching process works egocentrically based on landmarks identified from their individual characteristics, hymenoptera have to head in the same compass-based direction as the one used when memorizing the goal location as a snapshot to be able to solve the navigational task, and the global geometric shape of the environment seems to play only a secondary role. Although much less studied, other insect species may process landmark-based information in a more or less similar way.

Path Integration

Although it has been studied mainly in mammals and insects, path integration is a site-independent process used by numerous other taxa such as birds and spiders. It enables an animal to build up an egocentric vectorial representation, in terms of direction and distance, of its starting point. (Human navigators rely on a similar system, called 'dead reckoning,' but the frame of reference is reversed: the boat location is expressed exocentrically with respect to the starting harbor and a compass-based reference direction.) When moving, the animal must therefore recurrently update the goal-pointing vector by processing route-based information, that is, dynamic information collected *en route* about its changes of direction (rotations) and changes of location (translations). The rules used by an animal to combine such rotational and translational information, in order to infer the relative movement of its hidden starting point by using information about its own movement, are formally similar to those specifying the apparent movement of a fixed conspicuous object (optical flow), but work in the reverse way. As a result, a simple rotation of the animal on the spot leads to simple counterrotation of the inferred goal direction, whereas the direction and distance to the goal vary interdependently during an animal's translation: the change in the goal direction (inferred motion parallax) is proportional to the sine of the goal direction and inversely

proportional to the distance, which itself decreases linearly with the cosine of the goal direction. Inferring the apparent movement of a goal when performing a naturally curvilinear movement, in which rotations and translations occur simultaneously, is therefore a very complex task. For this reason, it is usually admitted that only a single goal location – the starting point of the path – can be memorized using path integration, or possibly two goal locations in the simplest case of an animal shuttling back and forth between them (the inferred movement parallax is then null). Memorizing several goal locations simultaneously would require the concurrent use of several independent path integrators, but this possibility has not yet been demonstrated.

As it involves a recurrent updating of the vectorial coding of the goal location, path integration is a process prone to accumulate random measure errors, and so generates increasing inaccuracy in the memorized goal location during large-scale movements. It is therefore useful only to reach an area surrounding the goal. Afterward, the animal will have to shift to place navigation to pinpoint the exact goal location. However, it has been shown that path integration is relatively insensitive to errors occurring in the estimation of translations, which therefore need only to be roughly measured by kinesthetic systems or possibly by the visual system using the self-induced optic flow from the ground. In contrast, the way rotations are measured is of major importance, as it drives the speed with which measure errors accumulate. Hymenoptera, which are able to use a sun (or polarized skylight) and, possibly, a magnetic compass as a reliable external reference direction to estimate their rotations, can rely on path integration to return close to their home after a long sinuous outward foraging path. In contrast, mammals, which acquire this information only internally by means of their vestibular and other kinesthetic systems, can rely on path integration only for relatively short distances. In addition, a systematic error is generated in both mammals and hymenoptera when left and right turns are not balanced in the outward path. The occurrence of this error, which looks like an overestimation of the inferred motion parallax of the goal, indicates that neural computation of path integration is only able to approximate the correct mathematical rules. However, the neural structures involved are not yet well known. In mammals, the caudate nucleus seems to play some role.

Navigation through Large Familiar Areas

The landmark-based processes used by an animal to navigate through large familiar areas (home ranges) remain poorly understood, whereas they are of paramount importance, notably in mammals which often use several homes at the same time but whose path integrator

is not only restricted to a single goal location but also becomes quickly inaccurate when they move long and sinuous paths. It has been hypothesized that mammals and birds, and even bees, might be able to mentally build up a global exocentric frame of reference, based on the whole set of familiar landmarks. Such a global representation of the familiar area, usually referred to as a mosaic map, can be seen as a puzzle made by merging contiguous local exocentric frames of references, each one corresponding to the subset of landmarks that are within perceptual reach from a given location. It would be very useful to perform a generalized form of place navigation, from a current location surrounded by a specific subset of landmarks to a distant goal surrounded by another specific subset of landmarks (**Figure 1**, top). It has never been demonstrated in any species yet, excepted in human beings. This global-mapping ability may be linked to language – natural and mathematical. Indeed, using concepts such as Euclidean space and Cartesian coordinates makes the building of this kind of map relatively easy. Thus, early European navigators mapped the world in relying on dead reckoning (vectorial coding of the boat with respect to the starting harbor) to update their current location on a nautical chart, on which they indicated the locations of the new coasts they encountered as they went along. Because of the tinkering nature of evolutionary processes, it seems more likely that animals have evolved large-scale navigational solutions by mixing getting-there and knowing-where components that were already available rather than by designing fully rational cognitive maps as an engineer would do.

The simplest solution to reach a goal that is beyond perceptual reach involves the learning of purely motor sequences (praxis) or sensorimotor sequences (piloting), for example, walk a given distance toward a given beacon, or up to a given place, then turn left, and so on, or a chemical-trail-following mechanism, as used by numerous ant species. These getting-there procedures can be easily automatized, and so, are routinely used by numerous species (including human beings) when moving along usual itineraries through a familiar area. A simple set of independent and rigid itineraries is of limited use, however, as each one only enables an animal to reach a specific goal from a specific starting point. In turn, if a special status may be given to the choice points corresponding to the crossroads, the animal would progressively learn the global connectivity of a flexible topological network of itineraries, and learn at which neighboring crossroads the various possible roads lead when standing at any given crossroad (**Figure 1**, middle). For this purpose, the animal should, when arriving at a given crossroad, conjointly use an associative memory to link the current landmark configuration it experiences there with the backward direction leading to the crossroad it previously moved through, and a declarative

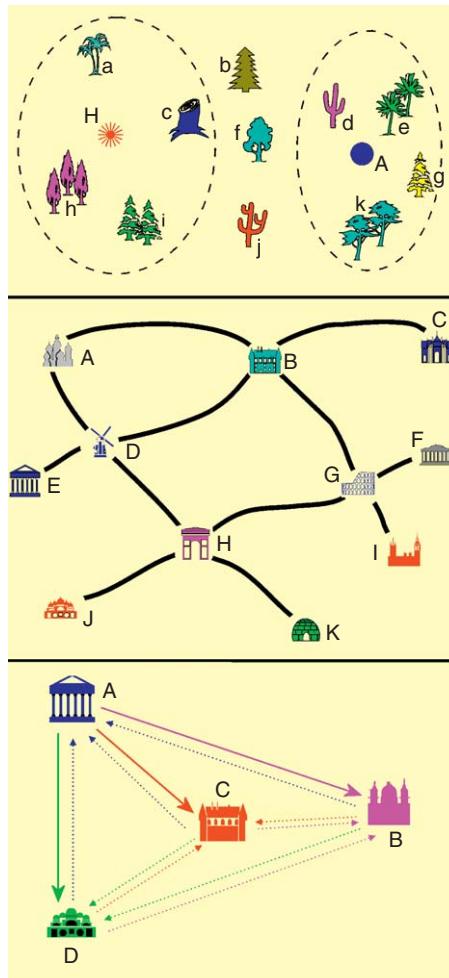

Figure 1 Schematic illustration of three models of navigation within a large familiar area. (Top) Mosaic map. The animal, at place A, knows where it is with respect to the subset of landmarks d, e, g, and k, which it can perceive from its current location, and also knows where its home H is with respect to the subset of landmarks a, c, h, and i, which it perceived from this place. The two dashed ellipses stand for the areas within perceptible reach from the two locations. Classical (i.e., short-scale) place navigation cannot be used to reach home because there is no common landmark shared by the two subsets. However, the animal might be able to determine its home location from a distant location if it has been able to map the whole set of landmarks (a-k) by mentally joining the various subsets perceived from other possible locations based on some common landmarks (e.g., subset of landmarks b, c, d, f, and j, which is assumed to be within perceptual reach at an intermediate location). (Middle) Topological network. Key places correspond to crossroads (and dead ends) occurring along familiar itineraries. For clarity, buildings stand for the subsets of landmarks perceived from these key places. The animal is assumed to learn as to how these various places are connected (e.g., place H is connected to places D, G, J, and K, place E is only connected to place D), and to recall which routes lead to which neighboring places when it perceives the subset of landmarks characterizing the current place. As movement is restricted on a topological network, the cognitive burden should be less heavy than the one involved by a mosaic map. (Bottom) Network of orientation tables. The animal is assumed to mnemonically associate the direction and distance (initially provided by path integration) of any key place with the subsets of landmarks perceived at the other key places (drawn as buildings). The animal is assumed not to know the spatial relationships between the various places (and their respective subsets of landmarks) independently of its own location, however. For instance, as illustrated here, the animal can recall where the places B, C, and D are (in terms of direction and distance) when it is at place A, but not where place B is with respect to place C at this time (this information is potentially present but will be recalled from memory only when the animal perceives the subset of landmarks corresponding to place C). In other terms, the animal is assumed to use a set of local, independent frames of references, each one being anchored to a key place, rather than a global cognitive map.

memory to assess that the current and previous crossroads are closely connected. In this way, it would progressively become able to quickly reach a remote crossroad, by relying on its declarative memory to sort the list of crossroads occurring along the best itinerary and on its

associative memory to recall the road to take at each intermediate crossroad to reach the next one.

Another parsimonious solution consists in associating the vectorial representation of the current starting point, as provided by path integration and assumed to

correspond to an important place, with the local landmark configuration experienced when arriving at another important place. After having explored its environment for a while, the animal may navigate thanks to a network of rudimentary orientation tables, the currently reached one indicating the direction and distance of the others (**Figure 1**, bottom). The animal is therefore not assumed to know the spatial relations between the important places of its home range independently of its current location (a useless possibility that is offered by a cartographic representation of the environment): it is only when the animal is standing in the vicinity of a given important place that the locations of other important places, relatively to the current one, may be recalled from memory. The ability to punctually associate a moving direction to a given landmark configuration has already been demonstrated in several taxa, but we do not yet know to which extent an animal may actually use it in a more global way to navigate through its home range.

Toward a Unified Approach of Orientation and Navigation Processes

Although they appear to be extraordinarily diverse in terms of information sources and mechanisms, all orientation behaviors can be conceptually unified by introducing the notion of generalized gradient field. In this framework, a goal is assumed to act as an attractor because it occupies the center of a radial gradient field, so that the goal direction systematically corresponds to the gradient direction, whatever the animal's location. The goal may by itself generate a radial gradient field by diffusing some light, heat, humidity, sound, or odor around it, but not necessarily. For example, hilltops can be said to attract uphill-moving animals (e.g., some butterfly species which aggregate there) in lying at the center of a radial altitudinal gradient field: the goal can be reached simply by heading in the direction in which the hill slope is maximum. The gradient field may even have no physical or chemical reality at all. For this purpose, we have to consider virtual stimuli, based on spatial memory, in addition to physical and chemical ones, giving birth to cognitive gradient fields corresponding to mental rather than actual buildings.

Consider first the role played by a visual beacon standing at the goal. If this beacon was luminous, the goal would be, by night, placed at the center of an illuminance gradient field which can be used by an animal to head toward it (e.g., an insect attracted by a lighting bulb). With an ordinary beacon in daylight, there is no more such a physical gradient field; however, if the animal has mnemonically associated the beacon

with the goal location, then the goal in some way occupies the center of a gradient field of beacon proximity, and orientating toward it corresponds to a form of taxis (similarly, the hot-and-cold game played by young people can be seen as a social form of DK kinesis). At least, the proximity gradient field generated by a beacon has some sensory, if not physical, reality: the field potential corresponds to the apparent size of the beacon, and the gradient direction can be directly inferred from retinotopic information. A further step is reached when considering an animal relying on place navigation or on path integration. Both provide a goal-pointing vector, and therefore in some way generate a radial proximity gradient field centered on this place, as would do a beacon set there, but which is a purely mental building: in path integration, it is generated by the recurrent updating of the goal location, thanks to route-based information, whereas in place navigation, it is generated by the discrepancy between the apparent landmark configuration currently experienced and the one that has been memorized at the goal location. A similar situation occurs in large-scale navigation based on two intersecting linear physical or chemical gradient fields. The home location has been memorized in the form of two coordinates corresponding to the potentials of these two gradient fields as experienced from this place, as hence can be said to stand at the center of a virtual radial gradient field whose potential corresponds to the discrepancy between the values of the current and memorized potentials of the two intersecting linear gradient fields.

With the generalized gradient field concept, taxes and DK kineses, which initially are elementary orientation mechanisms, can account for the operational working of much more complex navigation processes, possibly involving sophisticated spatial representations. This unified approach hence makes it possible to measure the orientational performance of an animal without having to make strong hypotheses about the actual level of its cognitive abilities, which can be assessed independently by analyzing the cognitive complexity of the task. This is a key point, because cognitive spatial abilities and orientational performances are not necessarily linked: despite having no cognitive abilities bacteria are quite efficient when orienting themselves in chemical gradient fields.

Glossary

Behavioral fever – The raise in body temperature resulting from the active exposure of cold-blooded animals to heat sources.

Disease – An illness affecting humans, animals, or plants, often caused by infection. An infectious disease results from the presence and activity of a microbial agent.

Host compensation – The physiological or behavioral processes by which a diseased host improves on its condition, without getting rid of the parasite or pathogen.

Hypothetico-deductive approach – An approach that consists of proposing a hypothesis leading to predictions, the relevance of which can be tested empirically. Any contradiction between the observed facts and the prediction leads to the hypothesis being rejected.

Infection – The act or process of causing a disease, for a parasite, of getting diseased, for a host. Infection can also be the outcome of a parasite's encounter with and establishment in or on its host, a term sometimes restricted to bacteria and virus.

Parasitic manipulation – The ability, shared by several parasite groups, to modify their hosts' phenotype to their own advantage, often through increasing the probability of transmission from a first host to a second.

Pathogenicity – The ability of an organism (a pathogen) to cause disease in another organism.

Symptom – A phenotypic change that reveals that the individual is ill.

What makes a locust go bathing in the sun, maybe at the cost of increased conspicuousness to predators? Why would an ant climb to the top of vegetation, exposing itself to be swallowed by a sheep, or why would some suicidal cricket jump into the water? What makes a fox so aggressive or a rodent fearless toward a cat? Why would chimpanzees swallow clay or whole leaves of carefully selected plants?

These odd behaviors all have the same ecological and evolutionary framework: host–parasite antagonistic interactions. Reporting on the many cases where the behavior of infected hosts is altered, compared to that of uninfected conspecifics, raises the challenging problem of the

causality of observed phenotypical alterations. Is a more aggressive fox more likely to get infected or is it the infection that makes the fox more aggressive? Is the locust increasing its body temperature through bathing in the sun to stimulate its immune defenses, to slow down the pathogen's proliferation, or, on the contrary, is it the pathogen that manipulates its host to speed up its own proliferation? Is the biting rate of *Plasmodium*-infected mosquito increased as a side effect of energy depletion due to infection, or is it specifically enhanced by the parasite to increase its transmission rate?

These questions must be addressed following a hypothetico-deductive approach to establish who, if any, between the host and the parasite, is benefiting from the change in behavior. The consequences of altered behaviors on both host and parasite fitness, as the target of natural selection, constitute the ultimate causality of this phenomenon (**Table 1**).

A second level of causality must be addressed to understand how, from a mechanistic point of view, the intimate relationship between a parasite and its host modulates the host's behavior. Proximate causality of behavioral changes, therefore, implies unraveling of the molecular, neuronal, and endocrinological pathways used by a parasite to hijack its host's behavior.

Pathogenic Effects on Host Behavior and Host's Compensatory Behaviors

Pathogenic Effects

The pathological influence of parasites on the behavior of their hosts often results from neuroendocrine, nutritional, or organ dysfunction. Indeed, general modes of pathology, such as reduced nutritional levels or damaged sensory organs or muscles, have behavioral consequences such as lethargy or reduction in feeding, courtship, parental care, migration, territorial defense, and so on. Although the array of sickness behaviors experienced by infected animals ranges well beyond the scope of this article, we will start by reviewing a few common examples.

Reduced feeding or decreased activity is often reported in infected animals, from invertebrates to mammals. Reduction in feeding rate is interpreted as a stress-induced alteration in host behavior with no adaptive value either for the host or for the parasite. Decreased activity can result from depleted nutritional levels due to energy uptake by the parasite or reduced assimilation

Table 1 Categories of changes in the behavior of infected hosts (or of hosts exposed to disease risk) compared to uninfected ones, according to their direct consequences on parasite and host fitness

Host fitness	Parasite fitness	Behavioral changes
Decreased	Unchanged	Pathogenic effect
Decreased	Increased (transmission)	Parasite manipulation
Increased	Decreased	Host defense (avoidance or resistance)
Increased	Unchanged	Host compensation

Increase or decrease in parasite or host fitness is estimated relative to an infected host not producing the observed change in behavior.

efficiency (for instance, when the gut mucosa or the liver is damaged). Daily tasks can also be compromised if altered oxygen delivery (due, for instance, to blood parasites or parasites damaging lungs) reduces activity. Both may be linked if activity is decreased below a threshold required to forage for food.

Cognitive tasks may also be affected in parasitized hosts. Reduced learning ability has been reported in infected insects and mammals. Bumble bees naturally or experimentally infected with the trypanosome protozoa *Cryptosporidium bombi* are less able to learn the color of rewarding flowers compared to uninfected foragers. Similarly, the learning performance of bees whose immune system has been challenged nonpathogenically, is significantly impaired. The physiological basis of such trade-offs between immune defense and learning is supposed to lie in the proteins fuelling both functions. Mice infected with the coccidian protozoa *Eimeria vermiformis* display significantly poorer spatial acquisition and retention of the water-maze task. The modulation of opioid systems by parasites may be implicated in the alteration of these cognitive tasks. In humans, cerebral malaria is associated with both short-term and long-term cognitive impairments, in particular, for attention and working memory. Two years after the initial malaria episode, children with cerebral malaria have a 3.67-fold increased risk of cognitive deficit compared with other children. How can infection alter the central nervous system (CNS) to the point where learning, memory, and decision making are compromised, even in animals harboring parasites at sites physically distant from the brain? It has been proposed that the bidirectional connections between the immune system and the nervous system may allow such pathological effects. Not only are a range of behaviors affected by an immune challenge, but conversely, an individual performing an elaborate cognitive task (such as multiple-odor training in mice) or experiencing a stressful situation may be immunosuppressed. Such interactions among immune, endocrine, and neural systems are well established in vertebrates and are highly suspected in invertebrates.

Parasitized animals may also experience impaired antipredator or competitive behavior. This could come as a consequence of reduced stamina, decreased activity, and/or impaired cognitive capacities (such as chemosensation). For instance, birds with a high prevalence of protozoan blood parasites are more vulnerable to predation by hawks than individuals with a low prevalence.

Host Compensation

The depletion of energy and nutrient stores resulting from infection may be compensated for by increased food consumption (but at the expense of other costs associated with foraging activities such as predation) or by selective changes in dietary choice.

One of the best-studied examples of behavioral compensation for depleted endogenous reserves is that of the cestode flatworm *Schistocephalus solidus* in its intermediate host – the three-spined stickleback. Parasitized fish both increase the time spent feeding and change their choice of habitat, while simultaneously reducing their natural aversion to predatory cues. Change in dietary choice can be a more specific behavioral response to unbalanced nutrient depletion. Caterpillars of the lepidopteran *Spodoptera littoralis* infected with an entomopathogenic virus grow and survive better when reared on a protein-rich diet (**Figure 1(a)**). This confirms that resistance to parasite demands greater investment in proteins rather than energy (carbohydrates). Interestingly, infected caterpillars compensate for protein costs associated with immune defense by shifting nutrient selection toward a protein-rich diet (**Figure 1(b)**).

Reduced activity can also be interpreted as a compensatory behavioral response if it is employed by infected individuals to save energy and fuel immune responses. An extreme form of reduced activity is sleep. Both in the human and rodents, sleep is known to be altered in sick individuals. However, recent studies suggest that such behavior could be part of the host defense against infection rather than just a compensatory response to save energy (see below).

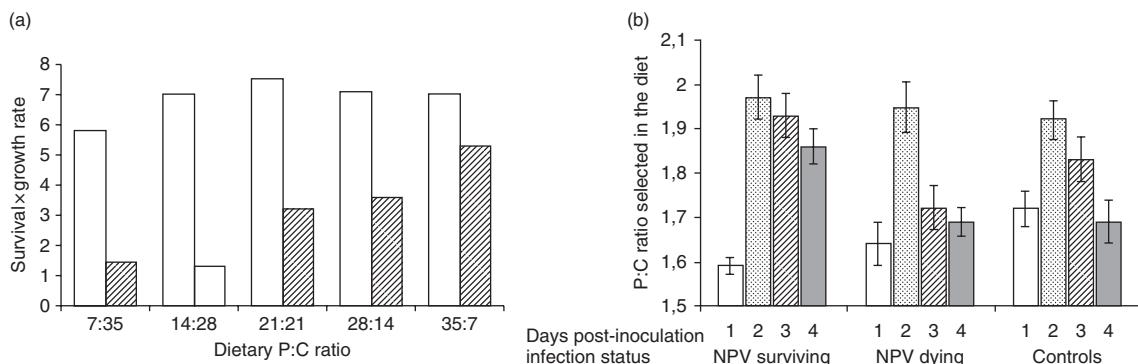

Figure 1 (a) Performance of *Spodoptera littoralis* caterpillars infected with entomopathogenic virus (NPV; dashed bars) or uninfected (control; empty bars), as a function of protein–carbohydrate ratio in their diet. Performance is estimated as a product of growth rate (body mass gain divided by development time) and survival. (b) Diet choice of *Spodoptera littoralis* caterpillars surviving infection with entomopathogenic virus (NPV), dying from infection or not infected (Controls), as a function of time after challenge. Diet choice is expressed as the protein to carbohydrate ratio selected from the two diets offered (P:C ratio: 35:7 and 21:21). A selected P:C ratio of 2:1 corresponds to a random choice.

Host Defense against Infection: Avoidance and Resistance

Several host behavioral traits affect disease risk, such as dietary choice, mating system, group living, and habitat use. Some are, therefore, expected to have evolved not only to optimize life-history strategy, but also to limit the risk or consequences of infection, sometimes under opposing selective forces. Although it may be difficult to demonstrate the adaptiveness of some behavior specifically in response to infection risk, the importance and taxonomic ubiquity of parasite-avoidance behavior should not be underestimated. Indeed, behavioral responses offer a number of advantages over the activation of physiological and cellular defenses. Avoiding infection saves the energy expenditure associated with mounting an immune response (and its side-costs, such as autoimmunity or immunopathology) and/or pathogen development. Some behaviors may also contribute to resistance of the infected host to parasite development or multiplication, prior to, or in combination with, physiological and immune responses. However, the exploration of the molecular and physiological basis of parasite avoidance and resistance behavior is still in its infancy, and only a few studies so far have addressed the molecular or neurophysiological pathways underlying the observed alterations in the behavior of infected hosts.

Foraging and Feeding

Host behavior associated with feeding is a route of transmission for many parasites (especially those of the digestive track), either directly through contaminated food or water or indirectly through infected preys. Consequently, a number of behaviors associated with

foraging for food and dietary choice have evolved to decrease infection risk (avoidance or prophylactic strategies) or to increase host resistance (therapeutic strategies).

For instance, the nematode *Caenorhabditis elegans* can modify its olfactory preference to avoid toxic bacteria. This roundworm lives free in microbe-rich environments in which it feeds on soil microorganisms. Although attracted from a distance by the bacteria *Serratia marcescens* which is part of its diet, the nematode can exhibit immediate physical evasion when it comes into contact with certain strains. The repellent compound is a surfactant secreted in large quantities by some *S. marcescens* strains as a necessary attribute for swarming motility. Physical pathogen avoidance depends on identified chemosensory neurons, and is controlled by unknown G-protein-coupled receptors and others such as Toll-like receptors. Escape is associated with feeding inhibition upon pathogen exposure, a combined behavioral defense involving an insulin-like signaling pathway. In addition, the nematode selectively avoids an odor experienced simultaneously with pathogenic infection, a criterion for associative learning. Aversive olfactory learning is rapid and is highly specific to the pathogenic species to which the worms are exposed. It is mediated by an enhanced serotonin signaling in the ADF sensory neurons. This combined behavioral strategy of defense against pathogenic bacteria in *C. elegans* seems to be part of a more general response to stress.

Infection can also alter the taste of a host and shift its food selection in order to increase the consumption of compounds that are toxic to the parasite it harbors. The ingestion of specific plant products by individuals exposed to infection risk or already parasitized is akin to self-medication. The use by chimpanzees of plants with antibiotic, antiviral, or worming properties (either

mechanically or biochemically) is interpreted as a form of self-medication. More generally, fighting parasites using plants, bark, or soil with pharmacological activity has been suspected in all major lineages of primates and several other species of nonhuman vertebrates for more than 30 years. However, experimental tests are still needed to show that these self-medication behaviors decrease infection rate or increase recovery; and interpreting the ingestion of stems, leaves, and roots with stimulating, antihelminthic, or antibiotic properties may still be controversial. Yet, its repeated evolution suggests that animals gained adaptive defense against parasitism through the evolution of innate dietary behaviors or by individual learning or cultural transmission in dietary choice. For instance, the absorption of small quantities of bitter substances is observed in several mammal species despite their aversion to it: it seems that innate 'repeat sampling' behavior of unpleasant plant substances has evolved in connection with their prophylactic properties relative to protozoan (plasmodium, amebae, etc.) and other parasites. When mice have a choice between drinking plain water or a chloroquine solution, they include 10–40% of the latter solution in their total fluid intake over 24 h. Mice infected by *Plasmodium berghei* (the specific agent of murine malaria) thereby develop less intense parasitemia and have a higher survival rate as long as they have access to chloroquine.

Sequestering phytochemicals from the diet is known as a strategy in phytophagous insects to repel predators. However, some phytochemicals also provide a biochemical defense against larval endoparasitoids. Caterpillars of the tiger moths *Grammia geneura* and *Estigmene acrea* parasitized by an endoparasitoid specifically increase gustatory responsiveness to pyrrolizidine alkaloids (PA) – a phytochemical toxic to the parasite. Specialist receptor cells (taste cells) of parasitized moths increase their firing rates in response to PA (but not to another deterrent compounds with no protective value against parasite). This specific signaling at phagostimulant cells stimulates feeding upon plants rich in PA in this otherwise generalist phytophagous lepidopteran.

Social Behavior, Mating

Resistance of infected hosts to infection most often relies on individuals changing their behavior as a consequence of their own health status (see sections titled 'Foraging and feeding' and 'Habitat use, hygienic behavior'). However, social behavior can also be implied in avoidance and resistance strategies. In that respect, discrimination of infected individuals is certainly the first mean of avoiding infection, if cues produced by infected conspecifics convey information on infection risk. In particular, recognition of a conspecific may often rely at least partly on chemical signals. Individual odors

that convey cues with regard to infection status can, therefore, provide valuable information mediating social relationships, such as territorial or foraging activities, group living, mate choice, and parental care. For example, rodents use social odors to distinguish between infected and uninfected individuals, displaying aversive responses to individuals infected with a wide range of parasites such as virus, protozoans, nematodes, or ectoparasites. In a choice test, estrous and nonestrous female mice avoid specific odors associated with either an infective or a preinfective male harboring the coccidian protozoan *E. vermiciformis*. The same discriminatory behavior is elicited by males infected with nematodes or virus. Analgesia is often an additional defensive response to the odors of an infected male since its anxiety or stress-associated behavior contributes to a reduced interest and avoidance of parasitized males by females. By contrast, such avoidance and stress-related responses in females are not elicited by castrated males (with low levels of testosterone) nor by physically stressed males. Male mice also face the threat of infection during social interactions involved in mating or during the establishment of social hierarchy. They discriminate against and selectively avoid the odors of other males (infected with the louse *Polyplax serrata* or with the nematode *Heligmosomoides polygyrus*) and of females infected with *H. polygyrus* or with the cestode flatworm *Taenia crassiceps*. Two highly polymorphic gene complexes, the major histocompatibility complex (MHC) and the major urinary proteins (MUPs) provide urinary odor cues that can be used for individual recognition. Changes in immune and endocrine functions induced by parasite seem to affect the production of MHC- and MUP-associated odor cues of parasitized male mice, hence signaling the infection to healthy individuals. Contrasting with studies on mate choice and infection risk in rodents and birds, there is so far no evidence that mate choice in primates acts to decrease the risk of disease transmission. Despite this, a large literature deals with the influence of parasites on mate choice. Females (being usually the choosy sex) may benefit in several ways from discriminating between infected and healthy males. A first direct benefit is, obviously, the avoidance of infection. However, when parasitic infection affects the body condition and stamina of males, females may benefit from discriminating between infected and uninfected males through securing various direct benefits such as larger nuptial gifts and/or increased assistance in parental care. Females may also benefit indirectly by increasing disease resistance in their offspring if resistance is heritable. It has, for instance, been suggested that the preference of female birds for ornamented males results from the fact that only males in good condition can maintain their bright colors or develop an extravagant plumage. More recently, it has been proposed that mating between genetically dissimilar individuals should result

in increased offspring heterozygosity, and, hence, better resistance to parasites and pathogens. Indeed, some studies suggest that genetic compatibility between partners, particularly at key loci such as the MHC, may influence mate choice in vertebrates.

Habitat Use, Hygienic Behavior

Hygienic behavior associated to the choice or maintenance of habitat ranges from simple cleaning to specific enrichment of a nest or burrow with plants having repellent or toxic properties. Rodents and birds bring to their home plants releasing volatiles naturally or after nibbling, thus reducing attraction, repelling, or killing ectoparasites or vectors. Leafcutter ants *Trachymyrmex* use bacteria with antibiotic properties to protect their fungal gardens from the pathogenic fungus, *Escovopsis*. Another famous example of hygienic behavior in social insects is the prospecting and cleaning behavior of *Apis mellifera* worker bees from chambers to remove dead pupae, thereby limiting the propagation of bacteria, virus, or mites.

Habitat choice as a defense against infection can be as simple as reaching the best place to boost the immune system or to limit proliferation of the parasite. In ectotherms, one behavioral response to infection is to choose an orientation in a thermal gradient or to sunlight, and/or a daytime activity, so as to increase body temperature. Such behavioral fever has been reported in several orthopteran species infected with entomopathogenic fungi for instance.

I Sleep Therefore I Fight

In humans, it has recently been suggested that the immune system would alter sleep architecture, when sick, to facilitate the generation of fever. Fever is an adaptive response to infection: it increases survival by potentiating immune response and by hardening the conditions for replication of the pathogen. Reciprocal interactions between immune signaling molecules such as cytokines and brain neurochemical systems have been evidenced in vertebrates. Thanks to these connections, neuromodulation of sleep (in particular, via the serotonergic system) may promote recovery by regulating three components of sleep architecture that allow the generation of fever: increased non-rapid eye movement (NREM) sleep (energy saving), shortened NREM-sleep bout length (reduced heat loss), and decreased REM-sleep amount (shivering permitted).

Parasite Manipulation

In the past 30 years, researchers have looked at the altered behavior shown by infected hosts from a perspective

different from pathological side effects or host compensation. Growing evidence indicates that in several host-parasite systems, the behavioral alterations observed in infected hosts can be viewed as an extension of the parasite's phenotype. Indeed, in several cases such behavioral alterations seem to benefit the parasite at the expense of the host's fitness. Therefore, the ability of parasites to manipulate the behavior of their hosts may have been favored by natural selection. In this line of reasoning, making a fox aggressive is like increasing a mosquito's biting rate, while having an ant firmly grasping the top of a grass exposing itself to be swallowed by a grazing sheep is similar to making an amphipod swimming toward its fish predator. In all cases, the parasite will increase its transmission chances to the next host, either by direct contact (of saliva on the wound), by a zealous vector (biting mosquito or tse-tse fly), or through the suicidal tendencies of its intermediate host. Any specifically altered behavior in the host that increases parasite survival at the expense of the fecundity and/or survival of the host will also qualify as parasitic manipulation.

As for avoidance and resistance behavior, studies exploring of the molecular and physiological basis of parasite manipulation are scarce, although the field is gaining much interest at present. A survey of the studies addressing the molecular or neurophysiological pathways used by parasites to hijack the behavior of their host already reveals some general patterns, such as the involvement of neuromodulators.

Manipulation by Parasites with Direct Transmission

Perhaps one of the most famous examples of behavioral alteration induced by a parasite is the increased aggressiveness of various mammals, such as foxes, skunks, bats, or dogs, infected with the rabies virus. The virus is inoculated via saliva when an infected individual bites a healthy one. During the period of cerebral infection and before the last stage of near paralysis, behavioral changes include signs of agitation and hyperexcitability. Abnormal aggressiveness develops and infected animals lose caution and fear of other animals including humans. The consecutive increased contact opportunities, mainly bites, thus facilitate the transmission of the virus by the saliva of rabid animals.

Among the diversity of ways a parasite can hijack the behavior of its host to facilitate its own transmission, an original strategy has been recently evidenced in a virus infecting the micro-hymenoptera *Leptopilina boulardi*, a parasitoid of *Drosophila* larvae. Infected females of this solitary wasp modify their host-acceptance behavior by increasing their tendency to superparasitize (i.e., to lay eggs in a host that is already parasitized). This behavioral alteration allows for the horizontal transmission of the

virus from infected to uninfected wasp lineage, within the superparasitized *Drosophila* larvae, extending transmission opportunities of the virus beyond vertical transmission.

Manipulated Vectors

Many studies have reported behavioral modifications in dipteran vectors infected with the mature transmissible stage of protozoa. The most frequently reported behavioral change induced by vector-borne parasites is the alteration of probing or biting behavior. The tse-tse fly *Glossina palpalis gambiensis* infected with the protozoa *Trypanosoma brucei brucei*, the sand fly *Lutzomyia longipalpis* infected with the protozoa *Leishmania*, and the mosquito *Anopheles gambiae* infected with the protozoa *Plasmodium falciparum* all increase probing or biting rate. These changes in feeding behavior include an increase in vector biting persistence (refeeding after interruption) and/or in feeding on multiple hosts; they specifically arise when the parasite has become infective to humans. In addition, human beings infected with the *Plasmodium*-stage infective to mosquitoes are more attractive for mosquitoes than those uninfected or individuals infected with asexual noninfective stages. Proteomic studies on mosquito-*Plasmodium* and tse-tse fly-trypanosome models have revealed a differential production in the head of infected vectors of proteins playing a crucial role in metabolism, neurotransmitter synthesis, cell-signaling pathways, and stress response (chaperones).

Manipulated Intermediate Host and Increased Trophic Transmission

Many parasites with complex life cycles bring about behavioral alterations in their intermediate hosts that appear to make them more vulnerable to predation by appropriate final hosts. For instance, crustacean amphipods infected with parasites that complete their life cycle in a fish, such as some trematodes or acanthocephalans, are typically attracted to light whereas uninfected individuals avoid lighted areas. Presumably, this reversed phototaxis makes infected amphipods more exposed to predation by fish. By contrast, amphipods infected with bird acanthocephalans do not show much alteration in their response to light, but show reverse movement in response to the stimulus of gravity. Swimming closer to the surface, they become more vulnerable to predation by waterbirds. Parasites may also directly affect the antipredator behavior of their hosts. For instance, it has been shown that *Gammarus pulex* amphipods infected with the fish thorny-headed worm *Pomphorhynchus tereticollis* become attracted to the odor of fish predators, whereas uninfected individuals are typically repulsed by the same stimulus. Similarly, rodents infected with the protozoa *Toxoplasma gondii* selectively lose their aversion to, and

fear of, cat pheromones. The consecutive increased vulnerability to predation by cat helps the parasite to reach its final host. This fatal attraction is not part of a parasite messing with its host neurophysiology, since infected rodents respond normally to other odors and no other behavior such as learned fear, anxiety-like behavior, or nonaversive learning is affected.

Manipulated Host and Increased Parasite Survival

In a few cases, parasite-induced alterations in host behavior do not contribute to transmission, but increase parasite survival. It is known that some parasites benefit from physically castrating their host, as the resources normally invested in reproduction by the host then remain available for the parasite to grow and mature. Parasites may also induce behavioral castration of their host. The infected hosts then reduce their courting activity or appear less inclined to engage in sexual activity. Such behavior can increase an intermediate host survival by decreasing predation risks associated with sexual activity, a pattern evidenced in the amphipod *G. pulex* infected with fish acanthocephalans. Similarly, *Plasmodium* oocytes (the nontransmissible developmental stage of the parasite) decrease the biting rate of its vector *A. gambiae* by decreasing the mosquito's motivation to bite. This behavior is exactly opposite of the manipulated feeding behavior seen above, when the parasite has reached the transmissible (sporozoite) stage. As biting is a major mortality risk for a mosquito, decreasing biting rate increases the probability of the vector-parasite pair to survive until transmission and manipulation can occur. Some parasites face evenmore risky interactions with their hosts. Parasitoid wasps must overcome the defensive behavior of their host upon stinging. One can imagine how risky approaching and stinging a host as large as a cockroach or a mantid can be for a parasitoid female at least 2 times smaller yet highly motivated to deposit an egg on it. Some fine-tuned strategies have evolved to control the host right from the first touch. The sphecid wasp *Ampulex compressa* first stings its cockroach target in the thorax, rendering the prothoracic legs transiently paralyzed. This leaves the wasp at ease to make a much more precise and time-consuming second sting through the neck into a specific part of the brain. The venom directly injected into the CNS induces a long-lasting lethargic state in the submissive but living cockroach, ready for consumption by the growing wasp larva in the burrow. A fairly astonishing case of behavioral manipulation has been described recently in the braconid wasp (*Glyptapanteles* sp.). This parasitoid wasp uses its caterpillar larvae host as a body-guard protecting the wasp pupae from predator attack. Several examples of parasitic manipulation investigated

so far suggest that the parasite interferes with host endocrine and neuromodulatory functions.

Conclusion

Behavior can be a major cause of the host's susceptibility toward or defense against infection, or of the parasite's transmission. However in most cases, there is an evolutionary trade-off between opposing selective forces upon the host reproductive success and the disease risk or consequences. Such compromise is expected to shape the host's behavior.

Besides, most of the time, it is a component of diversity of host traits that will determine encounters with and susceptibility to parasites, in conjunction with environmental factors and the parasite's transmission strategies. The intimate interaction that characterizes the partnership between host and parasite is multidimensional, in that the outcome of their molecular, cellular, and physiological cross-talks is expressed in several components of the host's life history, including behavior.

Glossary

Culture – Information produced by innovation, acquired from others through social learning (e.g., by observation or imitation), and shared by a group of individuals.

Exogamy – Literally, out-marriage, or marrying out of one's group, however the group is defined: families, villages, clans, tribes, nations, or others.

Homologous traits – Variants of the same trait present in two or more species and derived from the species' common ancestor.

Homoplasious traits – Similarities that evolved independently in distinct species as responses to similar selective pressures.

Human nature – Humankind's psychic unity. The universal biological constraints affecting human thought and behavior and transcending cultural differences.

Philopatry, male – A primate residence/dispersal pattern in which males remain in their natal group for life, whereas females move to another group around puberty.

Polygyny – A mating arrangement in which a male forms stable breeding bonds with two or more females simultaneously.

Sexual promiscuity – A mating arrangement in which both sexes have short-term mating relations with several partners.

Symbolic capacity – The ability to use arbitrary signs (sounds, gestures, pictures, etc.) to represent any aspect of the reality (objects, actions, emotions, concepts, etc.).

cumulative integration of more elementary units over time. As was long remarked by Charles Darwin in his book *The Descent of Man*, "if no organic being excepting man had possessed any mental power, or if his powers had been of a wholly different nature from those of the lower animals, then we should never have been able to convince ourselves that our high faculties had been gradually developed." Comparative behavioral primatology is the single most informative means at our disposal for reconstructing the evolutionary history of human behavior. Other disciplines are certainly helpful for this purpose but they present serious limitations: the paleontological study of fossilized hominids is basically silent about the evolution of most aspects of social behavior and mental processes, while archaeology – the study of the artifactual remains of hominids – does not go back in time far enough.

Homologies and Homoplasies

One basic principle underlying the use of nonhuman primates to probe the origins of human behavior is as old as evolutionary theory itself: a trait may exist under various versions in species that have inherited it from a common ancestor. Variants similar through common descent are called homologies. The concept of homology has been used by generations of comparative anatomists to infer degrees of relatedness between species and, on this basis, to reconstruct their evolutionary tree. Presently, it is used by molecular biologists to reconstruct phylogenies based on deoxyribose nucleic acid (DNA) or amino acid sequences. However, it is also possible to reverse the reasoning and infer homologies from phylogeny. Knowing the phylogeny of a group of species, one may – for any given trait – identify similarities based on common descent and gain insights into past stages in the evolution of the trait. This is particularly useful for reconstructing the evolutionary history of social behavior, which leaves very few traces in fossils. Behavioral homologies were analyzed systematically by ethologists beginning in the 1940s. Ethologists were primarily concerned with the evolution of stereotyped behavioral sequences, such as courtship displays in insects and birds. However, any behavior-related phenomenon – provided it has a genetic basis – may exist in homologous forms in related species, including patterns of social

Human behavior is an all-inclusive and extremely heterogeneous category of phenomena. It includes relatively simple motor patterns such as reflexes, facial expressions, and modes of locomotion; however, it also comprises complex social phenomena like marriage patterns, political alliances, kinship systems, war, and rituals. It is with the evolutionary origins of such higher-order behavioral entities – and with the related methodological and epistemological issues – that we shall be concerned here. It is not immediately obvious that the study of nonhuman primates should have anything to contribute to our understanding of what appear to be uniquely human forms of social behavior. However, as with complexity in general, social complexity results from the

interactions, cognitive abilities, emotions, motivational systems, and developmental processes.

Another basic concept for assessing the origin of human behavior is that of homoplasies. These are inter-specific similarities based on common adaptive function and resulting from similar selective pressures. Functional similarities between the human and other animals which cannot be explained in terms of descent from a common ancestor may be homoplasious. Homoplasies provide information about the ultimate causes responsible for the very origin of a human trait. Indeed, if the adaptive function of a trait observed in a number of different species is well established, it is possible to infer the same initial function for the human form of the trait.

Beyond Homologies and Homoplasies

That said, reconstructing the origins of human behavior involves much more than the straightforward identification of homologous or homoplasious traits. This might be the case when one is concerned with well-circumscribed motor patterns like communicative signals and facial expressions. For example, Jan van Hooff described the separate phylogenetic origins of laughter and smiling from, respectively, the relaxed open-mouth display (or play face) and the silent-bared-teeth display of nonhuman primates. In such a situation, the homologous portion of the expression may be relatively easy to recognize across species – in the same manner, for that matter, that anatomical homologies are recognized.

But owing to the complexity and variability of human behavior, homologous and homoplasious components usually do not reveal themselves so easily. Human behavioral entities such as sexual competition for mates, kin favoritism, conditional reciprocity, intergroup hostility, monogamy, or the sexual division of labor are composite traits that express the interplay of a large number of mental and social processes. Accordingly, the comparison of any human behavioral phenomenon with its primate counterparts typically results in the phenomenon breaking down into a number of components – or building blocks – that have different evolutionary origins. First, some components may have homologous counterparts in other primates – either in our closest relatives exclusively, or in a larger taxonomic fraction of the primate order, and even beyond. Second, some aspects may have homoplasious counterparts in other primates, in which case the similarities are observed in certain species but not in all of those intervening between the human and the species exhibiting the trait. Third, a significant number of components may be neither homologies nor homoplasies, but ancillary consequences – or emerging properties – of other traits merging together, as will be illustrated later on. Fourth – and here lies the single most significant peculiarity of human behavioral evolution – many aspects

of the phenomenon are bound to be cultural innovations and, moreover, innovations that take various forms across groups. Indeed, human behavioral traits are the product of the intricate amalgamation of biological components with cultural innovations over evolutionary time – a process which accounts for the interminable and often acrimonious debates that have marked the evolution of the social sciences over the past centuries

Culture

Culture as a Biological Phenomenon

To better appraise the problem and its solution, it is useful to look at culture from an evolutionary perspective. A basic characteristic of behavior is that it is most often modifiable by learning – the exceptions forming the category of instinctive behaviors. In group-living species, individuals may learn from their own experience on the basis of various associative processes, but they may also learn by observing others, that is, through social learning processes such as observational conditioning, goal emulation, and imitation. The capacity for social learning is the most basic prerequisite for the possession of culture by a species. If a new behavioral sequence is invented by an individual, if it is adopted by other individuals through social learning, and if it generalizes to the whole group, it becomes part of that group's cultural repertoire. Species other than humans have the capacity to copy the innovations of others and hence have cultural repertoires. These are mostly composed of environment-related techniques – for example, termite fishing and nut cracking in chimpanzees – and amount to cultural traditions differing between groups. Social learning is thus basically adaptive: it allows animals to bypass trial-and-error learning and benefit from the inventive capacity, or chance discoveries, of others. Stated otherwise, culture itself is a biological phenomenon.

The Symbolic Step

If culture – as defined earlier – is relatively common in animals, symbolic culture is uniquely human. The evolution of the symbolic capacity in the course of human evolution deeply enriched the basic phenomenon by providing it with an extremely powerful medium. The use of arbitrary symbols – whether they were initially gestural, pictorial, or vocal – to refer to and communicate about objects, techniques, feelings, ideas, intentions, past events, and relations between things considerably widened the domain of what could be learned and transmitted through social learning. The evolution of language – a symbolic form of vocal communication – in the course of human evolution had at least four major consequences on cultural transmission. First, it amplified the repertoire of cultural

innovations to an extraordinary extent. In addition to physical techniques, innovations henceforth included, for example, verbalized ideas and stories. Second, language created a particularly effective medium for the long-term storage of information and its transmission across generations – a medium initially based on oral memory. Third, it greatly accelerated social evolution because symbolically-mediated ideas generate further innovations through associative processes and do so cumulatively, if not exponentially. Fourth, as described below, language considerably amplified cultural differences between groups, setting the stage for a ‘culturalistic’ – or abiological – conception of human behavior.

Culture and Human Nature

The impact of the symbolic capacity on culture is so important that to a majority of social scientists culture is a phenomenon more or less independent of the biological constraints set by human nature. The problem lies in the extent of cultural variation. Culture builds from the vagaries of individual innovations and evolves cumulatively. As a result, social practices are extremely variable both in their form and meaning cross-culturally, so much so that ‘social universals’ are practically absent in the human species – as has been amply documented by anthropology. The concept of marriage, for example, subsumes such a wide array of forms, practices, and beliefs across cultures that, after decades of ethnographic research and theoretical discussion, there is still no unanimity among anthropologists on how to define marriage. One example suffices to illustrate the issue. In some cultures, a sterile woman may marry another woman and have children with her through a male genitor. From then on the sterile woman is considered a man and called father by her children. The accumulation of innumerable such examples over the last century led a majority of social scientists to the view that the extent of cultural variation constituted solid evidence that the influence of human nature on social behavior was necessarily marginal and limited to a few basic drives and emotions. Accordingly, some authors went so far as to treat culture as a superorganic phenomenon that obeyed its own laws, independently of human nature.

The autonomy of culture in relation to human nature is a deceptive appearance. Cultural variation conceals human nature, and very effectively so, but it has not erased nor marginalized it. Human nature is buried beneath thick layers of cultural diversity, and here lies the relevance of the primate data for understanding our origins. Stepping out of human societies and looking at them from the perspective of other primate societies, differences between cultures give way to similarities between them, and our species looks remarkably

homogeneous. It is with the origins of the very content of this homogeneity that comparative primatology is concerned.

Primate Frameworks for the Origins of Human Behavior

The human reproductive system provides a useful example. All aspects of the phenomenon – from marriage type and the exact composition of domestic groups to the sexual division of labor – vary to a considerable extent cross-culturally. Moreover, all aspects are governed by cultural norms and institutionalized. To many social scientists, this implies that the phenomenon has little, if anything, to do with human nature. Primatology, however, belies such a view.

The Human Reproductive System

From a primatological perspective, the human mating system combines two major features: enduring breeding bonds and sexual promiscuity – short-term mating relations with several partners. Stable breeding bonds take the form of monogamous marital unions, or polygynous ones (a man paired simultaneously with two or more women). Polygyny’s mirror system, polyandry, is extremely rare in the human species. The second feature, sexual promiscuity, is practiced either premaritally – in which case it is most often accepted – or postmaritally in which case it is universally disapproved of. Stable breeding bonds and some levels of sexual promiscuity consistently co-occur in all human societies.

Stable breeding bonds appear to be parental partnerships based on a sexual division of labor between the father and the mother. Two major correlates of this view are verified. First, the costs of raising children are disproportionately high in our species owing to mothers feeding slow-maturing offspring well into adolescence. As a result, human mothers must feed more than one child at a time; for example, they may be suckling one child while provisioning two others. Nonhuman primate mothers never have to feed more than one offspring at a time. Second, ethnographical evidence indicate that the father (among other individuals) does alleviate the costs of maternity, principally through provisioning his family. Taken together, the two points are compatible with the view that marital bonds are, in effect, cooperative breeding units. Notwithstanding this, primate studies suggest that the human family did not initially evolve for that purpose. Stable breeding bonds in other primates appear to reflect mating strategies rather than parental strategies – a fact that suggests that the human family was a mating arrangement before it became a parental partnership.

Some theory is needed at this point. Owing to the fact that females do the bulk of parental care in mammals they are physiologically limited in the rates at which they may produce offspring. In contrast, the males' contribution to reproduction is most often limited to insemination, so that males who attempt to maximize the number of females they mate with do increase their reproductive success. For this reason male competition for females is much stronger than female competition for males, and polygyny is the basic principle governing mammalian mating systems, including primates. Notwithstanding this so-called polygyny pressure, males cannot simply do as they wish. Ecological factors such as the abundance and distribution of food impose strong constraints on the spatial distribution of females, hence on the capacity of males to monopolize them. Only in situations in which females forage alone or in small groups is a male in a position to monopolize either a single female – the outcome being some form of monogamy – or more than one female (polygyny). As a result, stable breeding bonds in mammals are best construed as ecologically constrained mating arrangements. Not surprisingly therefore, direct paternal care and parental collaboration are absent in many mammalian species that form stable breeding bonds. Applied to the human case, this reasoning suggests that stable breeding bonds evolved initially as mating arrangements, the latter operating as pre-adaptations for the evolution of paternal care – fathers provisioning their family – when the costs of maternity began to increase in the course of human evolution.

In multimale–multifemale primate groups, males compete aggressively for females within the framework of a dominance hierarchy. However, from the time fathers began to provision their family, the old primate heritage of male rivalry came to encompass new objectives – notably the control of resources valued by mothers. Such a situation was conducive to the formation of new types of social rankings in which a male's position was determined not so much by his strict physical prowess (dominance status) as by his capacity to control or produce valued resources (socioeconomic status). Female interests thus had a major impact on the nature and object of male competition. A closely related phenomenon is that nonhuman primates often compete through the use of coalitions. By allying with others they may overthrow higher-ranking individuals or maintain their position above lower-ranking challengers. The novel human mating system – with its emphasis on the control of resources – afforded males with new means and incentives for alliance formation. Sex and reproduction lie at the heart of human politics because they do so in other primates.

Primate frameworks such as the one adumbrated here are informative about the portion of human nature that we owe to our primate heritage. They shed light on human nature as it was before it got blurred

through the multitude of its cultural expressions. Human mating systems are certainly governed by cultural norms, but all such norms are derived from the same biological foundation, and constrained by it. When trying to make sense of these norms, one can only benefit from knowledge about their common biological basis.

The Incest Taboo

The incest taboo provides another instructive example. All human societies have rules proscribing sexual relations between close relatives. However, beyond the universal proscription of incest between parents and offspring, grandparents and grand-offspring, and between siblings, the types of unions considered incestuous vary extensively across cultures. To a majority of social scientists, the very diversity of incest rules would indicate that the incest taboo is a cultural construct that has nothing to do with human nature. On the other hand, all known primate species also avoid mating with their close kin, a fact that strongly suggests that the human and nonhuman phenomena have a common biological foundation.

An empirically based primatological framework of incest avoidance for human evolution includes the following principles. (1) Nonhuman primates recognize their kin, in the sense that they treat them preferentially. The domain of kin recognition includes the mother (and sometimes the father, depending on the mating system), offspring, siblings, grandparents, grand-offspring, whereas aunts, nieces, and nephews are often part of a grey zone. (2) Nonhuman primates do not recognize genetic relatedness *per se* but recognize its correlates such as high levels of developmental familiarity and, perhaps, physical similarities. (3) Inbreeding among close kin reduces an organism's reproductive success by lowering its fecundity and/or its offspring's chances of survival; incest avoidance is thus adaptive. (4) As a rule, individuals disperse from their birthplace or natal group around puberty – a pattern that considerably limits opportunities for incest. (5) Among sexually mature individuals that reside in the same group, mating is nonetheless avoided among kin that are part of the domain of kin recognition. When sexual interactions between kin do occur, they are performed mostly by immature individuals and in a behaviorally atypical manner. (6) Incest avoidance appears to be mediated mainly through the familiarity correlate of close kinship bonds. In 1891, the sociologist Edward Westermarck described this effect in the human species by noting that persons raised together from childhood developed 'a remarkable absence of erotic feelings' for one another. The so-called 'Westermarck effect' – an expression coined by Robin Fox – is at work in primates in general. (7) Male primates seem less motivated than females to avoid incest. This accords well with the fact that the costs of reproductive failure are higher for a female than for a male. (8) Sexual

avoidance between close kin was clearly documented among homosexual female macaques, indicating that developmental familiarity inhibits both heterosexual and homosexual sexual activity.

In all likelihood, these principles – and many others awaiting investigation – were part of humankind's primate heritage and constituted the universal substrate upon which hominids elaborated symbolically mediated rules about incest avoidance. Thus, the diversity of cultural rules about incest, rather than negating the universal biological foundation of the incest taboo, indicates that hominids built upon a basic feature of human nature and adjusted it to various subsistence economies, marriage practices, kinship systems, and so forth. Implied here, rules and morality – a trademark of human society – originated in the behavioral and social regularities of our primate forebears and later grew in complexity in the symbolic realm.

The Primate Origins of Human Society

Several articles in this encyclopedia describe the animal bases of human behavior in various areas – altruism, cooperation, competition, reproduction, parenting, social cognition, and so forth – and provide, implicitly, general frameworks for characterizing human nature. However, comparative primatology may also serve to enlighten the evolutionary history of human society as a whole. This is a topic that deeply intrigued early philosophers and social scientists and led to highly speculative schemes about the society of the 'primeval ape-man,' before it was abandoned early in the twentieth century following harsh criticisms from more empirically grounded anthropologists. The progress of behavioral primatology in the second-half of the twentieth century provides the needed empirical evidence and allows one to tackle this old question anew. What does characterize human society in relation to all other animal societies, and how did this specific configuration of traits evolve? Bernard Chapais recently proposed a comprehensive model addressing these issues, which is summarized below.

Human Society from a Primatological Perspective

The modal composition of human groups is the community of conjugal families, or multifamily community, a rare form in the animal world which combines two elements: a multimale–multifemale composition (several males and females living together on a long-term basis) and stable breeding bonds (families). Other primate species do form families, or multimale–multifemale groups, but most often the two features do not co-occur in the

same species. Another prominent feature of human social structure is its nested or multilevel dimension. Any multi-family community is an integral part of higher levels of social organization – for example, villages may belong to the same band, bands to the same tribe, and so on. In other primates, in contrast, groups are autonomous entities; chimpanzee communities, for example, are not part of any supracommunity social structure. The ethnographic record indicates that the most basic process binding human groups together is exogamy – literally, marrying out of one's birth group. As emphasized long ago by the anthropologist Claude Lévi-Strauss, marriage is universally a means of alliance formation. Marriage binds the spouses' respective families (in-laws) and creates new kinship bonds between the intermarrying groups – for example, parents have grandchildren living in the group in which their daughter transferred and married. In short, exogamy generates intergroup alliances based on kinship. As far as the evolution of human society is concerned, therefore, understanding the origin of exogamy and between-group alliances – hereafter the exogamy configuration – is the central issue.

Figure 1 portrays the phylogenetic relationships of the human species and of other anthropoid primates. This phylogeny is the likeliest one based on several sets of molecular data. It indicates that the two chimpanzee species (*Pan* genus) are more closely related to humans (*Homo*) than they are to gorillas. Interestingly, on structural grounds the exogamy configuration appears to be the product of the combination of two sets of elements – namely, the basic characteristics of chimpanzee society and a new mating system based on enduring breeding bonds. This view is compatible with the hypothesis that the society of early hominids, immediately after the *Pan-Homo* split, was chimpanzee-like in its broad outline – an assumption supported on phylogenetic, anatomical, and socioecological grounds. Chimpanzees and bonobos form multimale–multifemale groups in which mating is promiscuous, and so did early hominids, presumably. When stable breeding bonds did evolve in the hominid lineage, this produced the modal composition of human groups – the multifamily community – and set the stage for the evolution of a primitive version of the exogamy configuration as is now briefly explained.

Chimpanzees and bonobos are markedly territorial and exhibit male philopatry – males breed in their birth group whereas females emigrate around puberty and breed in other groups. In turn, male philopatry determines the group's genealogical structure: males live with their father, sons, brothers, uncles, and other paternally related kin, but not with their mother's kin. However, although patrilineal kin live together they do not appear to recognize each other on this basis. Mating being promiscuous, paternity is not recognized in any way comparable with maternity recognition, which is based

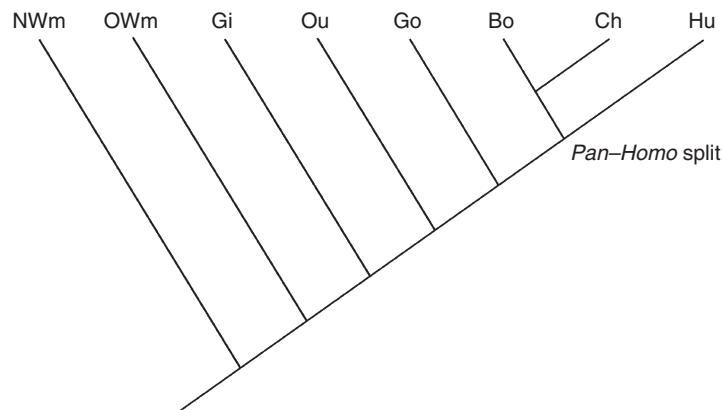

Figure 1 Phylogeny of anthropoid primates, one of the two suborders of primates. (Prosimians form the other suborder.) A phylogeny depicts the evolutionary relationships among species or larger taxonomic units such as genera or families. Intersections between two lines indicate speciation events – the divergence of two daughter species from a common ancestor. Hu: Humans. Ch: Chimpanzees. Bo: Bonobos. Go: Gorillas. Ou: Orangutans. Gi: Gibbons. OWm: Old World monkeys, which include cercopithecines (macaques, guenons, and other species) and colobines (guerezas, langurs, and others). NWm: New World monkeys (howlers, spider monkeys, and other species). The *Pan-Homo* split denotes the speciation that led to the separate evolution of the hominid (or hominin) lineage comprising the genera *Homo* and *Australopithecus* among others, and the chimpanzee lineage (*Pan*) comprising common chimpanzees and bonobos. The *Pan-Homo* split is dated between 6 and 7 million years.

on long-term, intimate bonds between mothers and offspring. If the father is not recognized, the father's kin cannot be either. Thus, chimpanzees and bonobos have a group-wide patrilineal kinship structure, but a socially silent one, and so would have early hominids. Notwithstanding this, chimpanzees and bonobos recognize their mother and their maternal siblings.

Stable Breeding Bonds as the Key to Human Society

Whatever their exact origins, stable breeding bonds had far-reaching consequences on human society. First, their integration to the pre-existent pattern of female transfer created a primitive form of exogamy. Indeed, from then on a female still moved into another group as before, but instead of mating promiscuously in it she formed a stable breeding bond. She was thus 'marrying-out' of her birth group and practicing a behavioral form of exogamy – one deprived of any exchange dimension or between-group agreement. According to this view, marital unions and the widespread practice of women-exchange by men would be cultural elaborations derived from this basic pattern. A further consequence of stable breeding bonds is that they revealed the hitherto silent kinship structure. Long-term associations between fathers and offspring enabled them to develop preferential bonds with each other – paternity recognition – while simultaneously making it possible for children to recognize their father's relatives, including their paternal grandfather and uncles. Stable breeding bonds generated what anthropologists long ago described as the most basic factor organizing social relationships in simple human societies: a group-wide kinship structure.

The extension of the domain of kin recognition, in turn, might have set the stage for the pacification of intergroup relations. Chimpanzees and bonobos are territorial. They avoid other groups and may even attack strangers. Again, presumably, so did early hominids. However, once kin recognition among paternally related kin had evolved, fathers, upon coming into contact with another group, could recognize their daughters and their newborn offspring – their grand-offspring – and refrain from attacking them. They could also recognize the preferential bond between their daughter and her 'husband' (their son-in-law) – a factor lowering the probability of conflicts between, this time, adult males. Similarly, grandfathers, brothers, and uncles could recognize their female kin and their in-laws living in other groups. In sum, a state of mutual tolerance based on kinship bonds would prevail between 'intermarrying' groups, a state that was possibly the phylogenetic antecedent of between-group alliances, or regional tribes.

Building upon this unique biological foundation and making use of their symbol-based capacity for culture, hominids have ever since been innovating in all areas of the social sphere, creating in the process a vast array of kinship systems and social structures in different physical and social environments. The upshot is that all such cultural variants, however peculiar, bear the stamp of humankind's stem social system. This reasoning illustrates the general principle underlying the solution to the old nature–culture opposition: culture certainly generates a tremendous amount of behavioral diversity, but it does so out of a universal set of biological constraints. Human nature is everywhere in cultural diversity, sometimes conspicuously but often

discreetly. If the neural and behavioral sciences are uniquely positioned to reveal the workings of human nature, only comparative primatology may shed light on its evolutionary history.

Glossary

- Coevolution** – The reciprocal selective pressures between species affect each others' evolution. Coevolution can thus be defined as covarying traits between different species in an environment. The evolution of prey–predator interactions constitutes an example of coevolution.
- Noise** – In the physical world, a noise is any time-varying or spatial-varying nonmeasurable quantity. It is an unpredictable event. In information theory, a noise is an undesired disturbance that may distort the information carried by a signal.
- Signal** – In the physical world, a signal is any time-varying or spatial-varying measurable quantity. It is a predictable event. In information theory, a signal is a codified message that carries information.

Communication is an important part of the behavioral repertoire of an animal. When the same individual both sends and receives any given signal, the process is called autocommunication. Echolocation (as used by bats and cetaceans) and electrolocation (as used by mormyrid and gymnotid fishes) correspond to this definition. Social communication involves at least two individuals. This process cannot occur in isolation and is consequently an inherently social behavior. It is the glue that holds animal society together. In general, sociality goes hand in hand with sophisticated communication. Sociality has not only several major advantages (e.g., numerous potential sexual partners, mutual aid for foraging activities, and better predator detection) but also some disadvantages. For example, it is well known that colonial breeding improves offspring care through communal protection. What is less known is the increased confusion in finding a young one or a mate. It is thus crucial for each individual to ensure an accurate identification. In animals, recognition between individuals is involved in the establishment of sexual and social relationships. In many cases, the ability to identify members of its own species and of different sex is essential to ensure the reliability of mating processes and reproduction. The discrimination between individuals of various social ranks or belonging to different social groups, between kin and nonkin, or between kin related by varying degrees can be of great interest in the context of sociality. Thus, the primary role of

communication signals is to ensure species, group, sex, or individual identification. Naturally and particularly within social groups, communication signals may also transmit information about prey detection, predator defense, spatial positioning, synchronization of activities, and hierarchy establishment within social groups. Finally, they can even reflect the motivational state of individuals.

Transmission of Information

According to the mathematical theory of information by Shannon and Weaver, the principle of animal communication could be summarized as follows: an emitter codes a message into a signal that propagates through the environment and that is transmitted to a receiver who decodes it to formalize a message (see **Figure 1**). This process corresponds to the sending of information. At the receipt of this information, the receiver reacts by modifying his behavior and consequently by sending back information. This exchange of information constitutes a communication process.

Several messages can be simultaneously encoded in the same signal. For example, numerous male birds use songs to delimit the boundary of their territory. A human translation of the message of the song should be as follows: "I am a territory owner and I am looking for a female." Besides this message, the bird provides numerous other information, principally about its species, sexual and individual identities, about its geographic location (the geographic variations of the songs are termed dialects, as for the human language), and about its motivational state.

When sending the signal, the emitter transmits a given volume of information and the receiver collects a part of this volume. The loss of volume between the information sent and received is due to the noise that impairs the system at different levels: at the level of the coding (bad motor control), propagation (bad transmission), and decoding (bad sensory reception). Thus, the semantic of the message sent and of the message received can differ, and the communication process will remain effective only if the parameters coding information are transmitted reliably between the emitter and the receiver. For example, for a sound, the volume of information is $V = FT\gamma$, with F representing the frequency bandwidth, T the duration, and $\gamma = \log_2(1 + S/N)$, S/N being the signal-to-noise ratio. If the sound signal propagates through a forest, the frequency bandwidth decreases due to selective filtering

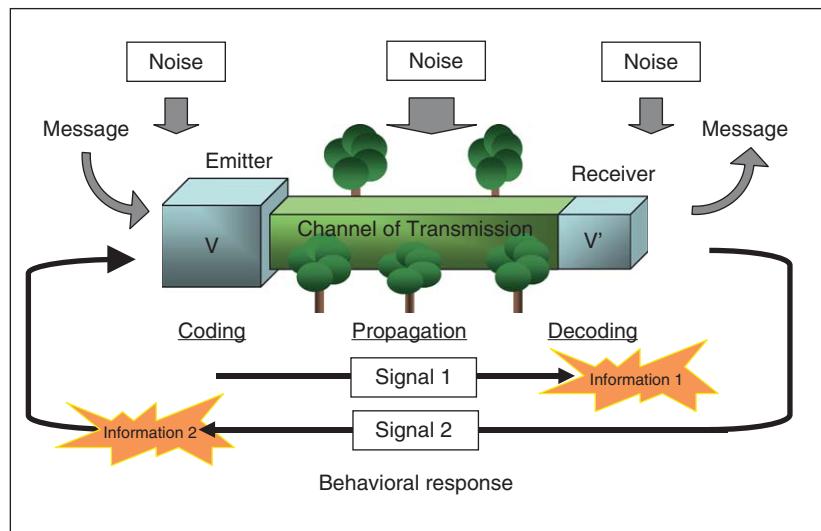

Figure 1 Principle of animal communication. A communication corresponds to an exchange of information (here signal 1 and signal 2) between an emitter and a receiver. In the process of being transmitted, different sources of noise and the properties of the channel of transmission are responsible for the decrease, which occurs between the volume of information sent (V) and the volume of information received (V'). This decrease affects the accuracy of the message finally received. Adapted from Shannon CE and Weaver W (1998) *The Mathematical Theory of Communication*. Chicago, IL: University of Illinois Press.

by obstacles (leaves, trunks) and the signal-to-noise ratio decreases due to the absorption and to the background noise of the environment. As a consequence, the volume of information collected by the receiver is weak. It can be so weak (e.g., in case of great emitter–receiver distance) that the message sent by the emitter will not be decoded by the receiver.

Sensory Channels

As seen above, communication implies exchange of signals between emitters and receivers. These signals can be light, sound (or vibration), chemistry, and electricity. The most widespread sensory channels used by animals to communicate are vision, hearing, and smell/taste. Other senses such as electrical, touch, or vibration perception are less common. Each signal modality has inherent properties, such as propagation speed, directionality, persistence, and resistance to obstacles. Thus, each sensory modality presents defaults and qualities that can be exploited by animals to establish efficient communication. Visual, acoustic, and even chemical signals operate at a long range contrary to tactile signals. The latter signals require a contact between two animals, and they are mostly used for reproduction, parental care, predation, and defense. Chemical signals have the particularity of being persistent, which can be advantageous (i.e., homing by tracks) or not (i.e., detection of the track by a predator). Chemical cues are used in a wide range of species, but mainly in insects and mammals. While chemical signals

are often emitted continuously during a given period, visual, acoustic, and tactile signals can be transmitted in temporally discrete sequences. Acoustic signals appear to be perfectly adapted for darkness or obstructed environments, and so they are intensely used by deep-sea fishes, nocturnal and forest birds, bats, and cetaceans. Contrary to chemical signals, visual and acoustic signals are rapidly transmitted, which may be an advantage with respect to localization for animals that move quickly in a three-dimensional space (e.g., flying insects, fishes, birds, and marine mammals). Thus, different sensory systems can participate in the communication processes, depending on the context and on the animal. Some communication processes require different senses that act in synergy. For example, identification of the mate or of the young requires olfactory and acoustic signals in shearwaters and seals (see [Video clip 1](#)) and identification of the species and of the sex requires tactile, visual, acoustic, and chemical signals in fruit flies *Drosophila melanogaster* ([Video clip 2](#)). In birds, selection by a female of a mate in arenas or leks associates the visual and acoustic signals displayed by males. Such communications are referred to as multimodal.

Physical and Biological Constraints

Animal species communicate within their own sensory worlds, and different species perceive their environment differently. The physical characteristics of the signals produced depend on the capabilities of their motor and

sense organs. For example, only big animals (e.g., elephants and whales) produce infrasound, and this ability is related to the sizes of their vocal and respiratory tracts. Among vertebrates, only some birds are able to simultaneously produce and modulate independently two frequencies. This process, called the two-voice phenomenon, is due to the low position of the vocal apparatus, the syrinx, on the two bronchi. Many insects, fishes, and birds are sensitive to ultraviolet light and to the polarization degree of light. This is not the case for mammals. Thus, physiological capacities of motor and sense organs define the physical and chemical properties of the signals used by a species.

As mentioned previously, the environment can be a source of noise (in the theory of information sense of the word) for communication. During propagation through environment, signals are subjected to attenuation and various other modifications, which decrease the reliability of information transfer. Physical or biological environmental noises can jam the signals and deeply modify their physical characteristics. In the acoustic domain, four different processes resulting in sound degradation can be identified: spherical spreading of sound energy, atmospheric absorption, scattering by heterogeneities of the propagation channel (e.g., physical obstacles, temperature gradients, and humidity), and boundary interference (interaction between direct and reflected sound waves). To these processes may be added the background noise due either to features of the habitat such as wind, ocean flow, and running water or to biological features such as the vocalizations of other animals. As a consequence, the signal arriving at the receiver is modified in the temporal, frequency, and intensity domains, and the information is degraded (see **Figure 2**). The

transmission of visual signals from emitter to receiver involves many of the same problems as sound transmission, such as attenuation, shape loss, and background noise. The main difference is perhaps the fact that light waves are more affected by obstacles since they cannot pass around an object as sound waves do. Indeed, only the sounds with a smaller wavelength than the obstacle's size are reflected. The environmental factors affecting the transmission at distance of chemical signals are mainly the properties of the current air or water flow of the habitat, and particularly its direction, speed, and type (laminar or turbulent). For deposited scent marks, other environmental factors, such as temperature and humidity, and physical and chemical characteristics of the substrate affect signal emissivity and longevity.

In some cases, the external constraints are very high and, by analogy with extreme arid or salty biotopes, the environment can then be considered as extreme for communication. For example, the absorbent environment of tropical forests or the noisy environment of bird colonies can be considered as extreme for acoustic communication.

Communication Strategies

Constraining environments constitute a strong selective pressure potentially driving strategies optimizing the reliability of communication processes. In this perspective, signal structure hypothesis predicts that the structure of animal signals will differ depending on the general features of the habitat. For example, again in the acoustic domain, bird songs optimized for long-range propagation in a forest should be as low in frequency as the sender can efficiently produce and slowly modulated in frequency. In

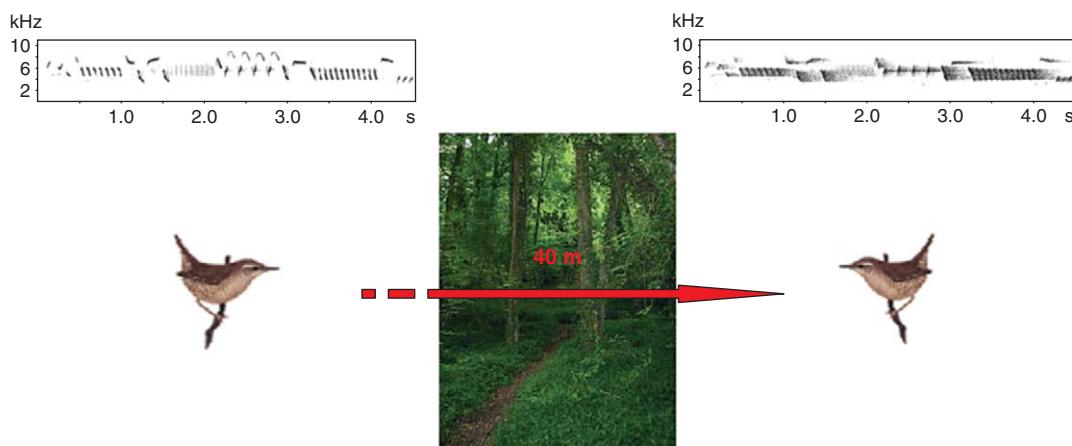

Figure 2 Effect of propagation through a forest habitat on the territorial song of the European wren *Trogolodytes troglodytes*. Spectrographic representations of songs recorded after a propagation of 1 m (left) and of 40 m (right). The effects of reverberations and high-frequency filtering are conspicuous in the 40 m propagated signal. Adapted from Mathevon N and Aubin T (1997) Reaction to conspecific degraded song by the wren *Trogolodytes troglodytes*: Territorial response and choice of song post. *Behavioural Processes* 39, 77–84.

addition, since the susceptibility of emitted signals to propagation-induced modifications depends on their acoustic characteristics, the emitter could enhance or, on the contrary, reduce the active space of its communication by coding information in more or less propagation-resistant parameters. This adjustment of the coding strategies according to the habitat has been experimentally demonstrated for the songs of some territorial forest birds. Due to the variable spacing of territorial individuals, some information may be coded to propagate only over a short distance and some might be coded such that it transmits over a long distance without much degradation. Thus, species-specific identity is encoded in propagation-resistant acoustic features, allowing individual to reach a wide audience. Conversely, individual identity is encoded by song features susceptible to propagation, this private information being reserved for close neighbors. Such processes have also been found in mammals. Pygmy marmosets *Cebuella pygmaea*, for example, emit a highly degradable call when individuals are close and a less propagation-sensitive signal when they are farther apart.

For visual signals, it is the contrast between the emitter and the background that determines the conspicuousness of the emitter. This contrast is based on four properties, which are brightness (or intensity), spectral composition (or color), spatial characteristics (e.g., size and shape features), and temporal variability (e.g., the pattern of movements). To maximize these parameters and thus to increase the signal-to-noise ratio, some animals choose particular light spots to communicate. This is the case of a jungle dancer: the Manakin bird (*Manacus* genus). It is a brightly colored bird of the forests of South and Central America. The courtship display of the male consists of rapid jumps and exhibition of its colored feathers on branches well exposed to sunlight.

In some social groups of animals, communication is particularly subjected to masking effects due to the numerous signals emitted by the conspecifics. In this case, the physical or chemical properties of the masker and those of the signaller are similar. The jamming effect is very important in these conditions of competing noise and increases the difficulty for a given individual to extract the information provided by the others. According to the information theory, an increased redundancy in signal improves the probability of receiving a message in a noisy channel. Experimental results corroborate this prediction. A nice illustration of this phenomenon can be found in penguin colonies. These birds use a particular call, the display call, to identify their mate, their chick, or their parent. Display calls of penguins appear to be highly redundant, consisting of more or less identical successive syllables with the same information, the individual identity, repeated many times. As penguins breed in dense colonies (up to one or two million pairs), calls emitted by other individuals generate

a huge background noise. The noise generated by birds in the colony is almost continuous, and periods of relative silence are short, infrequent, and unpredictable (listen to [Audio file 1](#)). Nevertheless, the redundancy of the vocal signature enhances the opportunity to find a quieter window in the almost continuous ambient noise. Experiments indicate that penguins detection is possible even when the intensity of the focus call is well below (-6 dB) that of the noise of simultaneous calls produced by other adults. This capacity to perceive and extract a given call from the ambient noise, and particularly from the calls of other individuals, is termed the ‘cocktail-party effect’ in speech intelligibility tests. Similarly, the information exchanged between individuals in insect and amphibian choruses is also redundant.

In addition to coding strategies, each animal tries to optimize its communication by managing where, how, and when to emit and how pertinent information can be gained from signals emitted by the others. In forests, the choice by birds of clear perching areas favors propagation of visual and acoustic signals. Numerous behaviors and movements enhance the transmission of chemical signals by spreading the odors or generating air or water current flows. Some insects thus disperse their cuticular pheromones by wing vibration. The choice of when to emit can be also an element allowing a sender to control the active space of its signal. For instance, some European bush-crickets mainly stridulate in the morning, avoiding problems of reduced transmission appearing in the afternoon due to negative temperature gradients. Similarly, a number of adaptations to environmental constraints allowing the decoding of information and the localization of the emitter can be found at the receiver level. Perching behavior of forest birds, besides improvement of the active space of emitted vocalizations, has a great influence on the potential received signals and, in reality, increases the active listening space more than the active space of the bird’s signals. Thus, during song reception in the Blackcap *Sylvia atricapilla*, a perching at 5 m high has the same consequence in terms of decrease in excess attenuation than a horizontal approach of 24 m to the emitter!

Signal Honesty

Communication systems are shaped by the extent to which emitters and receivers have mutual or conflicting interests. In behavioral ecology, traits that benefit the emitter are called signals, and those that benefit the receiver are called cues. For example, the roaring of stags constitutes a honest signal predictor of body condition. Nevertheless, roaring repeatedly may be costly in terms of detection by predators and in this case constitutes a cue. In the visual domain, sexual ornaments not only signal the quality of the male but also signal the emitter to

predators. It is the same for chemical tracks of ants, which allow homing not only for conspecifics but also for predators! So, the distinction between signals and cues is not clear. Similarly, the concept of signal honesty is controversial because it is difficult to determine the intent in animal communication. In fact, the term ‘honest signal’ must be used in a statistical sense. Signals can be considered honest if they carry information that will be on average useful to the receiver, particularly at the level of its fitness. Numerous honest signals have been described in the animal kingdom. For example, male and female blue-footed boobies have, as indicated by their name, colorful feet that are displayed ostentatiously during courtship. Feet coloration can change very quickly depending on food availability. Compared with males or females with duller blue feet, those with bright green-blue feet have better nutritional and health condition and are more attractive for the opposite sex. This has been experimentally demonstrated by modifying the male or female feet color with a make-up. Females decreased egg volume when the male feet color was manipulated to a duller blue. Similarly, experimental females with duller feet received less intra- and extrapair courtship (see **Figure 3**). In this species, feet color appears as a sexually selected trait.

The opposite of honesty is cheating (or deception). Cheating occurs when a signal has a positive informative value for the emitter but a negative one for the receiver. Senders are expected to try to manipulate receivers on their own, because the interests of senders and receivers conflict. Thus, animals are able to cheat when they communicate. A good example of cheating is the stag roaring, as described above. Formants (vocal tract resonances) provide a honest indication of body size in the rutting vocalizations of deer, and males use these formant frequencies in assessment during male–male contests. As adult humans, stags possess a descended larynx and this laryngeal descent serves to elongate the vocal tract and so to lower down the values of the resonant frequencies (see **Video clip 3**). This anatomical particularity allows some callers to exaggerate their perceived body size by decreasing vocal-tract resonant frequencies.

Through these different examples, we can see that the interests of emitters and receivers often conflict. As a consequence, the coevolutionary struggle between honest signal and cheating should lead to the extinction of honesty in animal communication. What prevents cheating from destabilizing signaling systems is the fact that receivers should ignore the signals if they are not useful to them.

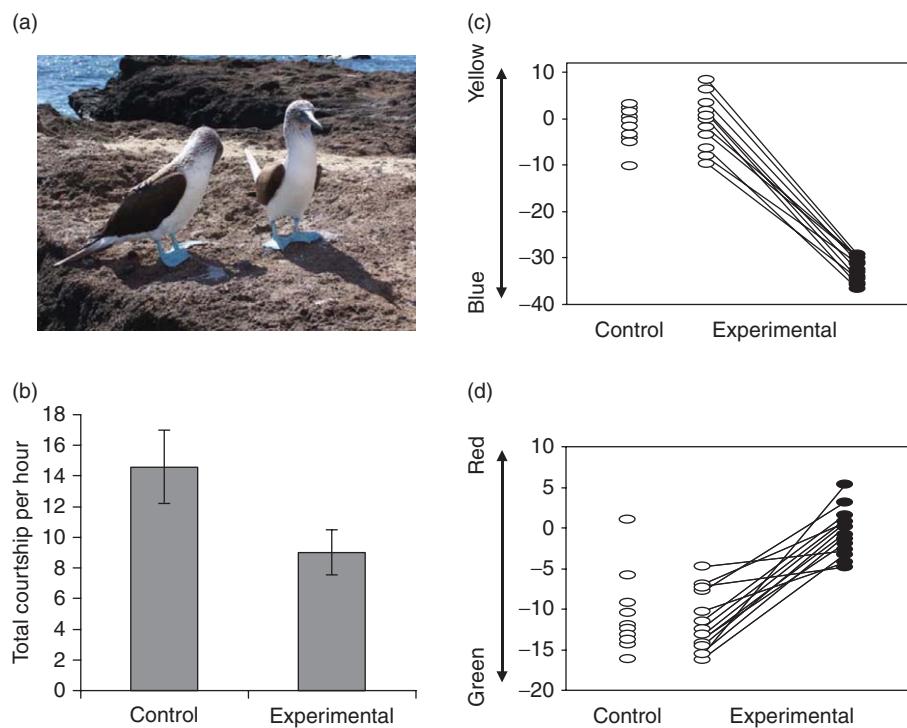

Figure 3 In the blue-footed booby *Sula nebouxii* (a) the foot color of paired females is a trait that influences male courting behavior (picture: T. Aubin). This was demonstrated by an experiment in which the foot color of females was modified with a make-up. (c, d) Chromaticity parameters of foot color (c: from blue to yellow; d: from green to red) of control ($n = 11$) and experimental ($n = 15$) females before and after the color manipulation. (b) Total courtship displays (e.g., parading and nest material presentation) received by the control and experimental females. Adapted from Torres R and Velando A (2005) Male preference for female foot colour in a seabird with a mixed mating strategy. *Animal Behaviour* 69: 59–65.

Communication Network, Eavesdropping, and Audience Effect

The simple relationship emitter–receiver mentioned previously gives a poor indication of the way communication occurs in animal groups or societies, because several individuals are often simultaneously involved in a communication process. In these communities of animals, communication occurs in a network rather than in a one emitter–one receiver dyad. Thus, studying communication in a network perspective appears as a necessity to decipher the behavior of complex groups such as social insects, birds, or mammals and to examine the dynamic nature of communication.

Social eavesdropping (interception of communication) is an illustration of communication network behavior. Eavesdropping occurs in a situation in which one or more observers (eavesdroppers) extract information from a signaling interaction between others. Eavesdroppers located near an emitter and receiver will collect information about their state, strength, and quality and will later use this information to adjust their own behaviors in following interactions with the original signalers. A classical example of visual eavesdropping is provided by experiments realized in laboratory conditions with Siamese fighting fishes *Betta splendens*. In these experiments, a subject sees two individuals in courtship interactions (male–female communication) or in aggressive interaction (male–male communication) and extracts relative information from these interactions. For example, a male assesses the competitive ability of two other males by watching their territorial contests. In future encounters, this male will avoid fighting the winner but will attack the loser. Eavesdropping can implicate different species. For instance, predators and parasites pay attention to signals of potential preys or host (e.g., bats preying upon calling frogs or insects, predator insects attracted by the sex pheromones of Lepidoptera or Coleoptera). This category of eavesdropping does not correspond to an exchange of information between preys and predators but has implications on the prey communication system. To avoid the attack of predators, the potential preys have then to keep their interactions secret. Reduction of signal range by the use of propagation-sensitive signals can be of a great interest to privatize communication. For example, numerous birds use quiet vocalizations that are less likely to be detected or localized when they want to limit eavesdropping. Similarly, in a species of cricket, *Teleogryllus oceanicus*, males of populations, in which a phonotactic parasitoid occurs, produce shorter and simpler sounds than males of parasite-free populations. Some acoustically orienting predators such as bats are so menacing for some species of crickets and katydids that they may have selected for the secondary loss of acoustic signaling. In these insects,

substrate vibrations partially replace vocalizations presumably because bats cannot eavesdrop on these signals.

Audience effect constitutes another illustration of communication network behavior. It corresponds to a change in signaling behavior of two interacting individuals in the presence of one or more external receivers (the audience). The audience is a nontarget receiver that nevertheless can act on the behavior of two individuals exchanging information. This process has been documented in numerous species and for different categories of signals. For example, it has been shown experimentally in a gregarious bird species, the zebra finch (*Taeniopygia guttata*), that the male pays attention to the mating status of conspecific pairs and uses this information to control its behavior toward its female partner. The experiment clearly demonstrates that the vocal response of males to their partner's calls and to the calls of familiar female changes depending on the composition of the audience – audience that was constituted either of males or of unmated pairs or of mated pairs (see [Figure 4](#)). This example reveals that signal production may depend on the social environment and the emitter's social status. A consequence of signaling in a network is that specialized behaviors or signals have evolved so as to direct a signal toward a particular part of the network rather than to the whole network. The capability of squids to produce visual signals on opposite sides of the body when surrounded by different individuals is an example of directing a signal to particular receivers and corresponds also to the privatization of information evoked above.

Referential Communication

When animals communicate, they typically convey information about their identity and their motivational state. In some cases, as mentioned previously, they can also indicate the discovery of food (resource-recruitment signals) or predators (alarm signals). The fact that an item that is present in an individual's proximal life space may be the topic of signal exchange constitutes what is termed a referential communication. The honeybee dance indicating a distant food source is an example of referential signaling in the visual domain. Sometimes, the information concerning the nature of the food or of the predator can be very precise. Thus, the chick-a-dee call of some tits (the chickadees) consists of four note types, and it is used in a wide variety of contexts, including not only contact between males but also alarm. Field scientists have observed that the number of repetition of the last note type (the dee note) was related to the size of the predator: the greater the repetition number, the smaller the predator size. Similarly, East African velvet monkeys categorize other species by giving acoustically distinct

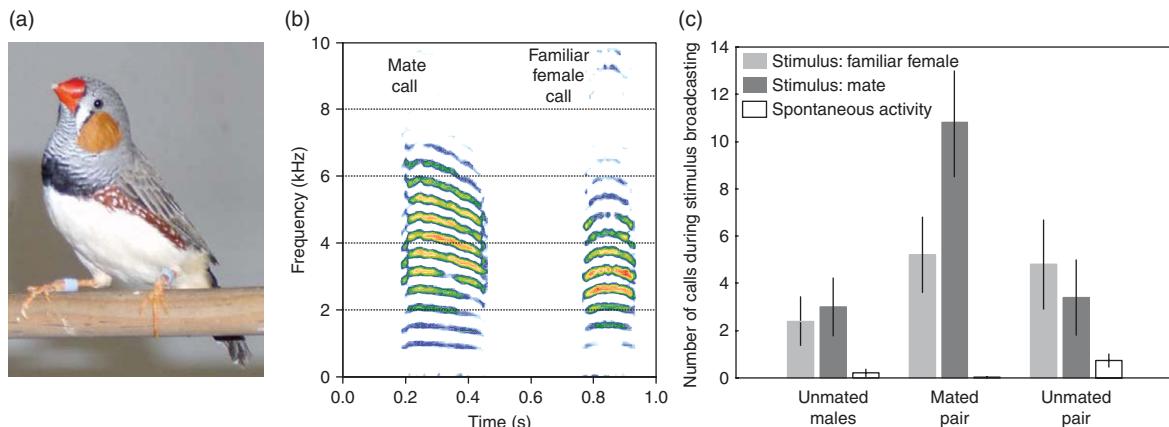

Figure 4 Importance of audience effect on the vocal response of male zebra finch to female voice. (a) Zebra finch *Taeniopygia guttata* (picture: courtesy of C. Vignal). (b) Male and female calls. (c) Response of males ($n = 15$) to the playback of female calls as a function of the mating status of the audience placed near the tested male in a companion cage: unmated male context: two single males; mated pair context: a normal male-female pair; unmated pair context: a male and a female not paired. During the experimental session, the male was presented with two sets of stimuli: a series of calls of its mate and a series of calls of a familiar female. Adapted from Vignal C, Mathevon N, and Mottin S (2004) Audience drives male songbird response to partner's voice. *Nature* 430: 448–450.

alarm calls to different predators. These calls allow the classification of three predator categories: two terrestrial predators, the leopard and the snake, and one aerial predator, the eagle. Associated with each alarm call type is a behaviorally appropriate response. The response to a leopard alarm is to run up into a tall tree. By contrast, the response to an eagle alarm is to run in a dense bush. Finally, the snake alarm elicits a mobbing behavior with the aim to move away from the intruder. Thus, in different animal species, there is evidence of referentiality, that is, of signals, which refers to significant targets in the environment such as food or predators. The ability to produce such signals is strongly related to the development of social life.

In animals, the communication systems play an important role in the realization of vital functions such as species, group, sex, individual identification, search of food, warning in relation to a danger, and contact between individuals. Some animals, principally social ones, are also able to use referential signals such as those related to the food or the predator nature. It is more particularly the development of the referential function, which is at the origin of the most sophisticated communication system: the human language.

Social Learning and Behavior Transmission

Glossary

Asocial learning – Asocial learning describes individual learning that occurs in the absence of social interaction.

Cultural variants – Group behaviors, or traditions, are considered culturally variable when they are present in at least one area, but absent in other areas with similar, if not identical, ecological conditions.

Culture – Culture refers to group-specific variation in behavior that is a result of social influences. Some reserve this term for the human alone, due to the complex nature of human culture. Others place the main distinction between tradition and culture on the behavioral processes involved in the development and maintenance of cultural attributes (e.g., imitation, teaching, and language).

Cumulative culture – When gradual modifications to behavior are added over time, a cumulative effect may lead to more advanced and complex traditions. Human cultural complexity is often attributed to this phenomenon.

Imitation – In 1898, Thorndike broadly defined imitation as: “learning to do an act from seeing it done.” It is, perhaps, the most debated social learning mechanism, as it is seen by many to require more complex cognitive abilities and mental representations of others. Whether it is seen in animals or not is also highly debated, and it is considered a hallmark of human cultural development.

Social learning – Social learning refers to a range of learning mechanisms that are socially influenced either by the observation of others, or as a result of interactions with an individual and/or the byproducts of that individual’s actions. Certain social learning mechanisms are thought to play a critical role in the development and maintenance of group-specific behaviors.

Teaching – In observational learning, it is possible for one individual to gain information by watching another’s actions or behavior. Teaching is the term used to distinguish the condition in which the model of the behavior modifies his or her actions in such a way that allows the observer to acquire that information more rapidly. Teachers often do this at a cost to their own productivity, and may even encourage or discourage the observer.

Tradition – Group-specific behaviors that are exhibited by members of one group, but not another of the same

species, are considered local customs, or traditions.

Traditions are transmitted socially, rather than genetically, and are not merely the result of adapting to local ecological conditions.

Introduction

Learning, whether social or asocial, can provide an individual with the opportunity to gain experiences that will help it to better adapt to changes in its environment. An individual’s environment can change many times and in many ways over its lifetime. In some cases, it may be better for a naive individual to gain information from another individual via social learning, because the risks associated with individual learning may be costly (e.g., learning to avoid a poisonous food-source). Depending on the costs and benefits, an individual should employ different social learning strategies, changing between asocial and social learning.

Social Learning

Most reports of social learning in animals involve the acceptance or avoidance of novel foods, mate-choices, and predator-avoidance strategies; these behaviors may be learned by observing others, or from artifacts produced by others. In some cases, learning socially may or may not require reasoning about other individuals, or even reasoning about one’s own behavior. Less common examples of socially learned behaviors include specialized grooming, communicative signals, and tool-use techniques. These types of activities may require that an individual understand their own relationship to the demonstrator (e.g., for copying motor patterns), or understand the goal of the demonstrator’s actions – both of which involve relatively sophisticated cognitive abilities. Determining what cognitive abilities are involved in the learning process has been the primary objective of social learning researchers for over a century, with a great amount of attention focused on nonhuman primates.

Imitation was initially considered one of the few traits that animals had in common with the human, and many languages even have terms that involve the words ‘ape’ or

'monkey' to describe imitation (e.g., aping). However, great debate exists over whether or not monkeys, apes, or any other animals are able to truly imitate, with a particular emphasis being placed on what the definition of imitation should be. Sometimes, imitation can be confused with more subtle forms of social influence that lead to learning the same behaviors as others. For this reason, the literature on social learning distinguishes terms for the different ways in which learning can take place, such as social facilitation, contagion, stimulus enhancement, local enhancement, emulation, imitation, and teaching. While having many terms for learning contributes to confusion in the literature, it also highlights the various ways in which social influences affect animal learning and behavior transmission.

Social Facilitation and Contagion

The presence of another individual may enhance or inhibit existing behavior in an individual. This is commonly referred to as social facilitation, but is also referred to as social enhancement – defined as the motivational state of an individual being enhanced by another (be it an increase or decrease in motivation). The mere presence of another individual has the potential to lead to synchronization of behaviors over space and time, which is crucial in group-living species with regard to group cohesion, behavioral coordination, foraging efficiency, and predator avoidance. While social facilitation alone does not lead to complex behavior matching, it has the potential to increase the opportunities in which observational learning can occur. When coordination of behavior occurs among two or more individuals, it is referred to as social contagion, because the mere act of seeing another individual engaging in a species-typical behavior elicits that same response in others. For example, satiated brown capuchin monkeys will resume feeding when a familiar conspecific is seen eating nearby and will also consume more food in the presence of another monkey than if alone. This facilitated feeding behavior is seen in other monkey species as well as dogs, chicken, fish, and the human.

Stimulus and Local Enhancement

One of the most common forms of social influence occurs when an individual's attention is drawn to a stimulus by another individual. This is referred to as stimulus enhancement. Similarly, when an individual is drawn to a specific location because of the actions or byproducts of the actions of another individual, it is called local enhancement. It is not always possible to distinguish these two forms of enhancement, because an object or stimulus may also be associated with a specific location.

In Great Britain, blue tits were observed drinking from the top of milk bottles left outside homes by milkmen.

The birds were seen piercing the foil cap of the bottles to gain access to the milk within. When this was first observed, it was assumed to have spread via social learning, but the specific mechanism was unknown. Following the presentation of pierced-opened milk containers to captive chickadees, the birds were able to deduce on their own how to pierce unopened lids, suggesting that they did not need to observe the behavior performed by a conspecific, merely, being drawn to the location and seeing the resulting condition of the bottles was sufficient.

Some have argued that stimulus and local enhancement are not social learning mechanisms *per se*, rather they are social influences that lead to individual trial-and-error learning, or in some cases facilitate opportunities for observational learning to take place. Nevertheless, local and stimulus enhancement are generally recognized as important processes in social learning, as they may facilitate the acquisition of behaviors from one individual to another.

Emulation

Emulation refers to a form of learning about the affordances of a task, or changes in the environment, as a result of a conspecific's behavior. Within the literature, four distinct aspects of emulation learning, which all relate to learning about the affordances of an object, have been defined: (1) setting a goal, (2) learning the physical properties of objects, (3) learning relationships among objects, and (4) learning what can be done with an object. Furthermore, the changes taking place in the environment are the primary focus of the learner; therefore, the demonstrator's identity (or even presence) may be irrelevant in instances of emulation, so long as the movements are observed. Other terms for emulation include goal enhancement and affordance learning.

Although some describe emulation as a less complex form of learning than imitation, stating that it does not require the need for perspective taking, it may still be a more efficient method of acquiring new information. In certain instances, choosing to ignore irrelevant information or actions conducted by another, in favor of more efficient actions that result in the same endpoint, may be a more efficient strategy. For example, chimpanzees readily switch between emulation and imitation in an experimental foraging task when they are able to distinguish between relevant and irrelevant actions that are demonstrated for collecting food. In one condition, a foraging apparatus is painted so that the inside of the box is not visible. An experimenter demonstrates poking a stick into a hole in the top of the box, and then pokes the stick in another hole on the side of the apparatus. Food is then released from the box and the chimpanzee is given the opportunity to attempt to extract food. In the second condition, chimpanzees are shown the same actions but

the box is not painted and the inside is clearly visible. The chimpanzees now can see that poking the stick in the top hole only hits a shelf inside the box, whereas the second hole on the side actually releases food. In the first condition, chimpanzees copy all the actions that were demonstrated, but in the second condition, they copy only the actions that result in the end-state reward. When human children are presented with these same experimental conditions, they imitate the actions demonstrated irrespective of its relevance to food collection, suggesting that there may be some intrinsic value for the human to do as others do.

Imitation

Imitation is linked with high copying fidelity that not only includes the same end results as the original demonstrator, but also any relevant or even irrelevant behaviors and actions involved. However, over time, varying perspectives and approaches to the study of imitation in animals has led to the belief that imitation is a specific form of social learning – one that is considered to be more cognitively advanced as it may also require perspective taking, or theory of mind. This may very well be the case, as it seems those who are more aware of the social affairs of others are better social learners. Arguably, the best examples of imitation come from animals that are believed to have a theory of mind. For example, chimpanzees have been shown to imitate novel actions of a human experimenter. In the ‘Do as I do’ (DAID) experiment, a chimpanzee is trained to respond to the phrase, ‘Do this!’, which is followed by a range of behaviors, all of which are novel to the chimpanzee. The actions included touching areas of the body that were visible to the subject, such as touching an elbow, the stomach, or a shoulder, as well as nonvisible areas, such as the ear, nose, and back of the head. While the two chimpanzees imitated the human demonstrator, they had more difficulty matching behaviors that were not visible to themselves than areas that were visible.

Teaching

The study of social learning in animals has primarily addressed the perspective and abilities of the learner, since these are the main determinants of the learning process. A less common influence found in animal social learning is the active teaching of a behavior by a conspecific. An individual may perform a behavior in the presence of another group-member, but this does not necessarily imply that they are actively teaching for the benefit of the observer. Teaching differs from merely demonstrating, because the teacher modifies its behavior in some way due to the presence of the observer. This change in behavior does not benefit the teacher, and can

sometimes even be at a cost to the teacher. As a result of the teacher’s change in behavior, the observer learns at a faster or more efficient rate than it would alone.

Teaching by nonhuman animals is not limited to a specific taxonomic group, nor is it only seen in cognitively advanced species. The most convincing examples of teaching come from animals that cooperatively breed, such as ants, pied babblers, and meerkats. In meerkats, most group members are related to other members of their colony and lead a relatively cooperative life. Group members take turns monitoring for predators while others forage for food; and in some cases, a group member will present young offspring with prey that is partially maimed in order to provide them with direct hunting experience. By doing this, a meerkat may lose the prey if the offspring are not successful in killing it, thus it is a potentially costly act to be a teacher. However, if the young are successful, they gain the necessary experience for successfully hunting their own prey. For this reason, it has been suggested that the act of teaching is a cooperative behavior that facilitates learning in others.

Traditions and Cultural Behaviors

Differences in learning abilities across species may not only reflect specific abilities for social learning, but also the ways in which social behavior and group dynamics interact to support behavior transmission. As with the debate over imitation in animals, the question of whether or not animals have culture has been, for the most part, definitional with a focus on the learning mechanisms that support the transmission of cultural behavior. Under a small range of conditions, there is increasing evidence that animals are capable of imitation, though they rely on simpler forms of social learning more frequently. The study of animal learning has shown that even the most basic levels of social influence can lead to behavioral differences between populations, which are referred to as local traditions or culture. Distinctions are made between the terms culture and tradition because for many, culture is a term associated with complex cumulative culture seen only in the human.

Field Studies of Cultural Learning

One of the first reports of animal culture came from the island of Koshima, where a group of Japanese macaques washed sweet potatoes that were provisioned to them (**Figure 1**). This behavior originated with one female, Imo, and, within 10 years, most others in her group were also washing their potatoes. The spread of potato washing was initially slow, with only one or two individuals acquiring the behavior per year. It has been suggested that imitation is an unlikely explanation for the spread of

Figure 1 Potato washing Japanese macaques submerge potatoes on the shore at Koshima. Photo credit: Frans de Waal.

this behavior due to the slow rate of transmission. If Japanese macaques were imitating what they observed, then the transmission rate would be much higher; however, the strict hierarchical nature of macaques restricts the proximity between unrelated individuals and those with the greatest rank disparity, and therefore limits social opportunities for individuals to observe the behavior. Furthermore, it assumes that cultural behaviors can only spread by complex social learning mechanisms such as imitation. While it is now widely assumed that potato washing did not spread by imitation, it is accepted as a feeding tradition of the monkeys at Koshima, since the behavior not only spread to most members of the group, but also endured beyond the influence of the original innovator, to future generations.

Another tradition in Japanese macaques is the handling of stones as an object-play behavior. Stone handling in Japanese macaques may not have a specific functional purpose beyond social play, as the behavior is not rewarded and does not involve food or food processing. New reports are emerging for variants of stone handling between groups, including stone throwing, as well as a novel fish-eating method in Japanese macaques, adding further support for variability in the types of traditions monkeys have.

The best evidence for variability of traditions comes from the long-term study of white-faced capuchin monkeys in Costa Rica. Some 19 000 h of field observations from 13 social groups over 13 years were combined from four field-sites, Lombas Barbudal, Santa Rosa, Palo Verde, and Curu. Five social conventions were described: (1) hand-sniffing: when an individual takes the hands or feet of another individual and deeply inhales, (2) body-part sucking: when an individual engages in lengthy period of time sucking a body part of another individual (e.g., ear, finger, tail), (3) finger-in-mouth game: when an individual puts his or her fingers in the mouth of another individual that then clamps down firmly for a lengthy

period of time, (4) hair game: when two individuals take turns biting hair from each other, and (5) toy game: when two individuals repeatedly take turns pulling nonfood objects from each other's mouths. Additionally, different food processing methods were described for some of the 13 field-sites. For example, at Lomas Barbudal, capuchins hunt squirrels by biting them on the back of the neck, whereas this method is not seen at all in Santa Rosa, and in Lomas Barbudal and Palo Verde, groups within and between sites vary in their use of pounding and rubbing foods. These capuchins appear to share the same food-processing methods as individuals with which they associate, suggesting that these behaviors are socially acquired.

An influential breakthrough for studying cultural variation in primates came from a combination of longitudinal studies in wild populations of chimpanzee throughout Africa. By systematically comparing the cultural variants for each site taking account of ecological conditions, 39 distinct behavioral variants were identified among seven chimpanzee research sites. Chimpanzees in some areas of Africa use stones as tools to crack open nuts, while chimpanzees at other sites select and modify tools for ant dipping – a foraging technique for consuming ants by using sticks. Chimpanzees also engage in traditions that do not have direct survival benefits. One example of this is the handclasp grooming (**Figure 2**). The handclasp grooming involves holding and supporting the arm of a grooming partner by the wrist or hand over the grooming pairs' heads. This behavior is seen at specific field-sites, and entirely absent in others; for example, the handclasp grooming has been observed in the Mahale

Figure 2 Handclasp grooming in chimpanzees. Photo credit: Frans de Waal.

Mountains but not at Gombe, a chimpanzee research site only about 150 miles distant.

The same approach has been used to study cultural variants in wild orangutan populations in Southeast Asia. Orangutans are relatively solitary, although still social, animals whose interactions with conspecifics are mostly limited to mother–offspring pairs and mating partners. Opportunities for social learning are inherently limited by the number of social encounters between individuals, so the opportunities for studying cultural learning in orangutans have also been limited. Despite this confine, a comparison of six field-sites showed that orangutans also exhibit cultural variants, including six social signals (e.g., kiss-squeaks), and 10 specialized feeding techniques – two of which involved tool-use. Data collected from these different sites confirmed that the reported cultural variants could not be attributed to ecological differences across sites, and furthermore, found correlations between the opportunities for social learning and the size of the local repertoire.

Captive Studies on Cultural Learning

Longitudinal studies in the wild (such as those mentioned above) are costly, both in time and money spent by researchers, which has in turn limited the amount of information available. In order to assess if wild traditions are the result of social learning, it is also necessary to conduct captive experiments that allow us to control for all instances of social influence. Two of the most influential experimental paradigms for uncovering social learning in the spread of behaviors are the ‘two-action task’ and the ‘group-diffusion’ methods.

The two-action task paradigm has mainly been used to control for the effects of local and stimulus enhancement on social learning while examining the imitative abilities of subjects in observational learning experiments. The test involves two distinct methods for solving a task. One method for solving the task is demonstrated to an experimental subject before the subject is presented with the task. Although both methods are possible, the subject only observes one of the two tasks. Therefore, if a subject performs the same task as the demonstrator, it is most likely a result of imitative learning. The two-action task is considered one of the best methods for testing imitation in animals.

Animals differ in their physical abilities (e.g., primates use their hands, while birds use their beaks for most foraging behaviors), and so an advantage of the two-action test, is that it can be designed specifically for the physical abilities of a given species. Two-action task experiments have been used to study imitation in pigeons, budgerigars, Japanese quails, rats, hamsters, brown capuchin monkeys, gorillas, orangutans, and chimpanzees, among other species. These experiments have typically investigated test subjects in pairs, and have suggested imitative, or

imitation-like, learning in the context of the two-action task paradigm. However, it is apparent that each of these species is distinct from the next with regard to social structure and cognitive abilities, and it is, therefore, to be expected that we find differences in how socially acquired information spreads among group members, and how new behaviors develop into group-specific traditions.

While the two-action task paradigm provides insight into the kinds of learning mechanisms involved in transmitting behaviors, it does not necessarily determine what social influences maintain and spread a behavior to the point at which it becomes a group-wide tradition. One approach to studying traditions in animals is to investigate the diffusion of a behavior pattern throughout a social group. In the wild, it is virtually impossible to witness or recognize the innovation of a novel behavior. It is also difficult to study the transmission of that behavior in a controlled manner, with some exceptions – such as potato washing and stone handling in Japanese macaques. Even in the Japanese macaque studies, with years of available behavioral data, the underlying social learning processes involved still remain a point of issue and debate.

As described above, the two-action task test allows us to study the extent to which individuals learn to copy by observation, and in most experiments to date, this paradigm has been used in a dyadic context. The ‘diffusion experiment’ can provide us with further details about how a behavior spreads socially beyond the artificial dyadic context imposed upon subjects.

The lack of persistent and thorough imitative abilities may be one of the key features that distinguishes the development and scope of cultural behaviors in humans from nonhuman animals, but whether imitation is a necessary component of culture remains debatable. What is more noteworthy is the cumulative culture the human exhibits. This is likely a combination of human ability for imitation, teaching, and language. With language providing the means for building upon passed generations, imitation providing the fidelity to details necessary for producing cognitively complex behaviors, and teaching playing an important role in maintaining group social norms, as teaching allows for rewarding and punishing behaviors that fall outside the norm. Irrespective of how similar or dissimilar animal and human cultures are, the study of animal cultural learning is imperative to a biological understanding of culture.

Social Relationships and Social Knowledge

T J Bergman, University of Michigan, Ann Arbor, MI, USA

Glossary

Attachment – Attachment is the social bond between young and their mothers. In most species, attachment manifests itself as proximity-seeking to an attachment figure, usually the mother, particularly in situations of perceived distress or alarm.

Friendship – Friendships are close, consistent relationships that do not involve mating between pairs of nonrelatives. They can occur between animals of any age or sex and have been described in many species. However, friendships have primarily been studied between adult male and adult female primates.

Inclusive fitness – Inclusive fitness is a measure of an individual's fitness that includes both 'direct fitness' (fitness of the individual) and 'indirect fitness' (fitness through shared genes with close relatives). Indirect fitness is calibrated by the degree of relatedness, or the relatedness coefficient. In many situations, animals perform altruistic acts for relatives because – despite reducing their direct fitness – the act results in a net increase in inclusive fitness.

Prolactin – Prolactin is a peptide hormone originally discovered in association with lactation. However, across a wide range of animals including nonmammals, prolactin is now known to play an important role in parent–offspring bond formation.

Reconciliation – Reconciliation is an affiliative interaction among a pair of animals that have recently had a conflict or aggressive interaction. Reconciliation may serve to repair a damaged relationship.

Operationally, reconciliation is a postconflict increase in the probability of affiliative interactions above the baseline levels of inter action.

Social cognition – Social cognition is one type of cognition (the acquisition, processing, and storage of information) dealing with members of the same species. Social cognition covers the cognitive processes involved with perceiving, understanding, and interacting with conspecifics.

involve stable patterns of association and affiliation that are hallmarks of social bonds. In many species, social bonds are critical for survival. Animals rely on their social companions to help them find and defend food resources, to avoid or defend against predators, and to engage in reproduction.

Most social interactions among animals are explained by one of two factors: kinship and mating. Animals socialize with their close kin largely because these behaviors can increase their own fitness through kin selection and inclusive fitness. For example, bonds between parents and offspring help the offspring survive, which increases the parent's fitness due to the large portion of the parent's genes carried in the offspring. Such inclusive fitness benefits extend to more distant relatives, and kin selection is a major influence on patterns of social behavior. Many affiliative social relationships in animals parallel kinship relations. For example, in groups of matrilocal Old World monkeys (groups where the females stay in their natal group for life), the strongest relationships are among closely related females (mothers, daughters, sisters, etc.). These bonds form as an extension of the mother–infant bond as the developing infant forms attachments with the mother and, by association, other animals with which the mother has social bonds. These bonds remain as long as both members are alive.

Kinship often explains many otherwise 'altruistic' behaviors through the action of kin selection. Kin selection occurs when one animal aids a close relative at a cost to themselves. If the benefits of shared genes (inclusive fitness) outweigh the cost of the behavior, such behaviors carry a fitness advantage. Kin selection explains why cooperation and altruism are more common among close kin than among unrelated individuals. The most widespread example of kin selection is the help parents provide to their offspring.

A critical component to kin selection is kin recognition, or the ability to differentiate kin from nonkin, since animals can only preferentially help kin if they are able to effectively recognize them. The ability to recognize kin is widespread across animals (and even occurs in some plants) and does not require sophisticated cognitive abilities. For example, it can be based on simple mechanisms such as chemical detection. Alternatively, however, kin recognition can occur via cognitively sophisticated mechanisms such as social knowledge using individual and attribute recognition (see below).

Introduction

Among the most salient and important aspects of animal behavior are the interactions animals have with members of their own species. These interactions frequently

Figure 1 A harem of geladas resting above a sleeping cliff in the Simien Mountains of Ethiopia. Harems are the basis of gelada society and consist of long-term relationships among an adult male (much larger than the females) and several adult females and their offspring. Within the harem, the male–female relationships are based largely on mating, while the relationships among the females are based on kinship.

Outside of kinship, the most common associations between animals occur in the context of mating. Such interactions can range from brief encounters that do not involve any social bonds, to lifetime monogamy – among the longest lasting social bonds in animals. For example, pairs of royal albatross have been known to stay together for over 20 years. Even many nonmonogamous species have social bonds in the mating context, as in the temporary consortships found in many primates. As such, kinship and mating are the major factors structuring animal social systems (Figure 1).

Types of Social Bonds

Attachment

Attachment is the social bond between young and their mothers. In most species, attachment manifests itself as proximity-seeking to an attachment figure (usually the mother), particularly in situations of perceived distress or alarm. Attachment is the fundamental bond in development. The bond with their mother is the first bond most animals experience, and other bonds later in life are influenced by the nature of this bond. For example, many birds attach to the mother (biological or foster) through imprinting and, later in life, male birds will seek mates that resemble their attachment figure (even a human). Furthermore, most social bonds involve similar behaviors and biological bases, and it is likely that many social bonds are rooted in attachment. As such, understanding attachment sheds light on all social bonds.

Human attachment has a long history of study, and many early theories, including Freud's, pointed to the food provided by the mother as the critical component of attachment formation. This view was rejected by John Bowlby in the 1960s. Bowlby's theory of attachment focused on the role of the social interaction and proximity between the mother and the infant. Bowlby's views were influenced by ethological studies of imprinting that suggested that there is a critical window for the bond to form and that the bond formed early in life with the mother can affect adult behavior. The importance of social contact over food provision was supported by Harry Harlow's studies of attachment in orphaned rhesus monkeys. When given a choice between a soft, cloth-covered dummy 'mother' that provided no food and a wire dummy that provided food, the infants attached to the soft mother. Thus, the 'cupboard versus comfort' debate has largely been resolved in favor of contact-comfort as the critical component driving the attachment of babies to their mothers. As such, attachment is now often studied from both directions – infants to their mothers, and mothers to their infants. Functional imaging studies in humans are now revealing the biological bases of attachment from the mother's perspective (see below).

Familiarity

Familiarity is the simplest and weakest form of relationship among members of the same species. While most social bonds involve high rates of proximity and affiliative interaction, familiarity only requires visual, olfactory, tactile, or acoustic exposure to another animal.

Therefore, even animals that have little or no social interactions can be familiar with other members of their species. Even in the absence of social interaction, numerous studies show that familiarity influences an animal's behavior. For example, guppies are more likely to find hidden foods in the presence of familiar animals, and male red-winged blackbirds are better able to attract females if they are familiar with their male neighbors. Many animals go beyond familiarity and individually recognize other animals, making familiarity also one of the simplest forms of social knowledge (see below). Sustained contact and social interaction are thought to be important in transitioning from familiarity to stronger bonds.

Friendship

Close, consistent relationships have been observed in many taxa, and these are sometimes referred to as 'friendships.' In many species, pairs of unrelated animals (female–female, female–male, or male–male) maintain proximity and interact affiliatively at high rates over long periods of time outside of a mating context. Thus, these relationships resemble human friendships. Friendships were first described in anubis baboons by Shirley Strum and Barbara Smuts, who noted consistent associations among adult males and females. Friendships can be among the strongest and most enduring male–female bonds in many species. Because little is known about the biological and emotional correlates of animal friendships, they are defined by measures of proximity and affiliation. To separate friends from other types of relationships, they are defined as close social bonds among nonrelatives outside of a mating context. Some definitions require that the relationship be symmetrical (with both sides being equally responsible for maintaining the relationship) to qualify as friendship, although this standard is not often applied in practice.

From the time friendships were first identified, they have also been described in macaques, and chimpanzees. However, similar relationships are more widespread than the use of the term friendship would suggest (as many researchers are hesitant to use the anthropomorphic term 'friendship' and refer instead to 'associations' or 'bonds'). Relationships that resemble friendships have been identified in many species, including many nonprimates (e.g., dolphins and wolves). Because friendships cannot be explained by kin selection or mating, there has been considerable debate about why animals might form friendships.

Why form friendships?

Parenting

Many friendships between males and females, including the first friendships observed in baboons, appear to be related to parenting. In some populations of baboons,

these friendships function as a form of paternal investment because male friends, who are often the father of their female friend's infant, protect the infant from harassment, predation, or infanticide. Thus, both the male and female benefit from the relationship through increased offspring survival. In chacma baboons, where infanticide is common, many lines of evidence gathered by Ryne Palombit and colleagues point to the role of friendships in protecting against infanticide. First, friendships usually involve a female with a dependent offspring and a male that mated with the female when she conceived that offspring. Second, males preferentially respond to distress calls of their female friends when paired with vocalizations of possibly infanticidal males. Third, baboon friendships often dissolve if the infant disappears or is weaned. Finally, during periods of infanticide risk, lactating females with male friends have lower levels of physiological stress (as determined by levels of 'stress hormones,' or glucocorticoids) than other lactating females. Friendships between males and females with dependent offspring in many species are likely to involve a parenting function.

Mating

While friendships are specifically defined to occur outside of mating contexts, some friendships may still have a mating function. For example, a friendship may increase the chances that the two friends will mate in the future. Thus, one of the participants (usually the male) can gain a fitness advantage through increased mating success. There is some evidence for this explanation in anubis baboons where friends often have not mated in the past yet subsequently mate. Nevertheless, in many species it is difficult to demonstrate that two friends are more likely to mate than they would be if the relationship did not exist, particularly after controlling for factors like dominance rank and previous mating history. Despite the lack of evidence, it remains possible that friendships serve both a parenting and a mating function, much as male–female relationships in monogamous species do.

Reciprocal altruism

Friendships may represent an extended form of reciprocal altruism in which an actor provides a service to another animal with a previous history of providing the actor with a similar service (such as grooming or alliance support). The classic example of reciprocal altruism comes from vampire bats that are more likely to share their food (by regurgitation) with hungry social companions if they have received food from them in the past. While theoretically appealing, examples of altruism in nature are rare and some researchers question if it even exists. However, recently, social interactions have been analyzed using a biological marketplace framework where animals exchange interactions as a type of commodity exchange. For

example, a low-ranking animal may groom a higher-ranking animal in exchange for support in an alliance. Such exchanges appear to represent a form of reciprocal altruism.

Given the lack of mating or parenting benefits, reciprocal altruism is most likely to occur in male–male or female–female friendships. Such friendships are less common but do occur, perhaps most famously in male chimpanzees. In chimpanzees, strong relationships among males can help in rank acquisition, mate acquisition, and group defense. Many of these relationships can be explained by kinship (male chimpanzees remain in their natal group and thus have the opportunity to interact with close relatives). However, recent genetic work suggests that many alliances among chimpanzee males are between nonrelatives and consequently resemble other primate friendships. Chimpanzees in captivity have been shown to monitor animals that help them and, in turn, use this information in deciding who to help. Thus, chimpanzees are capable of reciprocal altruism, and friendships among male chimpanzees may represent reciprocal altruistic relationships.

Stress reduction

Several lines of evidence indicate that social support and affiliative contact among individuals can reduce anxiety and stress. For example, across several primate species it has been shown that animals being groomed have lower heart rates. Additionally, following an aggressive interaction, reconciliation between opponents produces a rapid reduction in rates of self-directed behavior – a behavioral correlate of stress. In male baboons, basal cortisol levels are negatively correlated with social integration. Across many primate species, subordinates have higher baseline stress hormone levels in part because they lack social support. Similarly, in humans, social support protects against minor chronic stress. Together, these findings suggest that social affiliation may have the direct benefit of reducing stress. Thus, animals may engage in friendships for this benefit.

Alliances

An alliance is a social relationship in which two (or more) animals cooperate to compete with a third animal. Each competitive encounter is called a coalition, and repeated coalition formation among the same animals leads to an alliance. Coalitions and alliances are widespread across the Primate order, but have also been observed in species as diverse as hyenas, lions, canids, dolphins, and rooks. In primates, alliance formation often parallels kin relationships with close kin teaming up to threaten an unrelated animal. One of the most striking examples of primate alliances that are not necessarily kin-based are the boundary patrols of chimpanzees. During these boundary

patrols, males from the same community join together to walk the boundary of their territory and attack (and sometimes kill) any extra-community animals they find.

Alliance formation has important implications for social cognitive evolution, which may explain why alliances have been described only in species with sophisticated cognitive abilities. First, the formation of an alliance involves choosing an effective ally. For example, baboons routinely choose allies that are (1) higher ranking than their opponent and (2) unrelated to their opponent. Therefore, choosing an effective ally requires knowledge of third-party relationships such as relative dominance rank and family relationships. Depending on the size of the social group, it can be cognitively challenging to keep track of such third-party relationships. Furthermore, in cases where alliances are due to reciprocal altruism (i.e., animals preferentially ally with animals that have helped them in the past), animals must monitor and remember previous interactions. Consequently, the cognitive challenges associated with alliance formation may be one of the most important reasons why living in complex social groups is thought to drive cognitive evolution (see below).

Biological Bases of Social Bonds

The biological bases of social bonds are best understood in the realm of parenting and, to a lesser extent, mating behavior. It appears that all bonds share behavioral similarities and biological underpinnings with the mother–offspring bond or pair bonds and, thus, understanding these bonds sheds light on all social bonds. These bonds have been studied from both an endocrinological and a neurological perspective.

Endocrinology of Social Bonds

Prolactin is a peptide hormone primarily associated with lactation. However, across a wide range of animals, prolactin is also important in parent–offspring bond formation. Prolactin has been widely studied in birds, where it has been associated with both maternal and paternal care for the young. Among female birds, prolactin is responsible for ‘broodiness’ – a behavior where female birds seek contact-comfort that leads to protecting and covering eggs and young. Many seasonally breeding birds have high prolactin only while providing parental care. In many species, male birds demonstrate a trade-off between testosterone and prolactin when shifting from mating to parenting, with high testosterone and low prolactin in the mating season and low testosterone and high prolactin once chicks hatch.

A similar pattern has been observed in some mammals, with elevated prolactin and reduced testosterone being

associated with paternal care in California mice and common marmosets. Similarly, pituitary prolactin and placental lactogen play leading roles in maternal behavior. However, the biological basis of parental care is understood to be more complex in mammals with oxytocin playing an important role. Oxytocin, a neurohormone which is released during mating, has also been implicated in monogamous pair bonds among rodents. This finding is based on the distribution and density of oxytocin receptors in the brain. Similar data show that vasopressin is also important in rodent-pair bonds. However, antagonist studies indicate that the roles of oxytocin and vasopressin are complicated and, at least among prairie voles, there are sex differences. Oxytocin is important for pair-bonding in females, while vasopressin is important for males. Corticosterone, a steroid hormone, shows a similar sex difference, appearing important for bond formation in male, but not female, prairie voles. More generally, other hormones released around the time of birth or during mating, such as β -endorphin, dopamine, prostaglandins, relaxin, progesterone, and estrogens, also play a role in mammalian social bonds.

Less is known about the endocrine correlates of maternal behavior and pair-bonding in primates and humans. Experience plays a significant role in the expression of primate maternal behavior, suggesting that hormones may have a priming role in first-time mothers but are less important in experienced mothers. In solitary captive rhesus monkeys, nulliparous females avoid unfamiliar infants when they are placed in their cage, while experienced mothers express maternal behavior toward them, irrespective of their own endocrine status. Studies in marmosets show that estradiol can increase motivation relating to maternal behavior. In the human, hormone levels may affect maternal attraction toward infants and general arousal and responsiveness but they cannot explain the occurrence of basic parenting behaviors. Human paternal behavior appears to have more direct endocrine correlates with elevated prolactin and reduced testosterone found in expectant and recent fathers.

Neural Bases of Social Bonds

In birds, the preoptic area (POA) anterior to the hypothalamus is essential for the expression of parenting behavior, and prolactin receptor expression is high in this region throughout brooding. Cowbirds – a brood parasite that lays its eggs in the nests of other birds and does not provide parental care – have reduced prolactin binding in the POA. Lesion studies suggest that the ventromedial nuclei (VMN) and the paraventricular nuclei (PVN) are also involved in paternal care. In mammals, much of our understanding about the neural basis of parental care comes from studies of rats. In rats, estrogen promotes maternal behavior by enhancing offspring-stimulated

neural activity in the medial preoptic area (MPOA), the bed nucleus of the stria terminalis (BNST), and the dorsal and intermediate lateral septum. The shell of the nucleus accumbens appears to be important for pup-retrieval behavior. The vomeronasal organ and amygdala are involved in inhibiting maternal behavior in rats through inhibitory action on the MPOA. Hormones that favor maternal behavior (estrogens) apparently act by releasing the MPOA from this inhibition. One result of this release from inhibition may be the production of oxytocin receptors that, in turn, increase maternal care.

In humans, romantic and maternal love evoke similar pathways (involving the anterior cingulate cortex, ventral anterior cingulate cortex, medial insular cortex, caudate nucleus, and the striatum). These highly conserved neural systems underlying love have also been linked to addiction and obsessive compulsive disorders. Functional magnetic resonance imaging (fMRI) studies indicate that the anterior cingulate and right medial prefrontal cortex are involved in parental (and especially maternal) responsiveness. Amygdala activation also occurs in response to infant sounds. The orbitofrontal cortex is preferentially activated by images of one's own offspring compared to images of other infants. More recent fMRI studies have found that images of one's own infant smiling preferentially activate reward-processing regions (including the ventral tegmental area/substantia nigra regions, the striatum, and frontal lobe regions involved in emotion processing – medial prefrontal, anterior cingulate, and insular cortex). Thus, attachment may be maintained by the pleasure mothers and infants experience from being exposed to each other.

Social Knowledge: The Cognitive Aspects of Social Bonds

Animals keep track of many types of information about their social companions and in doing so, engage in social cognition. Social cognition covers the cognitive processes involved with perceiving, understanding, and interacting with conspecifics. While very little research has quantified the adaptive value of social cognition, it is likely beneficial because it allows animals to predict and influence the behavior of others in their group, to resolve conflicts efficiently, or to recruit allies successfully. Additionally, some argue that more complex types of social cognition (e.g., deception) are important in a Machiavellian way as animals try to outmaneuver each other in social competition. Indirect support for the value of social cognition comes from recent studies in baboons where, within a population, baboon mothers that are more social have greater reproductive success. What remains uncertain is how social-cognitive ability translates to social integration and status. However, there is considerable indirect evidence that social complexity and

cognitive ability evolve together, and it is likely that the cognitive demands of social life drive some cognitive evolution.

Types of Social Information

There are three types of social information that animals can ‘know’ about another animal. First, animals may recognize specific individuals or the groups that they belong to. Examples of this type of recognition include (in increasing specificity): species, sex, familiar versus unfamiliar, group membership, kin versus nonkin, and individual recognition. These recognition abilities are crucial for recognizing social partners and discriminating between appropriate and inappropriate ones. Second, animals may know various attributes of individuals. For example, an individual may attend to the dominance status, breeding state, and other attributes of its social partners. Third, some animals are able to track and understand third-party relationships, or how different individuals relate to each other. Understanding of third-party relationships includes cognitive abilities of transitive inference and hierarchical classification.

Individual recognition

This is the most specific type of recognition and has been demonstrated in many species from wasps to hyenas. Cues involved in recognition can be visual, olfactory, acoustic, or tactile. Recognition is most common between mothers and offspring. Mothers and offspring are most likely to recognize each other in species where mothers and offspring must find each other among many other members of their species (e.g., in a herd of ungulates). Many such species have specific mechanisms for improving mother–offspring recognition. For example, the calls of nestling sparrows are more variable (and thus, more identifiable) in colonial nesting species than in solitary nesting species. Recognition also varies adaptively across development. Dolphin mothers give their individually distinct whistles at much higher rates following birth, apparently to help their offspring learn to recognize the vocalization. Furthermore, in primates mother–offspring recognition is strongest at the age when infants first start to leave their mothers and move around independently.

In many species, recognition extends well beyond mother–infant pairs. In nearly all primates, individual recognition typically extends to all the members of the social group and, in some cases, to members of neighboring social groups. Individual recognition is necessary for the types of differentiated relationships observed in primate and other complex societies. Such species appear to have evolved specific mechanisms involved in recognizing others. For example, primates (including humans) and sheep have areas of the brain (in the temporal and medial prefrontal cortices) that are specialized for processing

faces. Additionally, variation across species of wasps suggests that species with dominance hierarchies have the ability to recognize other individuals based on derived facial markings that vary among individuals. Species without hierarchies lack such markings and recognition abilities.

Attribute recognition

Most animals are able to recognize at least some attributes of conspecifics. In some cases, attribute recognition is in addition to individual recognition. However, in other cases, attribute recognition can occur in the absence of individual recognition. For example, the ability for males to detect when females are fertile is widespread in the animal kingdom. Additionally, many species (including plants) show the ability to differentiate kin from nonkin. Individual recognition is not required for either of these tasks as many species differentiate fertile from nonfertile animals and kin from nonkin based on simple cues (such as odors). However, in many animals attribute-recognition involves differentiating aspects of known individuals. For example, many primates appear to both recognize an individual and categorize that individual as kin or nonkin. In species with stable dominance hierarchies, animals must differentiate the animals that rank above and below themselves, and it appears that they do so by recognizing and then categorizing individuals. Furthermore, in some species (e.g., vervets and baboons) animals not only know where they themselves fit into the dominance hierarchy, but they also know exactly where other individuals fit into the dominance hierarchy. For example, an individual (ranked number 15) knows that the third-ranking individual out-ranks the fourth-ranking individual, and so on. Because rank is a relative measure, knowledge of others’ ranks must involve an understanding of third-party relationships (see below).

Third-party relationships

Some animals are sensitive to relationships among others. Such knowledge of third-party relationships is among the most sophisticated forms of social cognition, and it is undoubtedly important for predicting the behavior of social companions. For example, an individual baboon may be less likely to attack a juvenile baboon if the juvenile’s mother is sitting nearby – presumably due to a higher cost (i.e., the mother may retaliate). Third-party information is also necessary for choosing allies in alliance formation. If you are seeking an ally to attack another member of your group, you want to pick an ally that outranks and is unrelated to your opponent.

Some of the earliest evidence for third-party knowledge in animals comes from the work of Dorothy Cheney and Robert Seyfarth on wild vervet monkeys. Responses to playback experiments suggest that vervets know the kin relations of others, even beyond their own family unit.

This ability has now been demonstrated in baboons and hyenas. Captive research on captive primates has additionally shown that long-tailed macaques can learn to match pictures of mothers with their offspring and can generalize this pairing to new mother–infant pairs, suggesting they understand something about the underlying relationship between the animals.

In addition to kinship relations, there is a large body of evidence indicating that primates keep track of the relative dominance ranks of others as well. This ability was first demonstrated in wild baboons and has also been found in several macaque species as well as in hyenas. Captive studies suggest that macaques are very good at list learning and transitive inference – two abilities that might be involved in learning dominance ranks of others in the wild. Recently, it was shown that social corvids (jays) with dominance hierarchies can use transitive inference to infer the ranks of other conspecifics. Other evidence of complex social cognition comes from experiments indicating that baboons simultaneously recognize others' kin and dominance relations and thus appear capable of classifying others hierarchically according to both individual attributes and kin-group membership. Such studies support the hypothesis that sociality is cognitively challenging and can drive cognitive evolution. It is perhaps not surprising that sociality can have such far-ranging consequences given the central role that social relationships play in the lives of animals.

Glossary

Cognition – The process of knowing, perceiving, etc. (Webster).

Emotion – Strong feeling (Webster).

Brain – The central nervous system, where all the processes listed below take place.

Learning – The acquiring of knowledge or skill (Webster).

Memory – The power or act of remembering (Webster).

Mind – Memory, the seat of consciousness in which thinking, feeling, etc., take place (Webster).

Motivation – That which causes one to act (Webster).

Behavioral neuroscience is literally the study of the neural bases of behavior, which forms a major discipline within the field of neuroscience and also within the field of psychology. By the same token, behavioral neuroscience has two historical roots, one in psychology – physiological psychology – and one in the brain sciences.

The great questions of philosophy – the mind–body problem and the nature of knowledge – were also the questions that drove early developments in physiological psychology. Wilhelm Wundt, who founded experimental psychology, entitled his major work *Foundations of Physiological Psychology* (1874; see 1908). William James, the other major figure in the development of modern psychology, devoted a third of his influential text *Principles of Psychology* (1890) to the brain and nervous system. Both Wundt and James studied medicine and philosophy, and both considered themselves physiologists. Their goal was not to reduce psychology to physiology but rather to apply the scientific methods of physiology to the study of the mind. The other driving force in early behavioral neuroscience was the study of the brain and nervous system.

The major topics in modern behavioral neuroscience are the neural bases of learning and memory, motivation and emotion, and cognition. A number of other areas began in behavioral neuroscience and have spun off to become fields in their own right. Thus, ‘sensation and perception’ have become separate fields (e.g., vision, audition, olfaction, etc.). We first sketch very briefly the recent philosophical and physiological roots.

The Mind

The history of such issues as the mind–body problem and epistemology is properly the domain of philosophy. Our focus in this brief section is on the history of the scientific study of the mind, which really began in the nineteenth century.

Psychophysics

Perhaps the first experimental attacks on the nature of the mind were the observations of Weber as generalized by Fechner. Ernst Weber, a physiologist, was attempting in 1834 to determine whether the nerves that respond to the state of the muscles also contribute to judgments about weights. As the reader knows, he found that the “just noticeable difference” (jnd) in weight that could be reliably detected by the observer was not some absolute amount but rather a constant ratio of the weight being lifted. The same applied to the pitch of tones and the length of lines.

Gustav Fechner realized that Weber had discovered a way of measuring the properties of the mind. Indeed, in his *Psychophysics* (1860; see 1966) he felt he had solved the problem of mind and body. He generalized Weber’s observations to state that as the psychological measurement in jnd’s increased arithmetically, the intensity of the physical stimulus increased geometrically – the relationship is logarithmic. Fechner, trained as a physicist, developed the classical psychophysical methods and the concepts of the absolute and differential thresholds. The methods Fechner developed were of great help to the early experimental psychologists like Wundt and his student Tichner in their attempts to measure the attributes of sensation.

Tichner identified the elements of conscious experience as quality, intensity, extensity, protensity (duration), and attensity (clearness) (see Tichner, 1898). But for all their attempts at scientific observation, the basic approach of Wundt and Tichner was introspection, and other observers (e.g., Külpe at Bonn) had different introspections. Edwin Boring studied with Tichner and was for many years chair of the Department of Psychology at

Harvard. He attempted to recast Tichner's views in more modern terms by emphasizing that the dimensions related to discrimination of physical stimuli. His student S.S. Stevens showed that trained observers could reliably form judgments of sounds in terms of pitch, loudness, 'volume,' and 'density.'

Stevens, at Harvard, later introduced an important new method of psychophysics termed direct 'magnitude estimation.' The subject simply assigned a number to a stimulus, a higher one to a more intense stimulus, and a lower number to a less intense stimulus. Somewhat surprisingly, this method gave very reliable results. Using this method, Stevens found that the proper relationship between stimulus intensity and sensation is not logarithmic, as Fechner had argued, but rather a power function: the sensation (i.e., sensory magnitude) equaled the stimulus intensity raised to some power, the exponent ranging from below to above one. This formulation proved very useful in both psycho-physical and physiological studies of sensory processes.

The key point of all this work on psychophysics is of course that it is not necessary to be concerned at all about subjective experience or introspection. The observer simply pushes a button, or states a word or number, to describe his/her judgment of the stimulus. The more the observer practices, the more reliable the judgments become and the more different observers generate the same results. Psychophysics had become purely behavioral.

Signal Detection

The modern era of psychophysics can perhaps be dated to a seminal paper by John Swets in 1961: "Is there a sensory threshold?" His answer was 'no.' He and David Green developed the theory and methodology of signal detection. There is always noise present with signals. When one attempts to detect a signal in noise, the criteria used will determine the outcome. This approach has proved immensely useful in fields ranging from the telephone to psychophysical studies in animals to detection of structural failures in aircraft wings to detection of breast cancer. But where is the mind in decision theory? It has disappeared. The initial hope that psychophysics could measure the mind has been reduced to considerations of observer bias. A similar conclusion led to the downfall of introspection.

The Brain

In the nineteenth century, debate focused on how mental activities (or cognitive processes) are organized in the brain. An early idea, which became known as the localizationist view, proposed that specific mental functions were carried out by specific parts of the brain. An alternative idea, which became known as the equipotential view, held

that large parts of the brain were equally involved in all mental activity and that there was no specificity of function within a particular brain.

The 'Thinking Machine' to Phrenology

Our concepts of mind, soul, body, and brain relationships come from a long history, and for the Western world, from a long battle between church dogma and progress of science. During the Renaissance, physicians began to explore the body. They dissected the brain and described it similarly to the other organs, emphasizing an intestine-like, random appearance of the convolutions. A landmark conceptual advance was René Descartes, who conceived of the 'thinking machine' (*la machine pensante*) about a hypothetical machine in the brain. In his treatise *De Homine* (1632–33) he wrote: I would like you to consider that all the functions I have allocated to this machine all depend by nature from the arrangement of the organs – – no more no less as the movements of a clock do, or an automaton moved by its counterweights and its cog-wheels – ... so that we do not have to conceive in the inner world of the body a soul or any other principle of movement or of life... other than of its blood and its spirits moved by the heat of the fire that burns permanently in the blood and that is not of a different nature of what exists in the inanimate matters". And also "... I suppose that our body is nothing else than a statue or a machine made of organic substances..." To move this thinking machine, and to be in accordance with the church, Descartes argued that the soul was necessary, but he put it in the pineal gland, a convenient organ in the middle of the brain and on its surface... and close to the ventricles. At that time, the ventricles were where the 'functional regions' for all of the faculties were organized, and the part of that brain was considered the common site for the sensations, reason, and memory. The sensations were created in the first 'cell' of the ventricles; they were transformed in the second cell (reasoning); and what remained was placed in the third cell (memory). For the Catholic Church to integrate and incorporate the soul was too much, and Descartes had to escape to Amsterdam to save his life.

A very important transition was the work of Nicolas Stenon (1638–86), one of the greatest and most famous anatomists of his time. He stated in a meeting in Paris as part of a strong critique of the pineal gland hypothesis, "There are only two ways to succeed in the knowledge of the machine in the brain: either the Master who conceived it deliver to us His secret for this ingenious device, or we dismantle piece by piece all its springs and examine them separately, exactly as we do for the other machines, and then, in a second time we will consider what these pieces can do as they work together". From that point, an enormous effort began to understand and

describe the different pieces of the brain and attribute functions to those pieces. Thus, by the eighteenth century, the search for the role and function of the small machines in the brain were already underway, supported by materialist and monist (as opposed to dualist) points of view.

Perhaps the most influential idea about localization of brain function derived from Franz Joseph Gall during the early part of the nineteenth century. Gall's insight was that, despite its similarity in appearance, brain tissue was not equipotential but instead was actually made up of many discrete areas that had different and separate functions. Eventually, Gall was able to characterize 27 different regions, or organs, of the brain in a scheme that he called organology. (Later, the term 'phrenology' came to be associated with Gall's work.) However, this term was coined by Gall's colleague, Spurzheim, with whom he had a falling out, and Gall himself never used the term.

Gall's ideas about the localization of cognitive functions began to tear at the religious and social fabric of the nineteenth century. In particular, his notion that various mental faculties were represented in different places in the brain was seen by various governmental and religious authorities as being in conflict with moral and religious views of the unity of the soul and mind. (In some ways this is reminiscent of current attacks on evolution by fundamentalist religious groups.)

Gall's theory had a limited factual basis. The way in which Gall had determined the locus and extent of each of the 27 organs was questionable, to say the least. Another scientific issue raised by critics during the nineteenth century was the fact that Gall never specified the precise extent or the anatomical borders of any of the organs. This lack of rigor, it was argued, made it impossible to correlate a specific faculty with the size of an organ or cranial capacity. Related criticisms involved Gall's seeming failure to acknowledge that there were variations in the thickness of the skull (i.e., variations from one individual specimen to another and from one locus to another within the same skull).

In a sense, Gall seemed to be vindicated in 1861 with the publication of Broca's discovery of the anterior speech area, now termed Broca's area, in his study of the patient Monsieur Leborgne. (This patient subsequently was referred to by the name 'Tan,' the only utterance Broca ever heard Monsieur Leborgne make; [Broca 1861](#).) Broca's finding from his patient Tan has been regarded by some historians as the most important clinical discovery in the history of cortical localization. Moreover, within the decade, what some historians regard as the most important laboratory discovery pertaining to cortical localization was reported (i.e., Gustav Fritsch and Eduard Hitzig discovered the cortical motor area in the dog). This proved that cortical localization was not restricted to a single function. The discoveries of the

speech area by Broca and the motor area by Fritsch and Hitzig were seen as support for Gall's ideas and reestablished him as the father of localization.

Evolution of Phrenology

Thus, phrenology continued into the nineteenth century from the early arguments that: (1) the mental functional organs definitively migrate from the ventricle to the gray substance, the "cerebral lobes" and (2) "attention, memory, imagination . . . are not primary faculties of mind BUT solely forms of activities of any intellectual faculty." Phrenology has been at the origin of a 'vertical' and a modular organization of the brain, one with the definitive implementation of the mind into matter. Paul Broca inherited directly from these hypotheses. A second phrenological revolution came with Wernike when he claimed that aphasia resulted from (dis)connections between modules and then evolved the modern hypothesis of function resulting from connections and fibers.

Phrenology further matured into the pursuit of function during the twentieth century. Spearman (1937) argued that "the basic idea of the scientific enterprise consists in reducing the countless actual activities to a small number of underlying separable principles named faculties or capacities."

Herbert Simon argued in his parable of the two watch makers, Hora and Tempus, "The time required for the evolution of a complex form from simple elements depends critically on the number and potential intermediate stable forms." David Marr (1976) stated, "A large computation should be split as a connection of small subparts that are as clearly independent of one another as the overall task allows . . . if not, a small change in one place will have consequences in many other places."

Following the pioneering study by [Fritsch and Hitzig \(1870\)](#) on the localization and organization of the motor area of the cerebral cortex, localization of function quickly won the day, at least for sensory and motor systems. In the last three decades of the nineteenth century, the general locations of the visual and auditory areas of the cortex were identified. The field of physiology, in particular neurophysiology, for example, in the work of Sir Charles Sherrington, together with clinical neurology and neuroanatomy, were exciting new fields at the beginning of the twentieth century.

At this time, the only experimental tools for studying brain organization and functions were ablation and electrical stimulation. Neuroanatomy was in its descriptive phase; thanks in part to the Golgi method, the monumental work of Ramon y Cajal was completed over a period of several decades beginning near the end of the nineteenth century. Neurochemistry was in its descriptive phase, characterizing chemical substances in the brain.

Finally, the birth of neuropsychopharmacology, involving the discovery of the first antipsychotic and then of the biogenic amines in Sweden (1963–1964), has stimulated much research in the realm of ‘brain and behavior,’ leading to a sort of parallel ‘chemical phrenology.’ While it is now clear that the highly distributed monoamine systems have more specific actions related to the regions of the brain they innervate, residual roles for serotonin in depression, dopamine in incentive salience, and norepinephrine in arousal still carry significant weight today.

Neurophysiology

The first recording of a nerve action potential with a cathode ray tube was done by Gasser and Erlanger in 1922, but the method was not much used until the 1930s. The human EEG was rediscovered in 1929 by H. Berger, and the method applied to animal research and human clinical neurology, particularly epilepsy, in the 1930s, for example, by Alexander Forbes, Hallowell Davis, and Donald Lindsley.

The pioneering studies of Adrian in England (1940) and of Wade Marshall, Clinton Woolsey, and Philip Bard (1941) at Johns Hopkins were the first to record electrically evoked potentials from the somatic sensory cortex in response to tactile stimulation. Woolsey and his associates developed the detailed methodology for evoked potential mapping of the cerebral cortex. In an extraordinary series of studies, Woolsey and his colleagues determined the localization and organization of the somatic sensory areas, the visual areas, and the auditory areas of the cerebral cortex in a comparative series of mammals. They initially defined two projection areas (I and II) for each sensory field (i.e., two complete functional maps of the receptor surface were found for each sensory region of the cerebral cortex; e.g., two complete representations of the skin surface in the somatic–sensory cortex).

In the 1940s and 1950s, the evoked-potential method was used to analyze the organization of sensory systems at all levels, from the first-order neurons to the cerebral cortex. The principle that emerged was strikingly clear and simple: in every sensory system, the nervous system maintained receptorotopic maps or projections at all levels from receptors (skin surface, retina, and basilar membrane) to cerebral cortex. The receptor maps in the brain were not point-to-point; rather they reflected the functional organization of each system (fingers, lips, and tongue areas were much enlarged in primate somatic cortex; half the primary visual cortex represented the fovea, and so on).

The Microelectrode

The evoked potential method was very well suited to analysis of the overall organization of sensory systems in

the brain. However, it could reveal nothing about what the individual neurons were doing. This had to await development of the microelectrode (a very small electrode that records the activity of a single cell). Indeed, the microelectrode has been the key to analysis of the fine-grained organization and ‘feature detector’ properties (most neurons respond only to certain aspects or features of a stimulus) of sensory neurons. The first intracellular glass pipette microelectrode was actually invented by G. Ling and R.W. Gerard in 1949 – they developed it to record intracellularly from frog muscle.

Metal electrodes were generally found to be preferable for extracellular single-unit recording (i.e., recording the spike discharges of a single neuron where the tip of the microelectrode is outside the cell but close enough to record its activity clearly). Metal microelectrodes were improved in the early 1950s. R.W. Davies at Hopkins developed the platinum–iridium glass coated microelectrode, and D. Hubel and T. Wiesel at Harvard developed the tungsten microelectrode. The search for putative stimulus coding properties of neurons was on. The pioneering studies were those of V. Mountcastle and associates at Hopkins on the organization of the somatic–sensory system, those of [Hubel and Wiesel \(1959\)](#) at Harvard on the visual system, and J.E. Rose, J.E. Hind, C.N. Woolsey, and associates at Wisconsin on the auditory system.

Thanks to the microelectrode and the careful and painstaking studies of a number of investigators, we now know that each sensory ‘area’ of the cerebral cortex consists of a number of subfields, separate areas coding different aspects of the stimulus. There are now more than 30 functionally distinct areas within the visual cortex of monkey and human (Zola-Morgan, 1995). This is localization of function with a vengeance!

It was not until many years later that imaging methods were developed to study the organization and functions of the normal human brain (see below). Heroic studies had been done on human brain functioning much earlier in neurosurgical procedures (heroic both for the surgeon and the patient; e.g., Penfield and Rasmussen, 1950). However, these patients typically suffered from severe epilepsy. The development of positron emission tomography (PET), functional magnetic resonance imaging (fMRI), and other modern techniques is largely responsible for the current explosion of information in cognitive neuroscience (see below).

Learning and Memory

Karl Lashley is the most important figure in the development of physiological psychology and the biology of memory in America. He obtained his PhD at Johns Hopkins University. At Hopkins, he studied with John

Watson and was heavily influenced by Watson's developing notions of behaviorism. While there he also worked with Sheherd Franz at a government hospital in Washington – they published a paper together in 1917 on the effects of cortical lesions on learning and retention in the rat. Lashley then held teaching and research positions at the University of Minnesota (1917–26), the University of Chicago (1929–35), and then at Harvard from 1935 until his death in 1958. During the Harvard years, he spent much of his time at the Yerkes Primate Laboratory in Orange Park, Florida.

Lashley devoted many years to an analysis of brain mechanisms of learning, using the lesion-behavior method, which he developed and elaborated from the work with Franz. During this period, Lashley's theoretical view of learning was heavily influenced by two congruent ideas: localization of function in neurology and behaviorism in psychology. Lashley describes the origins of his interest in brain substrates of memory and Watson's developing views of behaviorism in the following letter written to Ernest Hilgard in 1935:

In 1914, I think, Watson called attention of his seminar to the French edition of Bechtereve, and that winter the seminar was devoted to translation and discussion of the book. In the spring I served as a sort of unpaid assistant and we constructed apparatus and planned experiments together. We simply attempted to repeat Bechtereve's experiments. We worked with withdrawal reflexes, knee jerk, pupil. Watson took the initiative in all this, but he was also trying to photograph the vocal cord, so I did much of the actual experimental work. I devised drainage tubes for the parotid and submaxillary ducts and planned the salivary work which I published. As we worked with the method, I think our enthusiasm for it was somewhat dampened. Watson tried to establish conditioned auditory reflexes in the rat and failed. Our whole program was then disrupted by the move to the lab in Meyer's clinic. There were no adequate animal quarters there. Watson started work with the infants as the next best material available. I tagged along for awhile, but disliked the babies and found me a rat lab in another building. We accumulated a considerable amount of experimental material on the conditioned reflex which has never been published. Watson saw it as a basis for a systematic psychology and was not greatly concerned with the nature of the reaction itself. I got interested in the physiology of the reaction and the attempt to trace conditioned reflex paths through the nervous system started my program of cerebral work. (Letter of May 14, 1935, K.S. Lashley to E.R. Hilgard, reproduced with the kind permission of E.R. Hilgard).

It was in the previous year, 1913, that Watson published his initial salvo in an article entitled, "Psychology

as the behaviorist views it." He was elected President of the American Psychological Association in 1914.

As we noted earlier, localization of function in the cerebrum was the dominant view of brain organization at the beginning of the twentieth Century. In Watson's behaviorism, the learning of a particular response was held to be the formation of a particular set of connections, a series set. Consequently, Lashley argued, it should be possible to localize the place in the cerebral cortex where that learned change in brain organization was stored – the engram. (It was believed at the time that learning occurred in the cerebral cortex.) Thus, behaviorism and localization of function were beautifully consistent; they supported the then notion of an elaborate and complex switchboard where specific and localized changes occurred when specific habits were learned.

Lashley set about systematically to find these learning locations – the engrams – in a series of studies culminating in his 1929 monograph *Brain Mechanisms of Intelligence*. In this study, he used mazes differing in difficulty and made lesions of varying sizes in all different regions of the cerebral cortex of the rat. The results of this study profoundly altered Lashley's view of brain organization and had an extraordinary impact on the young field of physiological psychology. The locus of the lesions is unimportant; the size is critically important, particularly for the more difficult mazes. These findings led to Lashley's two theoretical notions of equipotentiality and mass action (i.e., all areas of the cerebral cortex are equally important, at least in maze learning; what is critical is the amount removed).

Lashley's interpretations stirred vigorous debate in the field. Walter Hunter, an important figure in physiological-experimental psychology at Brown University who developed the delayed response task in 1913, argued that in fact the rat was using a variety of sensory cues – as more of the sensory regions of cortex were destroyed, fewer and fewer cues became available. Lashley and his associates countered by showing that removing the eyes has much less effect on maze learning than removing the visual area of the cortex. Others argued that Lashley removed more than the visual cortex. Out of this came the long series of lesion-behavior studies analyzing behavioral 'functions' of the cerebral cortex. Beginning in the 1940s, several laboratories, including Lashley's and those of Harry Harlow at the University of Wisconsin and Karl Pribram at Yale, took up the search for the more complex functions of association cortex using monkeys and humans.

Lashley's pessimistic conclusions in his 1929 monograph subsequently put a real but temporary damper on the field concerned with brain substrates of memory:

This series of experiments has yielded a good bit of information about what and where the memory trace is

not. It has discovered nothing directly of the real nature of the memory trace. I sometimes feel, in the reviewing the evidence of the localization of the memory trace, that the necessary conclusion is that learning is just not possible. It is difficult to conceive of a mechanism that can satisfy the conditions set for it. Nevertheless, in spite of such evidence against it, learning sometimes does occur. (Lashley, 1950, pp. 477–478).

Milner and H.M.

Perhaps the most important single discovery in this field is Brenda Milner's studies with patient H.M. who, following bilateral temporal lobectomy (removing the hippocampus and other structures), lived forever in the present (see below). Work on higher brain functions in monkeys and humans is one of the key roots of modern cognitive neuroscience, to be discussed below. Since the discovery of H.M., the hippocampus has been of particular interest in biological psychology. Another facet of hippocampal study in the context of the biological psychology of memory is long-term potentiation (LTP), discovered by Bliss and Lomo (1973). Brief tetanic stimulation of monosynaptic inputs to the hippocampus causes a profound increase in synaptic excitability that can persist for hours or days. Many view it as a leading candidate for a mechanism of memory storage, although direct evidence is still lacking.

Yet another impetus to the study of the hippocampus is the remarkable discovery of 'place cells' by John O'Keefe (see O'Keefe, 1979). When recording from single neurons in the hippocampus of the behaving rat, a given neuron may respond only when the animal is in a particular place in the environment (e.g., in a box or maze), reliably and repeatedly. There is great interest now in the possibility that LTP may be the mechanism that forms place cells. A number of laboratories are making use of genetically altered mice to test this possibility.

Riesen and Hebb

Lashley's influence is felt strongly through the many eminent contemporary physiological psychologists who worked or had contact with him. We select two examples here: Austin Riesen and Donald O. Hebb. The basic problem of the development of perception fascinated Lashley and his students. How is it that we come to perceive the world as we do? Do we learn from experience, or is it told to us by the brain? Riesen did the pioneering studies of raising monkeys for periods of time in the dark and then testing their visual perception. They were clearly deficient.

This important work served as one of the stimuli for Donald Hebb to develop a new theory of brain

organization and function, *The Organization of Behavior*, published in 1949. This book had an immediate and profound impact on the field. Hebb effectively challenged many traditional notions of brain organization and attempted to pull together several discordant themes – mass action and equipotentiality, the effects of dark rearing on perception, the preorganization of sensory cortex, the lack of serious intellectual effects of removal of an entire hemisphere of the brain in a human child – into a coherent theory. Important influences of Gestalt notions can be seen in Hebb's theory. He is a connectionist but in a modern sense – connections must underlie brain organization, but there is no need for them to be in series.

One concept in Hebb's book has come to loom large (too large perhaps) in modern cognitive-computational neuroscience: The Hebb synapse:

When an axon of cell A is near enough to excite a cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that A's efficiency, as one of the cells firing B, is increased (Hebb, 1949, p. 62).

Pavlov and Classical Conditioning

But there were other major traditions developing. Perhaps the most important of these was the influence of Pavlov. His writings were not readily available to Western scientists, particularly Americans, until the publication of the English translation of his monumental work *Conditioned Reflexes* in 1927. It is probably fair to say this is the most important single book ever published in the field of behavioral neuroscience. Pavlov developed a vast and coherent body of empirical results characterizing the phenomena of conditioned responses, which he termed "psychic reflexes." He argued that the mind could be fully understood by analysis of the higher order learned reflexes and their brain substrates. As an example of his influence, Clark Hull, in his *Principles of Behavior* (1943) wrote as though he were a student of Pavlov.

W. Horsley Gantt, an American physician, worked with Pavlov for several years and then established a Pavlovian laboratory at Johns Hopkins. He trained several young psychologists (e.g. Roger Loucks and Wulf Brodgen) who became very influential in the field. Perhaps the most important modern behavioral analyses of Pavlovian conditioning are the works of Robert Rescorla and Allan Wagner (e.g., Rescorla and Wagner, 1972).

Although Pavlov worked with salivary secretion, most studies of classical conditioning in the West tended to utilize skeletal muscle response, a la Bechtereiv. Particularly productive have been Pavlovian conditioning of discrete skeletal reflexes (e.g., the eyeblink response)

characterized behaviorally by Isadore Gormezano and Allan Wagner and analyzed neuronally by Richard Thompson and his many students, showing localization of the basic memory trace to the cerebellum, specifically the cerebellar interpositus nucleus (Thompson, 1986; Christian and Thompson, 2003). Masao Ito and associates in Tokyo had discovered the phenomena of long-term depression (LTD) in the cerebellar cortex (see Ito, 1984). Repeated conjunctive stimulation of the two major inputs to the cerebellum, mossy-parallel fibers and climbing fibers, yields a long-lasting decrease in the excitability of parallel fibers – Purkinje neuron synapses. Ito developed considerable evidence that this cerebellar process underlies plasticity of the vestibular–ocular reflex. Thompson and associates developed evidence, particularly using genetically altered mice, that cerebellar cortical LTD is a key cortical mechanism modulating classical conditioning of eyeblink and other discrete responses.

Fear Conditioning and Consolidation

Fear conditioning was characterized behaviorally by Neal Miller and analyzed neuronally by several groups, particularly Michael Davis (1992), Joseph LeDoux (2000), and Michael Fanselow (1994) and their many students. They showed that at least for classical conditioning of fear, the essential structure is the amygdala, which may contain the basic memory trace for this form of learning. The process of LTP may serve to code the amygdalar fear memory.

Duncan's discovery of the effects of electroconvulsive shock on retention of simple habits in the rat, in 1949, began the modern field of memory consolidation. Hebb and Gerard were quick to point out the implication of two memory processes, one transient and fragile and the other more permanent and impervious. McGaugh and his associates have done the classic work on the psychobiology of memory consolidation (McGaugh, 1989). McGaugh and his colleagues introduced posttraining treatment and demonstrated memory facilitation with drugs and showed that these effects were not due to effects on performance or to possible reinforcement effects of the drugs (and similarly for impairment due to electroconvulsive shock (ECS) impairment).

The amygdala is critical for instrumental learning of fear. James McGaugh and his associates demonstrated that for both passive and active avoidance learning (animals must either not respond, or respond quickly, to avoid shock), amygdala lesions made immediately after training abolished the learned fear. Surprisingly, if these same lesions were made a week after training, learned fear was not abolished, consistent with a process of consolidation (see McGaugh, 2000). The apparent difference in the role of the amygdala in classical and instrumental learning of fear remains a puzzle to this day.

Chemical approaches to learning and memory are recent. The possibility that protein molecules and RNA might serve to code memory was suggested some years ago by such pioneers as Gerard and Halstead. The RNA hypothesis was taken up by Hyden and associates in Sweden and by several groups in America. An unfortunate by-product of this approach was the ‘transfer of memory’ by RNA. These experiments, done by investigators who shall remain nameless, in the end could not be replicated.

At the same time, several very productive lines of investigation of neurochemical and neuroanatomical substrates of learning were developing. In 1953, Krech and Rosenzweig began a collaborative study of relationships between brain chemistry and behavior. Krech did classic early work in animal learning (under his earlier name, Kreshevsky) and was a colleague and collaborator with Tolman. Soon after they began their joint work in 1953, they were joined by E.L. Bennett and later by M.C. Diamond. Their initial studies concerned brain levels of acetylcholinesterase in relation to the hypothesized behavior and included analysis of strain differences (see Krechel *et al.*, 1960). They discovered the striking differences in the brains of rats raised in ‘rich’ versus ‘poor’ environments. William Greenough (1984), at the University of Illinois, replicated and extended this work to demonstrate dramatic morphological changes in the structures of synapses and neurons as a result of experience.

Where does the field now stand relative to the key issue of the localization of function, in this case of memory traces, the neuronal substrates for memory? It is now clear that memory traces for more elementary forms of learning and memory do have specific loci in the brain. The memory traces for classical conditioning of eyeblink and other discrete responses are stored in localized regions of the cerebellum. The traces for fear conditioning appear to be stored in localized regions of the amygdala. But for more complex forms of learning, the answer is still out. Certain brain structures (e.g., hippocampus) are critical for initial learning of declarative memories (e.g., experiential and semantic memories; see below) but the memory traces are not stored permanently there, but rather hypothesized to be stored in the cerebral cortex. Hebb's notion of distributed sets of traces, each with some specificity, but overlapping among the neurons of the cerebral cortex, continues to have appeal. This is high on the agenda for the next generation of behavioral neuroscientists to solve.

Model Systems

The use of model biological systems has been an important tradition in the study of neural mechanisms of elementary forms of behavioral plasticity and learning.

This approach has been particularly successful in the analysis of habituation – itself a very simple form or model of learning (see article on habituation). Sherrington did important work on flexion reflex ‘fatigue’ in the spinal animal at the turn of the century. In 1936, Prosser and Hunter completed a pioneering study comparing habituation of startle response in intact rat and habituation of hindlimb flexion reflex in spinal rat. They established, for habituation, the basic approach of Sherrington, namely that spinal reflexes can serve as models of neural–behavioral processes in intact animals. Sharpless and Jasper (1956) established habituation as an important process in electroencephalographic (EEG) activity. Modern Russian influences have been important in this field – the key studies of Evgeny Sokolov (1963), first on habituation of the orienting response in humans and more recently on mechanisms of habituation of responses in the simplified nervous system of the snail.

The defining properties of habituation were clearly established by Thompson and Spencer in 1966, and the analysis of mechanisms began. Several laboratories using different preparations – *aplysia* withdrawal reflex (e.g., Kandel and his many associates; see Kandel, 1976), vertebrate spinal reflexes (e.g., Thompson, Spencer, and Farel), crayfish tail flip escape (e.g., Krasne and Kennedy; see Krasne, 1969) – all arrived at the same underlying synaptic mechanism for short-term, within-session habituation, a decrease in the probability of transmitter release from presynaptic terminals in the habituating pathway. Habituation, at least short-term habituation, is thus a very satisfying field. Agreement ranges from defining behavioral properties to synaptic mechanisms. However, the mechanisms underlying long-term, between-session habituation are not yet known (Ezzeddine and Glanzman, 2003).

History of Motivation and Emotion

Emotion can be defined as “a psychic and physical reaction (as anger or fear) subjectively experienced as strong feeling and physiologically involving changes that prepare the body for immediate vigorous action” (*Webster’s Ninth New Collegiate Dictionary*, 1984). Although the introspective emphasis on the ‘feeling’ aspect of emotions played a prominent role in the development of many theories of emotion, much progress in the neurobiology of emotion has been made with the experimental analysis of behavioral phenomena objectively defined. Indeed, Darwin argued as early as 1872 that both observable expressions of emotions as well as underlying brain processes (direct action of the excited nervous system on the body are not unique to humans) (Darwin, 1872). Key emotional expressions were considered innate, instinctive

recognition of expression but subject to the evolutionary process:

That the chief expressive actions, exhibited by man and by the lower animals, are now innate or inherited – that is, have not been learnt by the individual – is admitted by every one. So little has learning or imitation to do with several of them that they are from the earliest days and throughout life quite beyond our control; for instance, the relaxation of the arteries of the skin in blushing, and the increased action of the heart in anger (Darwin, 1872, chapter 14).

Emotions: The Search for Biological Bases

Historically, for emotional behavior, the measurement of bodily changes associated with emotional behavior focused on a peripheral response mechanism largely related to the autonomic and endocrine system. Peripheral measures of emotion ranged from galvanic skin responses to heart rate to salivary secretion to levels of autonomic hormones. Consistent with a key role of peripheral physiological variables was the famous William James theory of emotion in which he argued, “Bodily changes follow directly the *perception* of the exciting fact, and that our feeling of the same changes as they occur in *is* the emotion” (James, 1884, p. 189–190).

Nevertheless the brain was pulled into serious consideration as a key mediator of emotion by parallel advances in conceptual framework, neuroanatomy, and actual experimental studies, some of which were initiated early in the history of behavioral neuroscience. In the latter half of the nineteenth century, Ferrier (1875) showed that orbitofrontal ablations in monkeys had no major effect on an organism’s sensory abilities but produced a definite change in the disposition of the animal. Broca (1878) described the “grand lobe limbique” (limbic indicates that this lobe surrounds the brain stem) which included the olfactory tubercle, prepyriform cortex, diagonal band of Broca, septal region, hippocampus, and cingulate as a common circuit in all mammals. Brown and Shafer (1888) showed that certain brain areas, such as the temporal lobe, were involved in emotion in which lesions of the temporal lobe in rhesus monkeys again had little effect on sensory abilities but produced a loss of ‘intelligence.’ The demonstration of decorticate ‘sham rage’ in the 1920s led to the hypothesis that emotional expression involved specific subcortical structures. Lesion studies led the way, followed later by stimulation studies by Hess, Ranson, and Masserman, all of which pointed to subcortical structures, such as the hypothalamus, soon to be labeled ‘limbic’ structures in the neural circuitry of the expression of emotional responses.

Early on, Cannon argued against the James-Lange theory, largely on the basis of the observation that animals continued to express emotional behavior in the absence of information from the periphery. Later, he hypothesized that emotional experience and emotional behavior were a release from cortical inhibition of neural impulses originating in the thalamus (Cannon, 1927, p. 120). Bard removed the neocortex of cats, leaving the rhinencephalon intact, which produced placidity that could be changed to ferocity by removal of the amygdaloid complex (Bard, 1951). Bard's extensive work made modifying Cannon's theory possible so that it could better define the neurocircuitry of emotional behavior.

A key influential study in 1937 by Kluver and Bucy found dramatic emotional changes with extensive temporal lobe lesions in rhesus monkeys, in which normally intractable animals became tame and friendly, were compulsively mouthing anything, and were markedly hypersexual. Concurrently, the elaboration of the now famous Papez circuit was proposed in 1937 as a circuit for emotion and evolved into the terminology and conceptual framework of the limbic system which remains today. The Papez circuit, discovered by injecting rabies virus into the cat hippocampus and monitoring its progression, included the hippocampus, mammillary bodies, anterior thalamus, cingulate gyrus, and parahippocampal gyrus. It was one of the first organized attempts to delineate cortical mechanisms involved in emotion. Thus, the limbic system came to represent not only Broca's 1878 grand lobe limbique, but also most allocortical regions of the brain from the Papez circuit, and from the conceptualizations of MacLean (1949) the amygdala and the hypothalamus for emotional expression. Brain circuitry explorations of emotion via interventions (lesions) evolved into more modern approaches, such as neuropharmacological challenges and probes and imaging of the human brain.

Recent Perspectives of the Biological Bases of Emotion

Key conceptual advances that laid the foundation for the modern neuroscience of emotion was the suggestion by Schachter and Singer (1962) that cognitive factors may be major determinants of emotional states. More specifically, they showed that cognition arising from the immediate emotional experience, as interpreted by past experience, provides the framework for labeling one's feelings, and thus cognition determines whether a state of physiological arousal will be labeled as a given emotion. Schachter in fact predicted the direction of research on emotion:

We will be forced to deal with concepts about perception, about cognition, about learning, and about the social situation. We will be forced to examine a subject's perception of his bodily state and his interpretation of it in

terms of his immediate situation and his past experience (Schachter, 1975, p. 561).

A strong argument for a biological basis for emotion also came from the pioneering studies of Ekman and Friesen (1986), in which a universality of six emotions was proposed based on extensive cross-cultural work on facial expression: happiness, surprise, fear, sadness, anger, and disgust combined with contempt. Ekman hypothesized distinctive patterns of central nervous system activity. A watershed translational approach far ahead of the field was the pioneering work of Jaak Panksepp identifying similar emotional states in rodents, including distress, anger, social bonding, play, and laughter (Panksepp, 1998). Others, such as Russell (2003), have eschewed a specific categorization of emotion and argued that any emotionally charged event is a state experienced as simply feeling good or bad, energized or enervated – in other words, a free-floating mood or core affect that is subject to interpretation by the perception of affective quality. In this context, the modern somatic marker hypothesis of Damasio (1996) in a sense validates some aspects of the original James-Lange theory in which decision-making is a process that is influenced by marker signals that arise in bioregulatory processes, including those that express themselves in emotions and feelings.

Brain Imaging and Emotion

Modern brain imaging studies have not only confirmed earlier work from lesion studies but are extending the circuitry to domains of emotion previously inaccessible in animal studies. Morris *et al.* (1996) showed that the amygdala in humans responds differentially in subjects shown facial expressions of fear and happiness, with the neuronal response in the left amygdala significantly greater to fearful versus happy faces. Damasio (2002) in a series of studies has argued that the term 'emotion' should be defined as specific and consistent collections of physiological responses triggered by certain brain regions when the organism is presented with a certain situation. The substrates for the representation of emotions include homeostatic circuitry in the brainstem, hypothalamus, basal forebrain, amygdala, ventromedial prefrontal cortex, and cingulate cortex. By contrast, Damasio defined 'feelings' as the mental states that arise from the neural representation of the collection of responses that constitute an emotion, and as such should be reserved for the private, mental experience of an emotion. Key structures involved in feelings, he argued, include the brainstem, hypothalamus, thalamus, cingulate, somatosensory cortices of the insula, and somatosensory I and II, and to monitor cognitive processing, the prefrontal cortex is engaged. This approach has led to arguments in which specific brain systems,

including the posteromedial cortices (precuneus, posterior cingulated cortex, and retrosplenial region) and anterior insula, are recruited in addition to the basic homeostatic circuitry for specific types of emotions, such as social emotions (e.g., admiration and compassion):

Overall, the finding that homeostatic regulatory mechanisms are engaged in the experience of admiration and compassion supports the hypothesis that social emotions use some of the same basic devices involved in primary emotions (Moll *et al.*, 2005) and the salience system (Seeley *et al.*, 2007) (Immordino-Yang *et al.*, 2009, p. 8024).

Behavioral Analysis of Emotion: Bridge to Motivation

The role of emotion in motivation also profited from conceptual and experimental advances. The behavioral analysis of motivational and emotional interactions championed by Brady (1978) led to a response-inferred foundation for a unifying operational framework relating motivational and emotional function that fueled the dramatic advances forming the experimental analysis of behavior:

Even the ‘hedonic’ characteristics of motivational functions can be accommodated within the empirical framework of this conceptual analysis by appealing to the experimentally based distinctions between ‘positive’ and ‘negative’ reinforcement operations. The evident byproducts (e.g., ‘euphoria’) of ‘appetitive’ consequating relations which increase the likelihood of behavior, on the one hand, and the ‘dysphoric’ accompaniments of ‘aversive’ consequences which weaken behavior (or strengthen escape and avoidance performances), would seem to provide a fruitful point of departure for the experimental analysis of this eudaemonic dimension (Brady and Emurian, 1978, p. 83).

Here, the basic building blocks are the contingencies relating ‘occasions’ and their ‘consequences’ (three-term contingency of Skinner: occasion, behavior, and consequences), and thus a motivational function would be any operation that would affect the potency of the ‘consequences’ (e.g., food deprivation potentiates the consequence or increases the likelihood of consummatory behaviors). Under this formulation, the analysis of emotional function focuses on procedures that affect the efficacy of occasioning events or enhance the discriminability of occasioning events in the occasion component of the contingency (e.g., startle effects may disrupt the occasioning situation and decrease the likelihood of a consummatory behavior). Such emotional functions emphasize the prominent role of inner events (e.g., feelings), and as such, terms related to hedonic function can be accommodated in terms of positive reinforcement, negative reinforcement, and punishment. Thus, the hedonic dimension of Brady’s

“behavioral universe” refers primarily to the affective valence of the bridge between emotion and motivation. Indeed, emotions are often linked to motivation but not necessary for motivation.

History of Motivation

Consistent with this view, an early motivational theory involving a key emotional component was the Miller (1948) and Mowrer (1950) two-process fear theory in which fear consisted of “an innate (internal) response to certain stimuli, such as pain, and the fear response innately produces the fear stimulus, just as electric shock produces pain”; or, in other words, the conditioned stimulus serves as a danger signal and elicits a state which has been described as fear. For example, a conditioned stimulus that produces fear then elicits a fear-reducing response, and the fear emotion is an explicit part of the motivation needed for conditioned response learning. Finally, Olds and Milner (1954) discovered that electrical stimulation of the medial forebrain bundle was highly rewarding to animals, providing a key experimental bridge of the neurobiology of emotion with the neurobiology of motivation. Early on theorists such as J. Anthony Deutsch argued that brain stimulation reward activated two pathways: a pathway conveying reinforcement and a pathway conveying excitation (motivation), another early link between emotion (hedonic function) and motivation (Deutsch, 1960).

Motivation, similar to emotion, is a concept that has many definitions. An early definition reflected the mixed dualism of later theories. Motivation was defined as “an inner psychological process or function, a driving force to be found chiefly within the organism itself and a plan, purpose or ideal with the definite implication of an ideational element,” that may not be consciously and overtly recognized (Perrin, 1923). Hebb argued that motivation is “stimulation that arouses activity of a particular kind” (Hebb, 1949), and Richter argued that “spontaneous activity arises from certain underlying physiological origins and such ‘internal’ drives are reflected in the amount of general activity” (Richter, 1927). Bindra defined motivation as a “rough label for the relatively persisting states that make an animal initiate and maintain actions leading to particular outcomes or goals” (Bindra, 1976). A more behavioristic view is that motivation is “the property of energizing behavior that is proportional to the amount and quality of the reinforcer” (Kling and Riggs, 1971). Finally, a more neurobehavioral view is that motivation is a “set of neural processes that promote actions in relation to a particular class of environmental objects” (Bindra, 1976).

These definitions trace the history of motivation and point to certain common characteristics of our concept of motivation. It is a state that varies with arousal and guides

behavior in relationship to changes in the environment. The environment can be external (incentives) or internal (central motive states or drives), and such motivation or motivational states are not constants and vary over time.

Influential Theories of Motivation

An early and influential theory of motivation by Hull (1943), termed the ‘drive-reduction theory,’ was predicated on the hypothesis of homeostatic mechanisms of motivation in which behavior could be regarded as an outward expression of the organism’s pursuit of biological health. Here, all motivation was theorized to derive from biological imbalances or needs. A need in this formulation, such as hunger (here, the need is for more energy), was a biological requirement of the organism. Motivation, according to Hull, then aimed at making up for or erasing a deficiency or lack of something in the organism. The word ‘drive’ was used to describe the state of behavioral arousal resulting from a biological need and was the energy that powered behavior. The animal searched for food to reduce the hunger drive. Hull theorized that the animal would repeat any behavior that reduced a drive, whenever such a need arose again. Drive-reduction theory was not supported by most research because it became clear that many of its tenets were unsupported. In particular, much motivated behavior could be generated without any biological drives being manifest. However, the theory did engage reactions that moved the field forward.

A key component of the development of incentive motivation theory was the major assault on drive-reduction, largely led by Bolles in the period around 1972 (Bolles, 1975) and followed by the work of Bindra (1974) and Toates (1981). Bolles argued that many issues remained unexplained by drive reduction theory, but a major issue was that individuals were motivated by incentive expectancies or learned expectancies of reward (stimulus–stimulus [S–S*] associations or what in Pavlovian associations are conditioned and unconditioned stimuli [CS and US]). Bindra argued that the CS for a reward came to elicit the same motivational state as the reward itself, thus causing the individual to perceive the CS as reward, not just the expectancy of reward. Toates (1981) further refined the model by arguing that physiological states (drive states) could enhance the incentive value of the reward. Others, including Konorski, Young, Solomon, Rescorla and Dickinson, contributed significantly to the development of modern incentive-motivation theory which guides the neurobiology of motivation, and the reader is referred to their scholarly works.

Subsequent theories of motivation have linked motivation with hedonic, affective, or emotional states and have postulated changes in motivation over time and experience. The incentive–sensitization (or incentive salience) theory of Robinson and Berridge (1993) divides, but in a sense extends, the power of incentives and moves them to

a neuroadaptive trajectory. Here, incentives have been split into two components – ‘wanting’ and ‘liking’ – based on the hypothesis that different brain mechanisms mediate these separate components in which ‘liking,’ mediated by opioid systems in the nucleus accumbens and ventral pallidum, is defined as hedonic impact or the brain response to sensory reward or pleasure without motivational power. In contrast, ‘wanting,’ mediated by the mesolimbic dopamine system, is hypothesized to be the incentive salience or the motivational incentive value of the same reward.

The extrapolation of behavioral sensitization (increases in the locomotor response to psychostimulant drugs with repeated administration) to increases in incentive salience in the incentive–sensitization model has early roots in the facilitation of conditioned reinforcement and drug-seeking behavior described by Hill and Robbins. Here, drug-seeking behavior is controlled by a succession of drug-associated discriminative stimuli, which can also function as conditioned reinforcers when presented as a consequence of instrumental responses. In addiction, many have argued that by means of associative learning, the enhanced incentive salience state becomes oriented specifically toward drug-related stimuli, leading to escalating compulsion for seeking and taking drugs. Originally, Mogenson (1980) proposed that the process of motivation to action involved ventral striatal–ventral pallidal–thalamic circuits, and others emphasized the role of the mesolimbic dopamine system innervating the nucleus accumbens in incentive salience. Everitt and Robbins (2005) extended a key motivational role for dorsal striatal–pallidal–thalamic circuits in the plasticity of motivational processing. The recruitment of the dorsal striatal circuitry is hypothesized to mediate habits and compulsivity associated with aspects of drug addiction and other motivational pathology. The underlying activation of neural structures involved in maintaining the incentive–salience state persists, making addicts vulnerable in the long term to relapse. Thus, the incentive salience component of incentive sensitization theory has significant heuristic value as a common element of drug addiction in that it narrows the focus to drug-seeking at the expense of natural rewards, and drugs are hypothesized to usurp systems in the brain put in place to direct animals to stimuli with salience for preservation of the species. The clinical observation that individuals with substance use disorders have an unusual focus on drug-seeking to the exclusion of natural rewards fits the incentive salience view.

Emotion and Motivation in Opponent Process

An alternate, potentially complementary, motivational theory also incorporating a strong emotional component is opponent process theory. Solomon and Corbit (1974)

argued that hedonic, affective, or emotional states, once initiated, are automatically modulated by the central nervous system with mechanisms that reduce the intensity of hedonic feelings and provide an additional motivational state for directing behavior. Solomon hypothesized that there is affective or hedonic habituation (or tolerance) and affective or hedonic withdrawal (abstinence). More specifically, a-processes, which could be either positive or negative hedonic responses, were proposed to occur shortly after presentation of a stimulus, correlate closely with the stimulus intensity, quality, and duration of the reinforcer, and show tolerance. In contrast, the b-processes appear after the a-process has terminated, are sluggish in onset, slow to build up to an asymptote, slow to decay, and get larger with repeated exposure. As such, the affective dynamics of the opponent process produces new motivation (i.e., new opportunities for reinforcing and energizing behavior).

From a neurobehavioral perspective, the initial acute effect of an emotional stimulus or drug in brain motivational systems is hypothesized to be opposed or counteracted by homeostatic changes in brain systems. Certain systems in the brain were hypothesized to suppress or reduce all departures from hedonic neutrality. This affect control system was conceptualized as a single negative feedback or an opponent loop that opposes the stimulus-aroused affective state. For example, in the context of drug dependence, Solomon argued that the first few self-administrations of an opiate drug produce a pattern of motivational changes in which the onset of the drug effect produces a euphoria that is the a-process which is followed by a decline in intensity. After the acute drug effect wears off, the b-process state emerges as an aversive craving state. Thus, in opponent process theory, drug tolerance and dependence are inextricably linked, and affective states, pleasant or aversive, were hypothesized to be automatically opposed by centrally mediated mechanisms that reduce the intensity of these affective states:

We have been taught to think of aversion and trauma as the only affective sources of physiological stress. The opponent-process model implies that often repeated pleasures are just as fertile a source of physiological stress (Solomon, 1980, p. 709).

During this period, Cabanac (1971) hypothesized a process by which a given stimulus can induce a pleasant or unpleasant sensation depending on the subject's internal state. This state was termed 'alliesthesia' and was applied to both temperature regulation and appetite. Here, for example, pleasant responses to sweet solutions occur with low gastric load, but aversive responses to sweet solutions occur with high gastric load. The existence of alliesthesia implies the presence of internal

signals modifying the conscious sensations aroused from peripheral receptors and supports the hypothesis that both peripheral and central processes contribute to motivation.

More recently, opponent process theory has been expanded by Koob and Le Moal (2001, 2008) into the domains of the neurocircuitry and neurobiology of drug addiction from a neurobiological perspective. Both within-system (mesolimbic dopamine dysfunction) and between-system (recruitment of corticotropin-releasing factor) neuroadaptations are hypothesized to mediate the opponent process. An allostatic model of the brain motivational systems was proposed that explains some of the persistent changes in motivation that are associated with vulnerability to relapse in addiction, and this model may generalize to other psychopathologies associated with dysregulated motivational systems. In this framework, during the development of drug addiction, counteradaptive processes such as opponent-process which are part of the normal homeostatic limitation of reward function fail to return within the normal homeostatic range and are hypothesized to form an allostatic state. The allostatic state is hypothesized to be a chronic deviation of reward set point that is fueled not only by dysregulation of reward circuits *per se* but by recruitment of antireward systems (e.g., brain and hormonal stress responses).

Conclusion

Thus, emotion can be defined as passions or sensibilities of both physiological responses and mental states, and motivation can be defined as a persistent state leading to organized activity. Both are intervening variables, are intimately related, and have neural representations in modern neuroscience. Emotional responses have long been associated with classic 'limbic' system circuitry, and modern imaging studies involve a cognitive component, can dissociate emotional expression from feelings and empathy, and identify an important role for the physiological responses in how feelings are interpreted as originally outlined in the James-Lange theory of emotion. Motivation has long been hypothesized to involve an emotional intervening variable, whether it be fear or incentive states, and neural substrates have been identified that have key roles in the incentive, hedonic, and aversive aspects of motivation – notably the circuitry involving the nucleus accumbens and amygdala which recruit dorsal striatal circuits and stress circuits respectively – as motivation becomes pathological such as observed in impulsive and compulsive disorders. Emotional and motivational circuits also color key elements of brain cognitive function that have important roles in the decision-making processes that guide all behavior.

Cognition

The term ‘cognitive neuroscience’ is very recent, dating perhaps from the 1980s. The *Journal of Cognitive Neuroscience* was first published in 1989. Indeed, Posner and Shulman’s comprehensive chapter on the history of cognitive science (1979) does not even mention cognitive neuroscience (human imaging techniques were not yet much in use then). Here we note briefly the biological roots of cognitive neuroscience (see Gazzaniga, 1995).

Karl Lashley was again a key figure. One of the most important aspects of cognitive neuroscience dates from the early days at the Orange Park laboratory, where young scientists like Chow and Pribram began studies of the roles of the association areas of the monkey cerebral cortex in learning, memory, and cognition.

H.M. and Primate Models

The period of the 1950s was an especially rich time of discovery regarding how cognitive functions were organized in the brain. Pribram, Mortimer Mishkin, and Hal Rosvold at the National Institute of Mental Health, using lesion studies in monkeys, discovered that the temporal lobe was critical for aspects of visual perception and memory. Work with neurologic patients also played a critical role in uncovering the neural substrates of cognition. As noted earlier, one particular discovery became a landmark in the history of memory research. “In 1954 Scoville described a grave loss of recent memory which he had observed as a sequel to bilateral medial temporal resection in one psychotic patient and one patient with intractable seizures. In both cases...removals extended posteriorly along the medial surface of the temporal lobes...and probably destroyed the anterior two-thirds of the hippocampus and hippocampal gyrus bilaterally, as well as the uncus and amygdala. The unexpected and persistent memory deficit which resulted seemed to us to merit further investigation” ([Scoville and Milner, 1957](#)).

That passage comes from the first paragraph of Scoville and Milner’s 1957 report, “Loss of recent memory after bilateral hippocampal lesions.” This publication became a landmark in the history of memory research for two reasons. First, the severe memory impairment (or amnesia) could be linked directly to the brain tissue that had been removed, suggesting that the medial aspect of the temporal lobe was an important region for a particular aspect of cognition (i.e., memory function). Second, comprehensive testing of one of the patients (H.M.) indicated that memory impairment could occur on a background of otherwise normal cognition. This observation showed that memory is an isolatable function, separable from perception and other cognitive and intellectual functions.

More specifically, H.M. could not remember his own experiences and could not learn new factual information after his surgery. This aspect of memory is termed ‘declarative’ memory because normal individuals, when asked, can state or declare the memories, and they can consciously retrieve and express them. But there are other types of memory, often grouped under the heading ‘procedural’ or nondeclarative (see below) on which H.M. performs like normal people. These include motor skills, Pavlovian conditioning of eyeblink and other aspects of basic associative learning, and even complex ‘cognitive’ puzzles like the tower of Hanoi, forms of memory that can be performed without conscious awareness of the memories, only the procedural performance of them.

H.M., whom we now know as Henry Molaison, died of respiratory failure at the age of 82 on December 2, 2008. He lived for many years at an extended care facility in Windsor Locks, Connecticut, where he served as the subject in hundreds of memory experiments. Those who worked with him described him as a very generous man, soft spoken, polite, and with a good sense of humor. The extraordinary depth of his declarative memory deficit was described to one of the authors (R.F.T.) by a colleague, Karl Pribram, a very senior neurosurgeon/neuroscientist when the two were colleagues at Stanford. He interviewed H.M. a few months after the surgery. They talked for a while, and Karl was impressed at how very bright and normal H.M. seemed (he had an above-average IQ). Then Karl had to leave the room for a phone call. When he returned a few minutes later, H.M. said, “Who are you? I have never seen you before.”

H.M. once said that everything seemed clear at the moment, but he worried about what had just happened. He felt as though he were just awakening from a dream and could not remember. He provided his brain to science, and it will be prepared in serial sections (2600 of them) by Jacopo Annese and colleagues at the University of California, San Diego. Mr. Molaison has contributed more to our understanding of human memory than any other human, and we will always be profoundly grateful to him.

The findings from patient H.M. ([Scoville and Milner, 1957](#)) early on identified a region of the brain important for human declarative memory (i.e., the medial portion of the temporal lobe). The damage was originally reported to have included the amygdala, the periamygdaloid cortex (referred to as the uncus in [Scoville and Milner, 1957](#)), the hippocampal region (referred to as the hippocampus), and the perirhinal, entorhinal, and parahippocampal cortices (referred to as the hippocampal gyrus). Subsequent, magnetic resonance imaging of patient H.M. suggested that his medial temporal lobe damage did not extend as far posteriorly as originally believed and that damage to the parahippocampal cortex was minimal (the lesion appeared to extend caudally from the temporal pole approximately 5 cm, instead of 8 cm, as originally reported; Corkin *et al.*, 1997).

While these observations identified the medial temporal lobe as important for memory, the medial temporal lobe is a large region including many different structures. To determine which structures are important required that studies be undertaken in which the effects of damage to medial temporal lobe structures could be evaluated systematically. Accordingly, soon after the findings from H.M. were reported, efforts were made to develop an animal model of medial temporal lobe amnesia. During the next 20 years, however, findings from experimental animals with intended hippocampal lesions or larger lesions of the medial temporal lobe were inconsistent and difficult to interpret.

In 1978, Mishkin introduced a method for testing memory in monkeys that captured an important feature of tests sensitive to human memory impairment (Mishkin, 1978). This method allowed for the testing of memory for single events at some delay after the event occurred. The task itself is known as the trial-unique delayed nonmatching to sample task, and it measures object recognition memory. In Mishkin's study, three monkeys sustained large medial temporal lobe lesions that were intended to reproduce the damage in patient H.M. The operated monkeys and three unoperated monkeys were given the delayed nonmatching to sample task in order to assess their ability to remember, after delays ranging from 8 s to 2 min, which one of two objects they had recently seen. The monkeys with medial temporal lobe lesions were severely impaired on the nonmatching task, consistent with the severe impairment observed in patient H.M. on delay tasks. Thus, lesions that included the hippocampal region and amygdala, as well as adjacent perirhinal, entorhinal, and parahippocampal cortices, caused severe memory impairment. This work, together with work carried out in the succeeding few years, established a model of human amnesia in nonhuman primates (Mishkin *et al.*, 1982; Squire and Zola-Morgan, 1983). Although other tasks have been useful for measuring memory in monkeys (object discrimination learning, the visual paired-comparison task, see below), much of the information about the effects of damage to medial temporal lobe structures has come, until recently, from the delayed nonmatching to sample task.

Once the animal model was established, systematic and cumulative work eventually identified the structures in the medial temporal lobe that are important for declarative memory. The important structures are the hippocampal region and the adjacent perirhinal, entorhinal, and parahippocampal cortices (for early reviews describing the medial temporal lobe memory system, see Zola-Morgan and Squire, 1993; Mishkin and Murray, 1994; for recent reviews, see Squire *et al.*, 2007, Eichenbaum and Lipton, 2008, Suzuki, 2009).

More Than One Kind of Memory

The medial temporal lobe is necessary for establishing a kind of memory that is termed long-term declarative or explicit memory. Declarative memory refers to the capacity for conscious recollection of facts and events (Squire, 1992). It is specialized for rapid, even one-trial learning, and for forming conjunctions between arbitrarily different stimuli. It is typically assessed in humans by tests of recall, recognition, or cued recall, and it is typically assessed in monkeys by tests of recognition (e.g., the delayed nonmatching to sample task). The medial temporal lobe memory system appears to perform a critical function beginning at the time of learning in order that representations can be established in long-term memory in an enduring and usable form (see also Eichenbaum *et al.*, 1994).

Another important discovery that paralleled in time the work on the medial temporal lobe system involved the understanding that there is more than one kind of memory. Specifically, work with amnesic patients and with experimental animals who sustained lesions to specific brain regions showed that other kinds of abilities (including skills, habit learning, simple forms of conditioning, and the phenomenon of priming, which are collectively referred to as nondeclarative or procedural memory) lie outside the province of the medial temporal lobe memory system. Nondeclarative forms of memory are intact in amnesic patients and intact in monkeys with medial temporal lobe lesions. For example, as noted above, classical delay conditioning of skeletal musculature was found to depend on the cerebellum (Thompson and Krupa, 1994), conditioning of emotional responses depends on the amygdala (LeDoux, 2000; Davis, 1992), and habit learning (win-stay, lose-shift responding) depends on the neostriatum (Salmon and Butters, 1995; Packard *et al.*, 1989). Nondeclarative memory thus refers to a variety of ways in which experience can lead to altered dispositions, preferences, and judgments without providing any conscious memory content.

Further work with monkeys has demonstrated that the severity of memory impairment depends on the locus and extent of damage within the medial temporal lobe memory system. Damage limited to the hippocampal region causes significant memory impairment, but damage to the adjacent cortex increases the severity of memory impairment. It is important to note that the discovery that larger medial temporal lobe lesions produce more severe amnesia than smaller lesions is compatible with the idea that structures within the medial temporal lobe might make qualitatively different contributions to memory function. This is because anatomical projections carrying information from different parts of the neocortex enter the medial temporal lobe memory system at different points (Suzuki and Amaral, 1994, Squire *et al.*, 2007). This might be

viewed as a modern reformulation of Lashley's principle of "mass action."

Another important brain area for memory is the diencephalon. However, the critical regions in the diencephalon that when damaged produce amnesia have not at the time of this writing (mid-2009) been identified with certainty. The important structures appear to include the mediodorsal thalamic nucleus, the anterior nucleus, the internal medullary lamina, the mammillothalamic tract, and the mammillary nuclei. Because diencephalic amnesia resembles medial temporal lobe amnesia in many ways, these two regions together probably form an anatomically linked, functional system (Squire and Zola, 1997; Gold and Squire, 2006).

These findings in monkeys are fully consistent with the findings from human amnesia. Damage limited to the hippocampal region is associated with moderately severe amnesia and more extensive damage that includes the hippocampal region as well as adjacent cortical regions is associated with more severe memory impairment (Zola-Morgan *et al.*, 1986).

The same principle, that more extensive damage produces more severe impairment, has also been established for the hippocampus proper in the case of the rat (Moser *et al.*, 1993). The dorsal hippocampus of the rat is essential for spatial learning in the water maze, and progressively larger lesions of this region produce a correspondingly larger impairment. Thus, in all three species, it has turned out that the brain is organized such that memory is a distinct and separate cognitive function, which can be studied in isolation from perception and other intellectual abilities. Information is still accumulating about how memory is organized, what structures and connections are involved, and what functions they support. The disciplines of both psychology and neuroscience continue to contribute to this enterprise.

Roger Sperry was another key player in the origins of cognitive neuroscience. After receiving his PhD in zoology, he joined Lashley for a year at Harvard and moved with Lashley to the Yerkes Laboratory at Orange Park, where he stayed for several years. Sperry did his pioneering studies on the selective growth of brain connections during this time (see Sperry, 1951). Lashley was fascinated by the mind-brain issue – the brain substrates of consciousness (although he never wrote much about it) – and often discussed this problem with his younger colleagues at Orange Park (Sperry, personal communication). Sperry and his associates at the California Institute of Technology tackled the issue with a series of commissurotomy patients – the human 'split-brain' studies. This work proved to be extraordinary, perhaps the most important advance in the study of consciousness since the word itself was developed many thousands of years ago (Sperry, 1968).

Brenda Milner studied for her PhD at McGill under Hebb's supervision. Hebb arranged for her to work with Wilder Penfield's neurosurgical patients at the Montreal

Neurological Institute. Her work on temporal lobe removal in humans, including H.M., really began the modern study of the memorial functions of the hippocampus (see above). She also collaborated on studies with Roger Sperry and Karl Pribram.

Another very important influence in modern cognitive neuroscience comes from the Soviet scientist Alexander Luria, who died in 1977. Luria approached detection and evaluation of damage to higher regions of the human brain both as a clinician with extraordinary expertise in neurology and as a scientist interested in higher functions of the nervous system (e.g., his book *Language and Cognition*, 1981).

EEG and Evoked Potentials

Yet another origin of cognitive neuroscience is recording the activity of the human brain, initially using EEG. Donald Lindsley was a pioneer in this work. After his PhD, he took a 3-year postdoctoral stage at Harvard Medical School (1933–35). The neurophysiologist Alexander Forbes was at Harvard doing pioneering studies on brain evoked potentials and EEG in animals. The first human EEG recording laboratory was set up at Harvard, and Lindsley and other pioneering figures (e.g., Hallowell Davis) did the first EEG recording in America (Lindsley, 1936).

More recently, the method of averaging evoked potentials recorded from the human scalp made it possible to detect brain signals relevant to behavioral phenomena that could not be detected with individual trial recording. Donald Lindsley was a pioneer in this field as well, doing early studies on evoked potential correlates of attention.

Brain Imaging

But the techniques that have revolutionized the study of normal human brain organization and functions are of course the methods of imaging. The first such method was X-ray computed tomography, developed in the early 1970s. The major innovation beyond simple X-rays was complex mathematical and computer techniques to reconstruct the images.

Somewhat later, PET was developed. It is actually based on a long used method in animal neuroanatomy – autoradiography. In this technique, a radioactive substance that binds to a particular type of molecule or brain region is infused, and brain sections are prepared and exposed to X-ray film. For humans, PET involves injecting radioactive substances, for example radiolabeled oxygen (^{15}O) in water. Increased neuronal activity in particular regions of the brain causes a rapid increase in blood flow to the regions, determined years earlier in work by Seymour Kety and others. Consequently, the radioactive water in the blood becomes more concentrated in active brain areas, detectable by radioactivity detectors.

The most widely used method at present is magnetic resonance imaging (MRI). This is based on the fact that changes in blood flow cause changes in the blood magnetic properties, which can be detected as changes in a strong imposed magnetic field. This method was first used in 1990 (Ogawa *et al.*, 1990). The current procedure is termed fMRI, involving very fast acquisition of images. A landmark publication in human brain imaging is the elegant book by two pioneers in the field, Michael Posner and Marcus Raichle, *Images of Mind*, 1994. The fMRI procedures have several advantages, such as the fact that they are noninvasive – no radioactive substance is injected – and this technique provides better spatial resolution than does PET imaging. Functional magnetic resonance imaging exploits variations in magnetic susceptibility that arises from molecular binding of oxygen to hemoglobin, which can be used to detect blood flow changes associated with neuronal activity (blood oxygen level reduction, BOLD). At the present time, these neuronal activity-related signals can be derived from areas of the brain with a spatial resolution of 1–2 mm. Moreover, the temporal resolution of this functional imaging technique is compatible with the time course needed to carry out most perceptual and cognitive operations. An important and promising strategy for the use of fMRI is its use in conjunction with other kinds of neurobiological techniques, including neurophysiology and anatomical and behavioral analyses. Thus, fMRI provides an extraordinary new window through which one can probe the neural machinery of cognition (Schacter *et al.*, 1998; Albright, 2000; Persson *et al.*, 2006).

Glossary

Acquisition – Mnemonic processes engaged at the time of learning (i.e., during the training phase of a memory study).

Consolidation – Mnemonic processes engaged for a limited period after encountering the events for which memory is later assessed. These processes are necessary for memories to be stabilized and made long term or permanent.

Eyeblink conditioning – A form of Pavlovian conditioning in which an animal learns to blink in response to a conditioned stimulus that signals a blink-inducing paraorbital shock or puff of air to the eye.

Hypothalamic–pituitary–adrenal (HPA) axis – The neuroendocrine system that is activated by stress and results in the release into the blood stream of glucocorticoids from the adrenal cortex.

Inhibitory avoidance – A fear-conditioning paradigm in which an animal learns, often after only one trial, to avoid making a previously punished response, such as stepping down from a raised platform or entering the darkened compartment at the end of a runway.

Morris water maze (MWM) – A spatial learning paradigm in which an animal can escape an opaque pool by locating a platform submerged beneath the water's surface.

Pavlovian (or classical) conditioning – A form of associative learning in which a previously neutral ('conditioned') stimulus becomes capable of producing an anticipatory response after one or more pairings with an 'unconditioned' stimulus that naturally produces a response. The occurrence of the unconditioned stimulus is not contingent on the animal's behavior.

Pavlovian fear conditioning – A form of conditioning in which an animal learns to associate a conditioned stimulus with the occurrence of an aversive unconditioned stimulus, typically a shock. The conditioned stimulus can be an explicit (e.g., visual or auditory) cue or the context in which the shock occurs.

Learning is assessed by the expression of fear-related behaviors (e.g., freezing or potentiation of the acoustic startle reflex).

Retrieval – Mnemonic processes engaged when memories are reactivated some time after learning has taken place.

Sympathetic-adrenal medullary system – The neuroendocrine system activated by stressors that results in release of epinephrine and norepinephrine. This system is responsible for producing the 'fight or flight' response.

In 1894, the French psychologist Théodule Ribot described how traumatic experiences could produce vivid and abiding memories, such as one subject's repeated experiences of dread upon revisiting his boarding school as an adult, or the recollection by another of the sound of the dentist's drill: "When I think of it I feel a chill run down my back and a slight trembling of the arms." However, Ribot also noted that many individuals experience 'affective amnesia,' in which strongly emotional material seems to "glide off their minds as a thundershower does off the roofs." These early case studies illustrate what has become a recurring motif in research on the effects of stress on learning and memory, that memories are sometimes enhanced by stress and at other times diminished.

Ribot ascribed this dichotomy to individual differences. But a seminal study of avoidance learning by Robert M. Yerkes and John D. Dodson, published in 1908, suggested this not to be the case, at least in rodents. They reported that the rate at which rats learned to avoid footshock was related to task complexity and to shock intensity. When the behavioral demands required for escape were made relatively complex, the relationship between shock intensity and learning rate followed an inverted-U function, with learning occurring most

rapidly in response to an intermediate level of shock. These findings demonstrated not only the existence of a bidirectional relationship between stress and learning in the rat, but also its moderation by specific experimental parameters rather than by individual differences.

Research in the current era has begun to characterize biological mechanisms underlying both the promotive and disruptive influences of stress on memory. By and large, progress in the investigation of each has moved along separate paths that have shown little overlap. This is perhaps because the range of behavioral paradigms and stressors used in different laboratories makes it difficult to synthesize across multiple sets of findings. One approach toward a more unified conceptual framework is to first identify from within this varied landscape the critical dimensions that are likely to determine whether stress promotes or prevents the formation and retrieval of memory. Parsing the field in this way better positions us to ask, in biological terms, how these bidirectional effects are achieved.

Critical Dimensions of Studies of the Stress–Memory Relationship

This article discusses the effects of stress on learning and memory by focusing on a number of behavioral paradigms that can be categorized according to the dimensions discussed below. As will be seen, three dimensions emerge as critically determining the effects of stress on memory and the neural mechanisms mediating these effects: the duration of stress (acute vs. chronic), the nature of the learning task (cerebellum- vs. hippocampus-dependent), and the relationship of the stressor to the learning task (intrinsic vs. extrinsic).

Type of Learning Task

Different forms of memory – from Pavlovian stimulus–stimulus (S–S) and stimulus–response (S–R) conditioning to declarative memory – depend upon different neural systems. In rodents, the effects of stress have been investigated primarily within Pavlovian eyeblink conditioning, fear conditioning, and spatial learning tasks. Although there are some commonalities in the neural circuitry underlying these three types of learning, they differ in relying most critically on three different neuroanatomical structures: the cerebellum, the amygdala, and the septal pole (i.e., dorsal region in the rodent) of the hippocampus, respectively. Moreover, procedural variations within each of these classes of learning are also important in determining the dependence of learning on specific neural structures. For example, whereas both trace (i.e., when the conditioned stimulus (CS) and unconditioned stimulus (US) are separated by an interval) and contextual

Pavlovian fear conditioning are frequently dependent on the dorsal hippocampus, delay conditioning (i.e., when the CS and US overlap in time) is not. Thus, if hormonal responses to stress affect hippocampal and amygdalar function differently, one might expect trace and contextual fear conditioning to be more sensitive than delay fear conditioning to the effects of stress.

Nature of the Stressor

Relationship to learning task

The source of stress can be either intrinsic or extrinsic to the experimental task. In fear-learning tasks, the stressor is intrinsic because it is typically the emotive event about which the subject learns. In eyeblink conditioning and navigational learning experiments, the stressor is typically incidental to the task at hand. It should be noted that even in learning tasks where an extrinsic stressor is applied, an intrinsic source of stress may also be present (e.g., shock to the orbit or airpuff to the eye in eyeblink conditioning, or immersion in a water maze).

Relationship to behavior

The impact on memory of an organism's responses to intrinsic stress differs widely depending on whether the source of stress is avoidable or not. Stress responses have a substantial impact on memory retention in passive, or inhibitory, avoidance paradigms but more nuanced effects on Pavlovian fear conditioning. There are similarly stark differences in the effects of inescapable and escapable stress on subsequent active avoidance responding – where intense, inescapable shock produces a state of learned helplessness. This condition, however, reflects a change (either adaptive or maladaptive) in performance of an escape response rather than in the strength of the underlying fearful memory itself.

Severity

Stress can range from relatively mild (e.g., exposure of a rodent to a novel context) to severe (e.g., restraint combined with frequent tailshock). Its duration can also range from single and brief (i.e., acute) to intermittent or continuous over days or weeks (i.e., chronic). Rarely is the dose of extrinsic stress varied systematically within a study. This contrasts with fear-conditioning studies, where the intensity of the US is often varied in a systematic manner. In the latter studies, however, it is difficult to distinguish the effects of stress responses of varying magnitudes from the predictable relationship between the strength of the US and the rate and asymptotic level of conditioning.

Acute Stress

Intrinsic Stress: Memory for the Stressful Event

Inhibitory avoidance

In inhibitory avoidance tasks, the measure of learning is the increase in the latency to make a previously punished response, such as stepping down from a raised platform or entering the darkened compartment at the end of a runway. Learning occurs extremely rapidly; often only one training trial is used. This means that the period of memory consolidation – beginning as soon as the training trial is terminated – can be clearly distinguished from prior acquisition. In contrast, when multiple training trials are used, intracellular and systems-level consolidation processes are inevitably initiated before later training trials have occurred. Furthermore, consolidation of inhibitory avoidance learning has proven to be exquisitely sensitive to stress and to manipulations of the individual's neuroendocrine responses to stress. For these reasons, inhibitory avoidance has become a mainstay of research in rodents into the effect of intrinsic stress on memory.

The inhibitory avoidance literature points to specific components of the individual's response to a stressful challenge that enhance consolidation of memory (**Figure 1**). Stress causes rapid activation of the sympathetic-adrenal medullary system, and slower activation of the hypothalamic–pituitary–adrenal (HPA) axis. The rapid release of epinephrine from the adrenal medulla and slower release of steroid glucocorticoid hormones (corticosterone or cortisol, depending on the species) from the adrenal cortex in response to shock initiates a cascade of events that ultimately affects consolidation

processes in the amygdala, hippocampus, and extrahippocampal cortical areas. Epinephrine binds to β -adrenergic receptors on vagal afferents, leading to excitation of ascending adrenergic neurons in the nucleus of the solitary tract (NTS) and the release of norepinephrine (NE) in the brain. Glucocorticoids cross the blood–brain barrier and bind to mineralocorticoid receptors (MRs), mainly located in limbic structures, and glucocorticoid receptors (GRs), distributed throughout the brain. Since MRs have a higher affinity for glucocorticoids, they are predominantly bound at rest. Surges in corticosterone triggered by stressors such as footshock therefore primarily produce increased GR stimulation.

Binding of NE to β -adrenergic receptors in the basolateral complex of the amygdala (BLA) is the key event in the enhancement of consolidation. Other receptors in the BLA that have been implicated in consolidation include α -adrenergic receptors and corticotropin-releasing factor (CRF) receptors. Stimulation of each enhances memory for the inhibitory avoidance task through facilitation of the adenylyl cyclase and cyclic adenosine monophosphate (cAMP) pathway initiated by β -adrenergic receptor activation.

Although much evidence supports the role of NE in consolidation, dopamine β -hydroxylase knockout mice, which are unable to produce NE due to dopamine β -hydroxylase's crucial role in the NE-synthesis pathway, are not impaired in the inhibitory avoidance task. These results may be attributable to long-term neural adaptations in response to NE depletion through development. Alternatively, consolidation may be achieved through other neurotransmitters if NE is unavailable, even in the healthy animal. This is supported by the

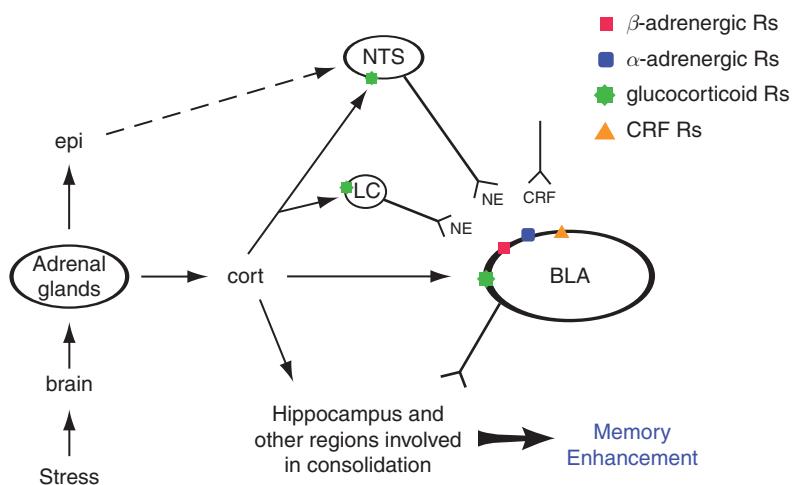

Figure 1 Neural mechanisms underlying inhibitory avoidance learning. A stressor such as footshock triggers the brain to send signals to the adrenal glands that cause release of corticosterone and epinephrine. Epinephrine binds to β -adrenergic receptors on the vagus nerve, sending an excitatory signal to the NTS and causing norepinephrine release in the BLA. Corticosterone binds to GRs in the BLA and facilitates norepinephrine release from the LC. The actions of NE, corticosterone, and CRF lead to changes in the BLA that ultimately cause memory enhancement. Abbreviations: basolateral nucleus of the amygdala (BLA), corticotropin-releasing factor (CRF), glucocorticoid receptor (GR), locus ceruleus (LC), norepinephrine (NE), nucleus of the solitary tract (NTS).

finding that learning occurs normally when β -adrenergic receptors are blocked pharmacologically before, as opposed to immediately following, training.

Beyond adenylate cyclase activity, the intracellular mechanisms through which β -adrenergic receptors in the BLA enhance consolidation processes remain to be determined. It is known that NE binding leads to facilitation of N-methyl-D-aspartic acid (NMDA) receptor-dependent plasticity, a necessary step in the consolidation of memories. BLA activation can also modulate long-term potentiation (LTP) in the hippocampus. Additionally, stimulation of β -adrenergic receptors in the BLA leads to expression in the hippocampus of *Arc*, an immediate-early gene (IEG) thought to play a role in synaptic plasticity.

Glucocorticoids enhance consolidation through two routes. First, they modulate NE release in the BLA via actions on noradrenergic cells in the NTS and locus ceruleus. Second, memory enhancement is achieved through binding to GRs in the BLA and hippocampus. In the BLA, GRs may interact with α -adrenergic and CRF receptors to enhance adenylate cyclase activity. Glucocorticoids may also act indirectly by sensitizing CRF systems in the amygdala. Importantly, GR binding in the hippocampus is ineffective if the BLA is lesioned. The BLA therefore seems to be critical in regulating the effects of stress on consolidation of memory in the hippocampus, and perhaps in other brain regions as well. This idea is supported by the finding that lesions of the stria terminalis, a major output pathway of the amygdala, also impair memory consolidation.

Water maze

In the spatial version of the Morris Water Maze (MWM), the animal learns to swim to a platform hidden in a pool of opaque water using distal spatial cues. Although the explicit focus of MWM studies is typically on the navigational learning component, this task actually represents a form of active avoidance learning; the act of swimming to the platform serves as a means of escape from the water. Findings in the limited number of studies that have focused on the role of the stress in MWM learning cohere with the inhibitory avoidance literature discussed above. Thus, corticosterone treatment after training increases retention, while intracerebroventricular and intra-BLA infusion of GR antagonists after training impairs memory, confirming that release of corticosterone from the adrenal glands and subsequent binding to GRs in the BLA plays a role in enhancing consolidation. A point mutation in the mouse's GR that prevents the receptor from binding to DNA also impairs spatial memory, suggesting that GR stimulation exerts genomic effects directly, rather than through interactions with other transcription factors. Studies involving posttraining infusions of specific noradrenergic drugs indicate the importance of stimulation of β -adrenergic receptors in the BLA in this form of learning as well.

Pavlovian fear conditioning

In Pavlovian fear conditioning, the organism learns to associate cues with the occurrence of an aversive US, typically a shock. Fear-conditioning paradigms differ from avoidance learning in that the incidence of the US is independent of the individual's behavior. This difference between S-S and S-R learning has important consequences in terms of the sensitivity of fear consolidation to modulation by stress system responses. Perhaps the most striking contrast between Pavlovian conditioning and avoidance learning is that post training, intra-BLA infusion of the γ -aminobutyric acid (GABA-A) receptor agonist muscimol, while profoundly impairing consolidation of inhibitory avoidance learning, leaves consolidation of auditory cue and contextual fear conditioning intact. Similarly, Pavlovian fear conditioning is not affected by systemic injection of a β -adrenergic receptor antagonist. These results suggest that NE release in the amygdala, critical for consolidation of inhibitory avoidance, is not necessary for the consolidation of Pavlovian fear memories. Despite being unnecessary for memory formation, NE nevertheless promotes it, since intra-BLA infusion enhances memory in contextual fear conditioning.

The role of HPA-axis activation appears to be more significant. Systemic administration of the GR antagonists RU38486 or RU40555 prior to conditioning disrupts acquisition of fear conditioning to contextual cues, but not to auditory cues. Because the dorsal hippocampus is a site of plasticity for contextual fear, it is likely that corticosterone ultimately has its modulatory effect in this region. Consistent with this idea, hippocampus-dependent trace fear conditioning, and not delay fear conditioning, is disrupted by the glucocorticoid-synthesis inhibitor metyrapone. However, changes in the dorsal hippocampus may be an indirect consequence of GR stimulation elsewhere, since contextual fear conditioning is disrupted by infusion of RU38486 directly into the BLA or ventral hippocampus but not by infusion into the dorsal hippocampus.

Interestingly, the critical window for stress-induced modulation of Pavlovian fear memory, like inhibitory avoidance, may be the phase of immediate posttraining consolidation. This is suggested by the discovery that injection of corticosterone itself potentiates contextual fear conditioning when administered immediately after, as well as before, training.

Extrinsic Stress: Memory for Events Incidental to the Stressor

Eyeblink conditioning

In Pavlovian eyeblink conditioning, the organism learns to blink its eye in response to a CS that signals a blink-inducing paraorbital shock or puff of air. Although these events are unpleasant and stressful, the measure of

interest is acquisition of a discrete motor response rather than the accompanying, coordinated set of diffuse, anticipatory fear responses. Eyeblink-conditioning paradigms also differ from fear-conditioning paradigms in that acquisition occurs over a much narrower range of temporal intervals between CS and US onset (usually <1 s) and over a much larger number of training trials. Finally, eyeblink and fear conditioning differ in the way in which the consequences of stress have been studied. To evaluate the effects of stress on eyeblink conditioning, the animal is exposed to an additional source of stress prior to the commencement of training. It may also be significant that the stressor is typically the same as that used to induce learned helplessness (one tailshock per minute over 60–90 min of restraint), and thus considerably stronger than the stress intrinsic to most fear-conditioning paradigms.

It is now well established that exposure to this form of stress facilitates acquisition of eyeblink-conditioned responses in male rats. This phenomenon is particularly intriguing because it occurs irrespective of whether training is initiated immediately after termination of stress or 24 h following it. *Per contra*, female rats show poorer eyeblink conditioning following stress exposure, apparently because stress disrupts the facilitative effects on learning otherwise exerted by estrogen. It is currently unknown whether as dramatic a sex difference characterizes other stress-related learning phenomena, since relatively little systematic research has been conducted on female rodents.

The neural mechanisms underlying the enhancement of eyeblink conditioning by stress in male rats have yet to be established, beyond the clear involvement – as with other stress-related phenomena described above and below – of the amygdala and activation of the HPA axis. Thus, both inactivation of the amygdala and adrenalectomy block the stress-induced enhancement of conditioned eyeblink responses.

A further potential region of interest is the cerebellum. Interestingly, the cerebellar cortex, where plasticity is necessary for normal acquisition of the conditioned response, is rich in corticosteroidal receptors. In contrast, the fact that stress enhances delay, as well as trace, eyeblink conditioning may make a role for the hippocampus less likely in this than in other stress-related memory phenomena. Consistent with this, the same stressful conditions that enhance eyeblink conditioning attenuate the cellular phenomenon of LTP in the hippocampus. Finally, the fact that eyeblink conditioning is enhanced immediately or 24 h after stress exposure suggests the influence of both nongenomic and genomic mechanisms.

Spatial learning

In contrast to Pavlovian eyeblink conditioning, exposure to stress prior to training has been found to impair male rats' long-term memory of the MWM. Retrieval or

expression of maze learning in rats is also disrupted by application of relatively mild acute stress prior to test. The time at which the stressor is given is critical: performance is affected when the stress is applied 30 min before test, but not 2 min or 4 h before test, thereby corresponding to the time course of corticosterone release. Consistent with this, exogenous corticosterone has the same effect. Local infusion of specific drugs indicates that this effect is mediated by the stimulation of GRs acting through a rapid, nongenomic mechanism to facilitate β -adrenergic transmission in the hippocampus.

The apparently divergent consequences of exposure to extrinsic stress prior to training, both across different paradigms and in relation to the well-established effects of intrinsic stress, require further exploration. The opposing effects of pretraining stress on eyeblink conditioning and spatial learning cannot be explained by differences in the intensity or timing of the stressor, since similar parameters were applied in both. Rather, the most likely, albeit as yet untested, explanation is that severe acute stress enhances the induction of cellular plasticity in the cerebellum while impairing the induction of plasticity in the hippocampus. Both phenomena are presumably mediated by activation of the amygdala, since its integrity is necessary for the impairment of spatial learning as well as for the potentiation of eyeblink conditioning.

It is perhaps more of a challenge to reconcile the deleterious effects of extrinsic stress on MWM learning with the facilitative effects of the stress of swimming that is inherent to the task. One possible explanation, reminiscent of the Yerkes–Dodson effect, is that this difference is simply related to the intensity of the stressor, with optimal learning occurring at intermediate stress levels. This notion is supported by the finding that learning in another spatial task (a Y-maze) is disrupted both when GRs are pharmacologically blocked and when they are highly saturated in adrenalectomized animals via application of corticosterone or a GR agonist.

A second possible explanation relates to the timing of stress. Extrinsic stress is applied before training and peak corticosterone release may, therefore, occur prior to the period of acquisition. Intrinsic stress, by definition, coincides with training and hence peak corticosterone release presumably coincides with the period of posttraining consolidation. As described earlier, the fact that almost all manipulations have been conducted immediately after training has shown that intrinsic stress specifically enhances consolidation of encoded memories. Interestingly, eyeblink conditioning is facilitated only when the stress is applied before, and not after, training. Whether and how exposure to extrinsic stress after MWM training would affect memory consolidation is not known, but it is intriguing to speculate that extrinsic stress, in general, may affect processes important for memory 'acquisition' and not those required for memory consolidation.

The neural mechanisms whereby extrinsic and intrinsic stressors exert different effects on memory are certainly worthy of further investigation. Whatever the specifics, the evolution of such distinctive mechanisms seems likely, since the idea is easily entertained that there is an adaptive advantage to having heightened memory for events directly associated with a traumatic episode, but not for events that are incidental to the trauma itself.

Chronic Stress

Where chronic stress, lasting at least several days, has been shown to have an effect on subsequent learning in rats, it has generally been to reduce the capacity for spatial learning. Three critical variables, all related to time, can be identified that influence whether spatial learning is impaired or spared by chronic stress: the age of the animals at the time of stress exposure, the duration of exposure to the stressor, and the interval between exposure to stress and the commencement of learning.

The broad picture is that only extensive periods of stress lead to impairments in memory and that these impairments may only be transient. A direct comparison of different periods of chronic stress revealed that spatial learning was impaired following 6 h/day restraint stress for 21 days but not following the same daily period of restraint for 7 days. Recovery of function is fairly rapid, even after the longer stress period, since no learning deficit is apparent when training commences 2 weeks later. In contrast, a deficit in spatial learning still remains 2 weeks after a much more extensive, 6-month, period of social isolation stress. This suggests that both the severity and persistence of memory impairments increase as a function of the duration of chronic stress exposure.

The third temporal variable, age, appears to be the most critical of all, for chronic stress-related manipulations beginning in infancy seem to have significant long-term consequences for mnemonic ability. Daily handling of rat pups during the first 2 weeks of life produces changes in reactivity of the HPA axis, and enhanced MWM memory is one of a complement of positive, long-term outcomes in the adult. As with other consequences of this intervention, the enhancement of memory is mediated by an increase in the organization of maternal behaviors on return of the pups to the nest. Indeed, even without handling, the pups of high-nurturing mothers show more rapid spatial learning as adults than the offspring of low-nurturing mothers. In addition, the offspring of mothers exhibiting low-nurturing maternal behavior show improved memory if reared by high-nurturing mothers. Hence, resilience is conferred through the quality of the mother's behavior during this critical period rather than through genetic factors alone.

Interestingly, rats may reenter a window of vulnerability later in life as well, because the 6 months of isolation stress referred to above affected spatial learning only when it began at 2 years, and not at 2 months of age, a time that corresponds to early adulthood.

The impairments to memory produced by chronic stress are likely mediated by alterations in regulation of the HPA axis. The effects of 21 days of restraint stress are mitigated by adrenalectomy and can be reproduced by 21 days of corticosterone supplementation, suggesting that chronic elevations in corticosterone are necessary and sufficient for memory impairments to ensue. A persistent increase in corticosterone secretion likely impacts memory via atrophy of apical dendrites in the CA3 region of the hippocampus; like the impairment of spatial memory, it is seen after 21 days stress exposure and subsides with the passage of time. As for mechanisms underlying the effect of early-life experiences on later measures of memory, expression levels of a wide variety of molecules in the brain of the adult are altered as a function of the repertoire of maternal behaviors experienced as a pup. Many, such as changes in GRs and CRF receptors, are closely associated with HPA-axis regulation, whereas others, such as NMDA-receptor-subunit composition, are associated with variations in plasticity and memory. It still not clear which of these variables interact with one another to specifically affect cognitive function later in life.

Although the extent to which other forms of memory are sensitive to chronic stress has not been established, it is noteworthy that prior exposure to the 21-day chronic stress protocol does not blunt either tone or contextual fear conditioning. Indeed, the expression of both forms of fear is enhanced by this treatment, suggesting a residue of anxiety following daily, repeated periods of stress. Thus, as in the case of acute stress, some forms of learning may be more sensitive than others to the ravages of chronic stress.

Conclusions

As first observed in studies of the human and animals over 100 years ago, stress can either enhance or diminish the efficacy of learning and the vigor of resultant memories. Through an overview of contemporary research in rodents, one can begin to discern the circumstances that determine which of these opposing effects are seen and how the HPA axis and sympathetic responses play their part in them. Three significant factors emerging from this analysis are the duration of the stressor, its relevance to the learning experience, and the nature of the learning task employed (see **Table 1**).

The most thoroughly studied phenomenon in this field is the strengthening of consolidation of memory for the stressor itself, measured as the animal's tendency to avoid future encounters with it. In contrast, consolidation of

Table 1 Summary of the effects of stress on memory in a variety of rodent models. Several factors determine whether stress enhances or impairs memory in a given paradigm, including the type of learning task, the timing of the stressor, its severity, and its relationship (i.e., intrinsic or extrinsic) to the learning task. These factors and the known neural mechanisms through which they exert their effects are summarized for each of the paradigms discussed in the text

	<i>Paradigm</i>	<i>Stressor</i>	<i>Memory processes affected</i>	<i>Effect on memory</i>	<i>Mechanisms</i>
Acute					
Intrinsic	Inhibitory avoidance	Shock	Consolidation	↑	β-adrenergic receptor stimulation in the BLA, GR stimulation in the BLA and hippocampus
	MWM	Water	Consolidation	↑	β-adrenergic receptor stimulation in the BLA, GR stimulation in the BLA and, possibly, hippocampus
	Pavlovian fear: Context	Shock	Consolidation	↑	GR stimulation in the BLA and ventral hippocampus
	Pavlovian fear: Auditory cue	Shock			
Extrinsic	Pavlovian eyeblink	Restraint and shock	Acquisition	↑	Amygdala and HPA-axis activation
	Spatial	Restraint and shock	Acquisition or consolidation	↓	Amygdala activation
		Shock	Retrieval	↓	GR stimulation in hippocampus acting rapidly to facilitate β-adrenergic transmission
Chronic					
	Early life	Reduction in maternal behaviors	?	↓	May relate to changes in regulation of HPA axis or proteins associated with plasticity
	Adulthood	21-days restraint	?	↓	Dendritic atrophy in the CA3 of hippocampus

BLA, basolateral amygdala; GR, glucocorticoid receptor; HPA, hypothalamic–pituitary–adrenal; MWM, Morris Water Maze.

simple Pavlovian (S-S) associations between environmental stimuli and the stress-inducing event are generally less affected by endogenous responses to the stressor. Stress can also affect learning of incidental information, but likely through an influence on its acquisition rather than on its subsequent consolidation. The nature of the learning task is important here as well, with diametrically opposed effects on Pavlovian motor learning and spatial learning. Finally, chronic stress, like acute stress, may also impact memory formation, but its timing is critical. Thus, stress of sufficient duration impairs the ability to form new memories, but only for a limited window of time after its cessation.

The diversity of approaches to the study of the relationships between stress and memory makes it difficult to identify unifying neurobiological mechanisms. Nevertheless, several commonalities emerge. Most significantly, both the enhancing and deleterious effects of acute stress appear to be mediated by activation of the amygdala that in turn influences plasticity in other regions of the brain. Second, HPA-axis activation has also been implicated in effects in both directions (and in both cases, through GR activation), as well as in the memory impairments caused by chronic stress. NE release plays a critical role in strengthening consolidation of stress-related information, but its involvement in the other interactions between stress and memory is still unknown.

Given that the same physiological responses to stress can have such discrepant effects on memory depending on the nature of the learning paradigm and the nature of the stressor, the interactions between stress and memory must be moderated by the specific neural changes associated with individual situations. Understanding the variables following trauma that cause some events to slip from the mind like ‘a thundershower does off the roofs’ and others to endure, sometimes to an unwelcome or even to a pathological degree, will bring us closer to a fuller understanding of the relationship between stress and memory.

Glossary

Dishabituation – An increase in the size of the habituated response to the habituating stimulus following presentation of a (usually) strong other stimulus.

Habituation – A decrease in the size of a response to repeated presentations of the same stimulus.

Sensitization – An increase in the size of a response to a given stimulus following presentation of a (usually) strong other stimulus.

Stimulus frequency – Here the rate at which the habituating stimulus is given.

Stimulus intensity – Here, the strength of the habituating, or sensitizing or dishabituating, stimulus.

some nine basic parametric properties or characteristics exhibited by behavioral habituation.

1. *Given that a particular stimulus elicits a response, repeated applications of the stimulus result in decreased response (habituation). The decrease is usually a negative exponential function of the number of stimulus presentations.* Examples of response habituation can probably be found in essentially all behavioral studies where a stimulus is regularly presented. In earlier experiments devoted to habituation, *per se*, parametric characteristics were studied for a variety of responses ranging from postrotatory nystagmus to startle and the galvanic skin response. With the exception of the knee jerk reflex, habituation was a consistent finding, usually exhibiting an exponential course.

2. *If the stimulus is withheld, the response tends to recover over time (spontaneous recovery).* Spontaneous recovery has come to be the most common method of demonstrating that a given response decrement is an example of habituation. The time course of spontaneous recovery is markedly influenced by many variables and is not necessarily characteristic of a given response. Thus, the habituated startle response to sound in the intact rat may recover in 10 min or fail to recover in 24 h depending upon details of testing. Consequently, any categorization of the types of habituation based solely on recovery time is likely to be somewhat artificial.

3. *If repeated series of habituation training and spontaneous recovery are given, habituation becomes successively more rapid (this might be called potentiation of habituation).* Konorski describes this effect for the orientating response, and it has been described in many studies where repeated habituation series were given.

4. *Other things being equal, the more rapid the frequency of stimulation, the more rapid and/or more pronounced habituation is.* Numerous examples of this were noted in the earlier reflex studies as well as in the work by Welker on curiosity. The effect occurs in terms of real time course and within certain limits in terms of the number of trials as well.

Habituation is defined simply as a decrease in response to repeated stimulation and considered a basic form of nonassociative learning. Response decrements due to injury, drugs, or other abnormalities are excluded. The responses studied in habituation vary from reflexes to autonomic measures to electroencephalogram (EEG) arousal and a wide range of behavioral phenomena such as activity, exploration, and response to novelty.

Following classical early studies by Humphrey, Prosser and Hunter, Harris, and Sharpless and Jasper, habituation is considered a central phenomenon, at least in animals with nervous systems; receptor adaptation and neuromuscular fatigue are excluded.

Sensitization is simply an increase in response to a stimulus due to the action of another (often strong) stimulus. Dishabituation is typically defined as the disruption of a habituated response, also due to the action of another (often strong) stimulus.

Some of the basic properties of habituation were described in the classic works noted above. In 1966, Thompson and Spencer surveyed the by-then very extensive behavioral literature on habituation and identified

2 Habituation

5. *The weaker the stimulus, the more rapid and/or more pronounced habituation is. Strong stimuli may yield no significant habituation.* This relationship is characteristic of most types of responses ranging from simple reflexes to complex exploratory behavior.

6. *The effects of habituation training may proceed beyond the zero or asymptotic response level.* Additional habituation training given after the response has disappeared or reached a stable habituated level will result in slower recovery. Although relatively few experiments have studied below-zero habituation as such, the observations may be viewed as an extension of the relationship between the number of stimulus presentations and degree of habituation. Zero response level is of course to some degree dependent upon the particular response measures used.

7. *The habituation of response to a given stimulus exhibits stimulus generalization to other stimuli.* This has been observed in many studies using auditory, visual, or tactile stimuli.

8. *Presentation of another (usually strong) stimulus results in recovery of the habituated response (dishabituation).* This phenomenon appears to be as ubiquitous as habituation itself and is commonly used to demonstrate that habituation has occurred. Pavlov was perhaps the first to describe this process (i.e., disinhibition) in relation to an extinguished conditioned response (CR), and also applied it to the habituated orienting response. Humphrey studied dishabituation extensively in lower vertebrates. Essentially, all responses of mammals that can be habituated can also be dishabituated. It is not always necessary for the dishabituating stimulus to be strong. In fact, Sokolov reported that a decrease in the intensity of an auditory stimulus results in dishabituation of the habituated orienting response in humans. Dishabituation, viewed as neutralization of the process of habituation, has perhaps been the most important method of distinguishing between habituation and fatigue.

9. *Upon repeated application of the dishabituating stimulus, the amount of dishabituation produced habituates (this might be called habituation of dishabituation).* Most studies of dishabituation (see above) have noted its habituation.

Thompson and Spencer argued that these nine common characteristics may consequently serve as the detailed operational definition of habituation, replacing the more general definition given above. The extent to which any other response decrements satisfy these characteristics will thus determine whether they can be called habituation.

However, Davis and Wagner challenged the parameter concerning stimulus intensity. They used the acoustic startle response in the rat and found that habituation to an intense stimulus caused a greater degree of absolute response decrement when tested with a weak stimulus than habituation to the weak stimulus. However, they also noted that if habituation and test stimuli were of identical

intensities, then the relative degree of habituation increases as stimulus intensity is decreased, in accordance with Thompson and Spencer's characteristic number 5. Therefore, the key is absolute versus relative measures of habituation. As Groves and Thompson stressed, characteristic number 5 must refer to relative rather than absolute measures of response strength.

Using the spinal flexion reflex, Spencer and Thompson were able to rule out changes in skin receptors, cutaneous afferent nerve terminals, and in motor neurons as loci of the decremental process underlying habituation, in accordance with Sherrington's earlier speculations. The decremental process must occur in interneurons. Perhaps their most important discovery was the fact that dishabituation was not a disruption of habituation but rather an independent superimposed process of sensitization. The decremental process underlying habituation was not disrupted at all by dishabituation. Indeed, in the flexion reflex, dishabituation (sensitization) always produces an increase in excitability of motor neurons. To the extent tested in mammalian systems, dishabituation is in fact a separate process of sensitization, but an exception has been noted in *Aplysia* by Rankin and Carew. These observations led Groves and Thompson to develop the dual-process theory (see below).

A number of theories, or at least hypotheses, concerning the process of habituation have been proposed over the years. In fact, many of these theories were more generally concerned with processes of learning and not developed specifically to deal with habituation. Three theories specific to habituation have been relatively successful and are still prominent today: Eugene Sokolov's stimulus-model comparator theory; Allan Wagner's revision of Konorski's gnostic hypothesis; and Groves and Thompson's dual-process theory. Each of these is briefly treated here.

Stimulus-Model Comparator Theory

Evgeny Sokolov developed a most influential stimulus-model comparator theory of habituation (see [Figure 1](#)). It was based primarily on his observation of the orienting response, often measured as arousal in EEG activity. The basic notion is that as a result of repeated stimulation, a stimulus model is formed in the brain, specifically in the cerebral cortex. In addition, there is an amplifying system that normally subverses behavioral output. A novel stimulus will result in a large orienting response, mediated by the amplifying system, identified with the ascending reticular activating system in lower brain regions. As the same stimulus is repeated, the stimulus model develops and as it develops, it exerts increasing inhibition on the amplifying system via descending corticofugal influences, thus yielding habituation. If a new

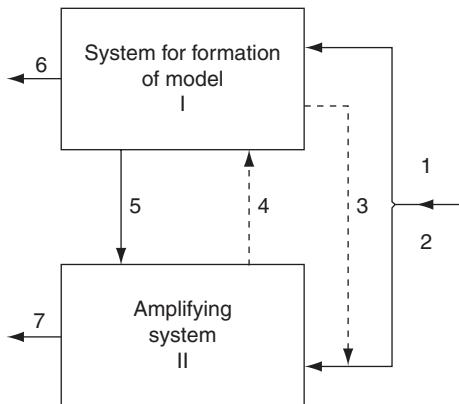

Figure 1 Sokolov's model of habituation. Sensory input through lines 1 and 2 projects to both the model formation and the amplifying systems. With repeated stimulation, the model develops and inhibits the amplifying system. See text for details. From Sokolov EN (1960) Neuronal models and the orienting influence. In: Brazier MA (ed.) *The Central Nervous System and Behavior: III*, pp. 187–275. New York: Macy Foundation.

or altered stimulus occurs which does not match the model, then inhibition is released and response strength recovers accordingly.

Wagner-Konorski Gnostic Unit Theory

Konorski briefly developed a theory of habituation that is, in many ways, analogous to Sokolov's theory. Allan Wagner elaborated Konorski's notion with greater emphasis on the roles of short-term memory and the existing associative network. This model is shown in [Figure 2](#). A stimulus

(SO = stimulus object) is processed via afferent fields to project to a memory system, the gnostic assembly, and to the arousal system. As the stimulus is repeated, a gnostic unit is formed, an increasingly accurate neuronal model or memory of the stimulus. As this model develops, it increasingly activates an inhibitory system that inhibits the arousal system, resulting in habituation. Wagner added two processes to Konorski's model, a reverberating circuit of transient memory (short-term memory – the two solid circles in the gnostic assembly) and the influence of the preexisting associative network. Indeed, Wagner's reformation of Konorski's model is in the mainstream of the information-processing theory, for example, Anderson and Bower. A key notion introduced by Wagner is that contextual cues may act via the associative network to excite stimulus representations in memory, that is, in the gnostic assembly. An important implication of this view is that some response systems should show context-specific long-term habituation.

Groves and Thompson's Dual-Process Theory

The basic assumption is that any effective stimulus will result in two independent processes in the central nervous system, one decremental (habituation) and one incremental (sensitization), that interact (see [Figure 3](#)). It is further assumed that habituation develops in the stimulus-response (S-R) pathway for whatever stimulus-evoked response is being habituated and that sensitization develops in a separate state system which then acts on the S-R pathway to yield the final behavioral outcome. Strong

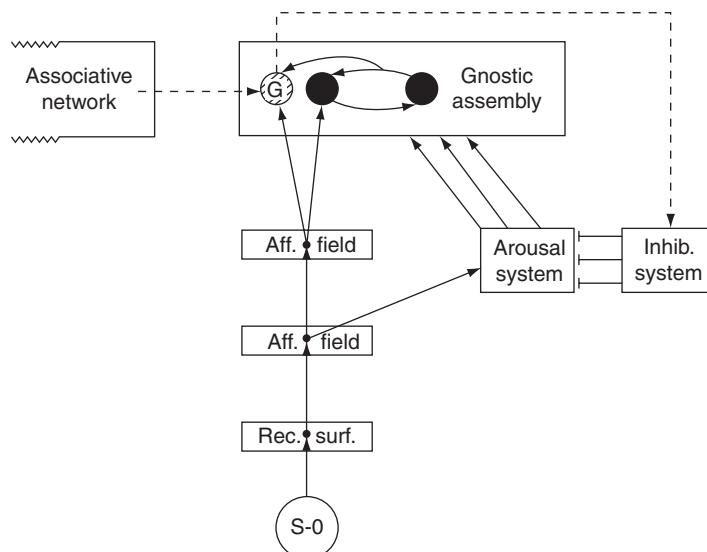

Figure 2 Wagner-Konorski's model of habituation. Sensory input forms a memory model in the gnostic assembly. As the model develops, it inhibits the arousal system. See text for details. Figure 3 Neuronal model of the dual-process theory. The S–R pathway develops habituation and the state pathway may develop sensitization. They interact to yield behavior. See text for details. From Groves PM and Thompson RF (1970) Habituation: A dual-process theory. *Psychological Review* 77: 419–450.

supporting evidence for this theory came from studies of the activity of interneurons in the spinal cord.

All three theories have much in common. First, they all propose that a model of the stimulus develops as a result of repetition. This model is viewed essentially as a memory trace in the Sokolov and Wagner–Konorski models and simply as a decrement in synaptic transmission in the dual-process model. Such a synaptic decrement can of course qualify as a memory. Second, all three theories have an arousal system (amplifying in Sokolov; arousal in Wagner–Konorski; and state in the dual-process model).

In terms of differences, both Sokolov and Wagner postulate a descending inhibitory system activated by the memory trace that inhibits the arousal system. The dual-process theory postulates no such inhibitory system. Instead, both the S–R pathway and the state system activated by stimulus repetition will habituate. Another difference is that Sokolov, and particularly Wagner–Konorski, focus on long-term or between-session habituation, whereas much of the focus in the dual-process theory is on short-term or within-session habituation.

Mechanisms of Habituation

In animals with nervous systems, the underlying processes yielding behavioral habituation are due to alterations in neurons and synapses (see below). However, single-cell animals that behave, for example, ameba and paramecium, also show at least some phenomena of habituation, and

they, of course, have no neurons. Perhaps the most simplified or reduced preparation used for habituation is the PC12 cell line, studied by Daniel Koshland and associates. The cells in this cell culture do not behave, but they do secrete. The PC12 cell culture is a pheochromocytoma (cancer) cell line from the adrenal medulla. The cells are immortal in that they stop dividing until activated by the nerve growth factor. When appropriately stimulated, they secrete norepinephrine (NE) and other neurotransmitters. Koshland stimulated PC12 cells by pulses of potassium ions (K^+) and measured release of ^{3}HNE from the culture. The amount released showed clear habituation and exhibited both the frequency effect (more rapid and pronounced habituation with more rapid frequency of stimulation) and the intensity effect (the weaker the stimulus, the more rapid and pronounced the habituation). Further, they showed both within-session and between-session habituation, that is, both short- and long-term memory. The PC12 cell culture appears to be a most promising model for the analysis of the physical–chemical bases of habituation-like phenomena.

In animals with nervous systems, a consistent picture appeared to emerge in the 1970s of the basic synaptic mechanism of habituation. In their work on spinal reflexes, Spencer and Thompson argued that synaptic depression seemed a likely mechanism. In a series of elegant experiments, Eric Kandel and associates analyzed within-session habituation of the monosynaptic gill-withdrawal response in *Aplysia*. In brief, repeated stimulation resulted in a decrease in the probability of neurotransmitter release at the sensory–motor synapse, a presynaptic process, due in turn to a decrease in calcium ion influx at the sensory nerve terminals. Therefore, a clear picture seemed to emerge, at least for within-session habituation. Unfortunately, more recent work, for example, by Glanzman and by Rankin suggests that the mechanisms of both short- and long-term habituation are far more complex than earlier believed.

Glossary

Episodic memory – Memory for specific events in the past.

Mental context – Any information that is actively represented in a person's brain at the time they are processing a particular stimulus.

Semantic memory – Memory for meanings.

The goal of learning and memory research is to understand how we store and retrieve information based on our experiences. Toward this end, computational models provide formal implementations of memory theories; these formal implementations facilitate hypothesis testing and the generation of novel predictions. Computational models of memory are constrained in two directions. One goal of memory modeling research is to capture the behaviors that participants exhibit during memory tasks. Another goal is to explain how the brain gives rise to these behaviors. High-level, abstract models focus on reproducing behavior but not neural data, whereas biologically based models attempt to explain both neural and behavioral data. This article focuses on models of declarative memory, which can be divided into two components: episodic and semantic memory. The first section of the article describes abstract models of episodic memory, our ability to remember specific, previously experienced events. The second section describes abstract models of semantic memory – our ability to learn and remember the meanings of stimuli. The final section describes the Complementary Learning Systems (CLS) model, which seeks to account for both semantic and episodic memory phenomena within a single, biologically plausible computational framework.

Abstract Models of Episodic Memory

Episodic memory experiments typically consist of a study phase (where subjects are exposed to a set of stimuli) followed by a test phase. The test phase takes the form of either a recognition-memory test (where subjects have to discriminate between studied and nonstudied stimuli) or a recall test (where subjects have to retrieve specific details from the study phase of the experiment). Abstract models of episodic memory try to describe the mental algorithms that support performance on recognition and

recall tests, without specifically addressing how these algorithms might be implemented in the brain. Although there is considerable diversity within the realm of abstract episodic memory models, most of the abstract models that are currently in use share a common set of properties: Individual memories, commonly referred to as memory traces, are typically represented as vectors – where each element of that vector represents a particular feature of the memory. At study, memory traces are placed separately in a long-term store. Because of this ‘separate storage’ postulate, acquiring new memory traces does not affect the integrity of previously stored memory traces. At test, the model computes the match between the test cue and all of the items stored in memory. This item-by-item match information can be summed across all items to compute a ‘global-match’ familiarity signal. Most abstract models posit that subjects make recognition-memory judgments based on the strength of the global-match familiarity signal (i.e., the stronger the match, the more likely it is that the item was studied). Some abstract models that conform to this overall structure are Search of Associative Memory (SAM) model (first implemented by Raaijmakers and Shiffrin), Retrieving Effectively from Memory (REM) model (first implemented by Shiffrin and Steyvers), and MINERVA 2 (developed by Hintzman).

In abstract models, the same ‘match’ rule that is used to compute the global-match familiarity signal is also used when simulating recall tasks, although the specific way in which the match rule is used during recall differs from model to model. For example, MINERVA 2 simulates recall by computing a weighted sum of all of the items stored in memory, where each item is weighted by how well it matches the test cue. In contrast, models like SAM and REM use the individual match scores to determine which (individual) memory trace will be recalled.

Collectively, abstract models have been very successful in explaining behavioral recall and recognition data from normal subjects. They have also been used to explain data from memory-impaired subjects, by finding a set of parameter changes that lead to the desired pattern of memory deficits. The remaining part of this section presents a detailed description of the REM model. REM is highlighted because of its principled mathematical foundation, and because (of all of the models mentioned above) it is the abstract model that is being developed and applied most actively.

The REM Model of Recognition and Recall

The REM model, first published by Shiffrin and Steyvers in 1997, is the most recent iteration of a line of models that dates back to the SAM model that was published by Raaijmakers and Shiffrin in 1981. One of the main differences between REM and previous models like SAM and MINERVA 2 is that REM implements a principled Bayesian calculation of the likelihood that the cue ‘matches’ (i.e., corresponds to the same item as) a particular stored memory trace, whereas the match calculation was not defined in Bayesian terms in previous models.

In REM, items are vectors of features whose values are geometrically distributed integers. The primary consequence of feature values being distributed geometrically is that high-feature values are less common than low-feature values. When an item is studied, the features of that item are copied into an episodic trace for that item via a two-step process. First, each feature is stored with a specified probability that is a parameter of the model. If a feature is stored, then a second probability determines whether that feature is stored correctly or whether it is replaced by a value sampled from the geometric distribution. A zero value means that no value is stored for the feature.

At test, the retrieval cue is compared to each stored memory trace. For each trace, the model calculates the likelihood that the cue and the trace match (i.e., they correspond to the same item). This likelihood is based on two probabilities: the probability of obtaining the observed pattern of matching and mismatching features – assuming that the cue and trace correspond to the same item – divided by the probability of obtaining the observed pattern of matching and mismatching features, assuming that the cue and trace correspond to different items.

The same core ‘match’ calculation is used for both recognition and cued recall in REM. The model is applied to recognition by computing the overall odds that the item is old (vs. new), calculated as the average of the likelihood values from the match calculations. If this odds value exceeds a preset criterion then the item is called ‘old.’ The fact that the effects of individual feature matches (and mismatches) are combined multiplicatively within individual trace comparisons and additively across traces ensures that multiple matches to a single trace have a larger effect on the odds that an item is old than the same number of feature-matches spread across multiple traces.

Recall (i.e., retrieval of specific stored details) in REM has both a sampling component (which picks a single trace out from the memory store) and a recovery component (which determines whether the sampled memory trace is retrieved successfully). The sampling probability for each item is based on the match between the memory cue and the item, scaled by the sum of the matches to all items. Once an item is sampled, the probability that the image will be recovered is based on the proportion of

correctly stored item features. Thus, in REM, well-encoded items are more likely to be recovered than poorly encoded items.

Recently, Malmberg and colleagues developed a dual-process version of REM that utilizes both the ‘global-match’ familiarity signal and the recall process described above. When a test item is presented, the model computes the global match and it also attempts to retrieve a specific stored memory trace that matches the test item. The key benefit of using recall is that it helps the model reject lures that closely resemble studied items. For example, if subjects study ‘rats’ but are tested with ‘rat,’ this test item will trigger a strong global-match signal, but it may also trigger recall that ‘rats’ was studied (not ‘rat’). This mismatch between the test item and the retrieved memory can be used to identify the item as a related lure. Malmberg argues that subjects primarily use this recall process to reject related lures, and that it does not play a significant role in recognizing actually studied items (this view is controversial).

Representative REM results

Researchers have demonstrated that REM can explain a wide range of episodic memory findings. For example, Shiffrin and Steyvers demonstrated that the ‘global-match’ familiarity mechanism described above can account for the list-length, list-strength, and word-frequency effects in recognition memory.

The list-length effect refers to the finding that recognition-memory performance tends to be lower for longer versus shorter study lists. REM explains this effect because adding words to the study list increases the odds that the test item will spuriously match a stored memory trace from the study list (i.e., the model will conclude that the test item matches a stored memory trace when in fact it does not). The (null) list-strength effect refers to the finding that strengthening some list items (by repeating the items or presenting them for longer periods of time) does not impair recognition of other, nonstrengthened items. REM explains this effect because strong items have more features stored (i.e., they have more ‘differentiated’ memory representations) and thus are less likely to be confused with other test items. The word-frequency effect refers to the finding that words that occur with high frequency in natural language are recognized less well than low-frequency words. In REM, high-frequency words have more common feature-values than low-frequency words, which makes them more likely to be confused with other test items.

Context and Episodic Memory

While the basic REM model provides a mechanism for how the memory system responds to a particular cue, it does not describe how the memory system behaves when

external cues are less well specified, and subjects have to generate their own cues in order to target a particular memory (or set of memories). Take the scenario of trying to remember where you left your keys. The most common advice in this situation is to reinstate your mental context as a means of prompting recall – if you succeed in remembering what you were doing and what you were thinking earlier in the day, this will boost the probability of recalling where you left the keys. This idea of reinstating mental context plays a key role in theories of strategic memory search. For the purposes of this article, mental context can be defined broadly as any other information that is actively represented in a person's brain at the time they are processing a particular stimulus.

Multiple laboratory paradigms have been developed to examine strategic memory search. The most commonly used paradigm is free recall, where subjects are given a word list and are then asked to retrieve the studied word list in any order. REM can be extended to simulate free recall by adding a set of contextual features to each memory trace. For example, all of the items in the study list could be given a shared set of contextual features (effectively, a 'context tag') that signify membership in the study list. To simulate free recall, we can cue with this 'list-context' representation and sample items that were paired with the list-context representation at study. However, while this simple context-tag representation gives REM the ability to simulate free recall, it does not allow REM to simulate more nuanced features of free recall data. To fit detailed patterns of free recall data, it is necessary to specify in more detail how context changes over time, and how context is used to cue memory at retrieval.

The Temporal Context Model

The Temporal Context Model (TCM; first published by Howard and Kahana) is the most recent in a long succession of models that use a drifting mental context to explain our ability to selectively target memories from particular time periods. The basic idea behind these models is that the subject's inner mental context (comprising the constellation of thoughts that are active at a particular moment) changes gradually over time. Early models viewed context as a vector that evolves as a function of random noise when each item is presented, with a drift-rate parameter governing the overlap of context from time-step to time-step. The main difference between TCM and previous contextual-drift models is that context does not drift randomly in TCM. Rather, contextual updating is driven by the features of the items being studied and recalled.

During the study phase of a memory experiment, two things happen when an item is presented: first, the item is associated with the state of the context vector at the time of presentation; second, context is updated by averaging together the current state of the context vector with the semantic features of the just-studied item. At test, the recall process is initiated by cuing with the current state of the context vector, which (in turn) triggers retrieval of items that were associated with these contextual elements at study. Specifically, each item is activated to the degree that the current state of context overlaps with the context that was present when that item was studied. In the most recent version of TCM, called TCM-A, these activated items compete with one another via a set of accumulators that add up evidence for each item over time (based on that item's level of activation and the activation levels of all the other items). If the level of evidence for an item reaches a prespecified threshold level, that item is recalled, and the current state of context is updated in two ways: first, by averaging in the semantic features of the just-recalled item, and second, by averaging in the state of the context vector that was present when the item was studied. This latter updating operation can be construed as 'mentally jumping back in time' to the moment when the (just-retrieved) item was studied. Once the context vector is updated, it is used to cue for additional items, which leads to additional updating of the context vector, and so on.

How TCM accounts for recall data

The drifting context vector in TCM explains a number of findings in episodic recall, including both recency and contiguity effects. In TCM, the current state of context acts as the cue for memory retrieval via context-to-item associations. Because context changes gradually, the state of context at the time of test will overlap most strongly with the contexts associated with recent items. This gives rise to the recency effect seen in all episodic memory tasks. TCM can also explain the temporal contiguity effect: the finding that, when a subject recalls a particular item from the study list, they show an increased probability of (subsequently) recalling items from nearby time points in the list. TCM shows this effect because recalling an item (at test) also triggers recall of the contextual state that was present when the item was studied. This retrieved context will closely match contextual states associated with temporally proximal items, thereby making it easier to retrieve these items. For example, the contextual state associated with the fourth item on the study list will closely match the contextual states associated with the third and fifth items; thus, recalling the 'fourth-item' context will make it easier to access the third and fifth items.

Abstract Models of Semantic Memory

Earlier, we defined semantic memory as the ability to learn and remember the meanings of stimuli. More concretely, semantic memory is our ability to construct an internal representation of the world that allows us to make predictions about ‘unseen’ aspects of stimuli. For example, the semantic memory system allows us to categorize the pig we see at the petting zoo as a mammal and to generalize that it has a brain and gives birth to its children alive following a gestation period, without having to take a magnetic resonance image of the pig’s head or watch it give birth. The semantic memory system also allows our friends to retrieve these basic features of a pig when we recount seeing a pig at the petting zoo.

Rumelhart Model of Semantic Cognition

We focus on the model of semantic memory developed by David Rumelhart and colleagues, because it is the simplest extant model that explains how we develop internal representations and make predictions using these representations. Our discussion here draws heavily on recent work using this model by Rogers and McClelland.

The goal of the Rumelhart model is to activate the proper set of attributes when probed with an item (e.g., ‘pig’) and relation (e.g., ‘can’). The basic structure of the Rumelhart model (see schematic in **Figure 1**) consists of multiple layers of units connected in a feedforward fashion. The item units specify the objects that are being observed, the relation units specify the contexts in which we observe these objects, and the attribute units specify

the ‘unseen’ aspects of the objects that we are trying to predict. When the network is probed by activating an item unit and a relation unit, activation spreads forward in the network (through the representational layer and the hidden layer) until it reaches the attribute layer. The spread of activation is governed by the strengths of connections between units, and the resulting pattern of activity in the attribute layer constitutes the model’s prediction (e.g., ‘pig’ + ‘can’ should yield ‘walk’ in the attribute layer). A critical aspect of the model is that it does not prespecify what patterns should appear in the representational and hidden layers. Rather, the network learns to generate patterns in these layers (by adjusting weights) that help it predict the correct attributes. The pattern of activity in the representational layer serves as the primary representation of the item’s meaning, whereas the pattern of activity in the hidden layer represents the meaning of the item in the context of a particular relation.

A central aspect of the Rumelhart model is that it learns to make better predictions by adjusting connection strengths. Learning takes place incrementally over many presentations of item, relational, and attributional patterns (i.e., seeing a fish swim in water would be represented by activating the ‘fish’ item unit, the ‘can’ relation unit, and the ‘swim’ attribute unit). On each trial, after generating its prediction, the network receives feedback on which attributes are actually observed for that item/relation combination. Learning in the network is driven by prediction error, that is, the discrepancy between attributes that are predicted to be present, and the attributes that are actually present. On each trial, after prediction error is computed, and weights are changed

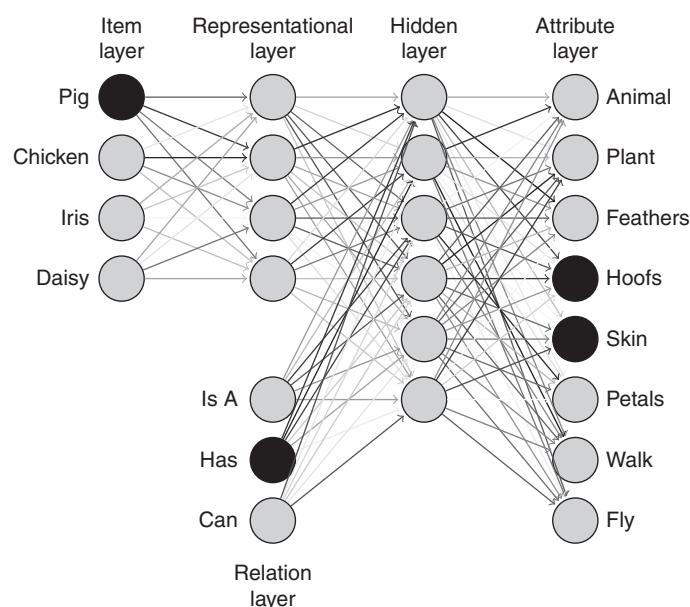

Figure 1 Simplified diagram of the Rumelhart model.

throughout the network in order to reduce prediction error.

Specifically, Rumelhart used the backpropagation neural network learning algorithm to adjust network weights. For each unit in the network (except for item and relation units), backpropagation computes a delta (δ)-value for that unit that indicates whether that unit was too active ($+\delta$) or not active enough ($-\delta$). First, backpropagation computes δ -values for attribute units; then it computes δ -values for each preceding layer (in turn) by multiplying δ -values by network weights. For example, if an attribute unit has a positive δ -value (i.e., it is too strongly active), active hidden units with positive connections to the overly active attributional unit are also assigned positive δ -values (indicating that they are ‘at fault’ for the prediction error, and that prediction error can be reduced by reducing the activity of hidden units). After δ -values have been assigned to all of the attribute-layer, hidden-layer, and representation-layer units, backpropagation changes network weights based on these δ -values: if a unit is too active, weights coming into that unit (from active sending units) are reduced, and if a unit is not active enough, weights coming into that unit (from active sending units) are increased.

Successes of the Rumelhart model

After a sufficient degree of training, Rumelhart showed that the model learns context-sensitive mappings between items and attributes. For example, after training, activating the ‘pig’ item and the ‘has’ relation will activate the ‘skin’ and ‘hoofs’ attributes. If instead we activate the ‘pig’ and the ‘can’ attribute, the ‘walk’ attribute will activate (and the ‘fly’ attribute will certainly not activate). This context sensitivity arises because the relation units modify the activation in the hidden layer, which is responsible for combining the activity in the representational and relational layers before activating the attribute units.

The most interesting aspect of the Rumelhart model is how internal representations (i.e., the patterns of activity in the representation and hidden layers elicited by different items) change during learning. Items with similar attributes come to elicit similar patterns of activity in the representation and hidden layers, and items with distinct attributes come to elicit distinct patterns of activity in the representational and hidden layers. For example, when training the sample Rumelhart model in **Figure 1**, the representations for ‘pig’ and ‘chicken’ start to converge, and these representations diverge together from the representations for ‘iris’ and ‘daisy’ because (for any given relation) ‘pig’ and ‘chicken’ are more likely to share attributes than, say, ‘pig’ and ‘daisy.’ In this way, the model learns just as a child would – by first forming a coarse representation of the environment that is refined over time based on experience.

A key property of the model is its ability to generalize to new stimuli based on their similarity to previously encountered stimuli. For example, after learning the various attributes of pigs and chickens, the Rumelhart network will be able to predict basic properties of a new animal, such as a cheetah, just by learning that it is an animal. This is because training the network to predict animal given cheetah will push the cheetah’s internal representation closer to the representations of other items that predict animal (e.g., pig and chicken). This overlap in internal representations will lead to cheetah predicting other attributes that were associated with pigs and chickens (e.g., that cheetahs have skin and can walk).

Temporal Context and Semantic Relationships

The Rumelhart model modifies its internal representations based on explicit instruction concerning which attributes should be active in a given context. Recently, several researchers have argued that meaning representations can also be acquired without explicit instruction, if the model keeps track of temporal context (i.e., it learns which items tend to be presented close in time to a given item). The key idea here is that items with similar meanings tend to occur in similar temporal contexts (e.g., couch and sofa both tend to occur close in time to other words like rug, lamp, and cushion). Given this premise, it should be possible to learn that couch and sofa have similar meanings by learning about which other words tend to co-occur with couch and sofa.

The Latent Semantic Analysis (LSA) algorithm developed by Landauer and colleagues provides a large-scale proof of the relationship between meaning and temporal context. Landauer and colleagues took a massive corpus of English texts and computed how often each word co-occurred in the same paragraph as every other word (normalized to account for differences in overall word frequency). The net product is a matrix of size $N \times N$, where N is the number of distinct words in the text corpus. One way of thinking about this matrix is that each word in the matrix is represented by a ‘temporal context vector’ of length N , listing how often that word occurred with every other word. In principle, it should be possible to estimate the similarity of word meanings by looking at the similarity of the N -dimensional temporal context vectors associated with each word. However, Landauer also had the insight that there is considerable redundancy in the $N \times N$ co-occurrence matrix, and that (because of this redundancy) words could be represented by vectors with many fewer-than- N elements. To eliminate this redundancy, LSA applies a technique called singular value decomposition (SVD) to the $N \times N$ matrix. SVD returns a set of N orthogonal temporal context vectors (each of size N), ranked by how much variance they explain (across words) in the original matrix

(technically, these are the eigenvectors of the original matrix). Landauer found that the first 300 or so of these vectors accounted for almost all of the variance in the original matrix. As such, he discarded the remaining vectors, and re-expressed each word's temporal context vector in terms of a weighted combination of these 300 'basis vectors.' The net result of this process to go from an N -dimensional representation for each word to a (much more manageable) 300-dimensional representation. Using these 300-dimensional vectors, Landauer and colleagues found that the cosine distances between these vectors map quite well onto the similarity values that people assign to pairs of words. For example, the cat and dog vectors are quite similar to each other (i.e., their cosine distance is very small), whereas the chicken and daisy vectors are not.

Importantly, while LSA substantiates the idea that temporal context provides information about stimulus meaning, it does not provide a mechanistic account of how the brain exploits temporal context to acquire semantic representations. Recently, Howard and colleagues argued that the TCM (described earlier) can meet these desiderata. The previous section discussed how TCM can account for episodic memory phenomena (by rapidly binding items with coactive contextual features, such that items can trigger recall of associated contexts and vice versa). TCM can be extended to address semantic learning by supplementing this rapid binding process with another learning process that gradually (across trials) learns which contextual features tend to be associated with a given item.

Another important point is that, while temporal context provides some information about word meanings, LSA-like algorithms are not meant to be a substitute for the kinds of error-driven learning that are built into the Rumelhart model. Meanings learned by LSA do not always coincide perfectly with human semantic judgments (e.g., LSA tends to give antonyms very similar meaning representations because they occur in similar contexts). To remedy these misconceptions, models of semantic memory need to receive feedback on how well they are predicting the item's attributes, and they need to be able to learn based on prediction errors. One way to update the Rumelhart model to take advantage of both error-driven learning and temporal context information would be (1) to include a representation of temporal context (akin to the representation generated by TCM) and (2) to train the model to predict the current state of the temporal context representation (plus other relevant attributes) when an item is presented. Forcing the model to predict temporal context will bias the model to assign similar internal representations to items with similar temporal contexts (just as forcing the model to predict attributes like 'animal' causes the model to assign similar representations to all of the 'animal' items).

Finally, while the above discussion focused on temporal context, other kinds of context also provide information about stimulus meaning. For example, knowing that two items tend to appear at similar spatial locations provides some information about their meanings, irrespective of whether they appear close in time to one another. The general principle of training models to predict contextual information (be it temporal, spatial, or some other type of information) will allow models of semantic memory to leverage all of these regularities when learning about meanings.

Learning, Memory, and the Brain

The previous sections focused on abstract models of episodic and semantic memory. This section describes the CLS model, which intertwines episodic and semantic memory into a single, neurally plausible computational framework.

The Complementary Learning Systems (CLS) Model

The CLS model (first outlined by McClelland, McNaughton, and O'Reilly) incorporates several widely held ideas about the division of labor between hippocampus and neocortex that have been developed over many years by many different researchers. (It is important to note that the CLS model is only one of many biologically-plausible models of the hippocampal role in learning and memory. For example, see Further reading for other influential hippocampal models by Gluck, Rolls, Hasselmo, and Eichenbaum.) According to the CLS model, the neocortex forms the substrate of our internal model of the structure of the environment. In contrast, the hippocampus is specialized for rapidly and automatically memorizing patterns of cortical activity, so they can be recalled later (based on partial cues). This characterization makes it clear that neocortex is the key substrate for semantic memory and that hippocampus is crucial for episodic memory, although (as discussed below) both structures contribute to both kinds of memory.

The model posits that the neocortex learns incrementally; each training trial results in relatively small adaptive changes in synaptic weights. These small changes allow the cortex to adjust its internal model of the environment gradually in response to new information. The other key property of neocortex (according to the model) is that it assigns similar representations to similar stimuli. Use of overlapping representations allows cortex to represent the shared structure of events, and therefore makes it possible for cortex to generalize to novel stimuli based on their similarity to previously experienced stimuli. In contrast, the model posits that hippocampus assigns

distinct, pattern-separated representations to stimuli, irrespective of their similarity. This property allows the hippocampus to memorize arbitrary patterns of cortical activity associated with particular events rapidly without suffering from unacceptably high (catastrophic) levels of interference.

Norman and O'Reilly model of episodic memory

Norman and O'Reilly constructed hippocampal and cortical networks that instantiate the CLS principles outlined above, and applied these networks to simulating episodic memory data. In both the hippocampal and cortical networks, to-be-memorized items are represented by patterns of excitatory activity that are distributed across multiple units (simulated neurons) in the network. Excitatory activity spreads from unit to unit via positive-valued synaptic weights. The overall level of excitatory activity in the network is controlled by a feedback-inhibition mechanism that samples the amount of excitatory activity in a particular subregion of the model, and sends back a proportional amount of inhibition.

The architecture of the model (illustrated in **Figure 2**) reflects a broad consensus concerning key anatomical and physiological characteristics of different hippocampal and cortical subregions, and how these subregions contribute to the overall goal of memorizing cortical patterns. The entorhinal cortex (EC) contains a compressed representation of information represented elsewhere in cortex. The hippocampal network memorizes patterns of EC activity

by linking these patterns to a set of units (an 'episodic representation') in region CA3, which is then linked back to EC via region CA1. When a pattern is presented, connections are strengthened between active EC and CA3 units, between active units within CA3, and between active CA3 and CA1 units; collectively, these synaptic modifications allow the network to recall entire stored EC patterns based on partial cues (pattern completion). To minimize interference, the network has a built-in bias to assign relatively nonoverlapping (pattern separated) CA3 representations to different episodes. Pattern separation occurs because of strong feedback inhibition in CA3, which leads to sparse representations (i.e., representations with relatively few neurons active). The dentate gyrus (DG) assists in the pattern separation process by forming an even more sparse representation of the EC pattern, which then projects into region CA3.

The cortical component of the CLS model consists of an input layer (corresponding to lower regions of the cortical hierarchy) which projects in a feedforward fashion to a hidden layer (corresponding to regions further up in the hierarchy, including perirhinal cortex (PC) and EC). As mentioned earlier, the main function of cortex is to extract statistical regularities in the environment. The two-layer CLS cortical network (where hidden units compete to encode regularities that are present in the input layer) is meant to capture this idea in the simplest possible fashion. In the Norman and O'Reilly simulations, learning in both the cortical and hippocampal subregions of the model was implemented by means of a simple Hebbian learning rule that strengthens connections between active sending and receiving neurons and weakens connections between active receiving neurons and inactive sending neurons.

As described by Norman and O'Reilly, the hippocampal and cortical networks constitute a biologically based dual-process model of recognition memory. As with the dual-process REM model described earlier, the CLS model posits that familiarity (i.e., global match) and recall of specific details both contribute to recognition memory. In the CLS model, hippocampus supports recall of specific studied details, but (because of its tendency to assign distinct CA3 representations to stimuli, regardless of their similarity) it is not well suited for computing the global match of the test cue to studied items. The cortex, on the other hand, does not learn quickly enough to support recall of details from specific events, but it can compute a scalar familiarity signal that tracks how well the test cue matches studied items. As items are presented repeatedly, their representations in the hidden layer of the cortical network become sharper: novel stimuli weakly activate a large number of hidden units, whereas previously presented stimuli strongly activate a relatively small number of units. Sharpening occurs in the cortical model because Hebbian learning specifically tunes some hidden units to

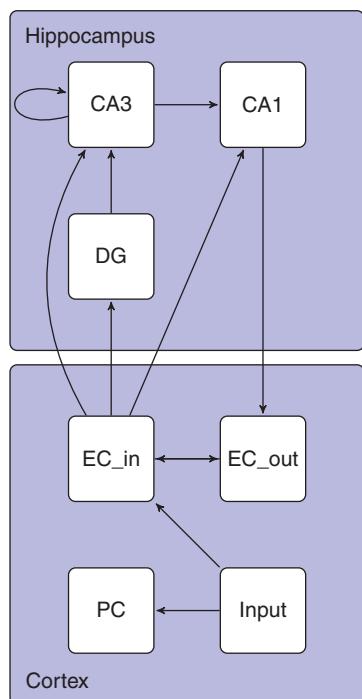

Figure 2 Architecture of the Norman and O'Reilly Complementary Learning Systems model of episodic memory.

represent the stimulus, and these units suppress the activity of other units (via the feedback-inhibition mechanism). Furthermore, since the cortex assigns similar hidden representations to similar stimuli, these sharpening effects generalize smoothly to other stimuli based on their similarity to the original stimulus (so sharpening tracks global match).

Norman and O'Reilly showed how, taken together, the hippocampal network and cortical network can explain a wide range of behavioral findings from recognition and recall list-learning experiments. For example, the model can account for the null-recognition list-strength effect described earlier, and it also makes the prediction that list-strength effects should be observed when recognition memory is driven by recall of specific details as opposed to familiarity. Furthermore, because the CLS model maps clearly onto the brain, it is possible to use the model to address neuroscientific data in addition to (purely) behavioral data. For example, the model correctly predicts that focal hippocampal lesions should differentially impair recognition performance on tests where distractors are very similar to studied items (because these tests benefit from the hippocampus' ability to assign distinct representations to similar patterns). The model also successfully predicts that lesioned patients' deficit on these tests can be ameliorated by giving subjects a forced choice between studied items and corresponding related lures (because the forced-choice procedure allows subjects to leverage small but reliable differences in cortical familiarity between studied items and corresponding lures).

The original form of the CLS episodic memory model also has some serious flaws. In particular, Bogacz and Brown showed that the cortical network's capacity for familiarity discrimination (i.e., the number of studied patterns that it can discriminate from nonstudied patterns with 99% accuracy) falls far below the documented capacity of human recognition memory. This problem can be traced back to the Hebbian learning rule, which is insufficiently judicious in how it adjusts synaptic strengths: it strengthens synapses between co-active units even if the memory is already strong enough to support recall, and it weakens synapses between active receiving units and other inactive units, even if those other units are not interfering with recall of the sought-after memory. This excess synaptic modification greatly increases the extent to which new learning interferes with stored knowledge. The solution to this problem is to switch to an error-driven learning rule that compares top-down expectations (generated by cortex's internal representation of the environment) to sensory inputs, and only modifies synapses when the model's expectations are incorrect. The backpropagation rule described earlier fits this description, but this rule is widely believed to be biologically implausible. Determining biologically plausible methods of enacting error-driven learning in cortex has

been a major focus of computational modeling research, and researchers have devised a wide range of potential solutions to this problem (see, e.g., the work of Carpenter and Grossberg). Recently, Norman and colleagues swapped out the Hebbian learning rule for a more judicious, biologically plausible rule that uses neural oscillations to probe for 'weak points' in cortical representations; this new learning rule greatly improves the cortical model's familiarity discrimination capacity.

Toward a full episodic/semantic CLS model

The Norman and O'Reilly CLS simulations focused on episodic memory. However, the CLS cortical model (equipped with an error-driven learning rule) should be able to account for all of the semantic learning phenomena that were discussed in the Rumelhart model section above; the key prerequisites for simulating these results are a learning rule that is driven by prediction error, and the ability to re-represent inputs in order to minimize prediction error. CLS can also be used to explore how hippocampo-cortical interactions shape semantic memory. One of the key claims made in the original formulation of CLS was that hippocampus could play back significant, once-presented events to the cortex during sleep, thereby allowing the slow-learning cortical network to absorb these events into its semantic network. Recent modeling work by Norman, Newman, and Perotte explored other aspects of learning during sleep (e.g., the possibility that learning during REM sleep could help to repair cortical memories that are damaged by new learning).

Another feature missing from most CLS models is a representation of context. Some CLS models have included a simple context layer (akin to the one used in the Rumelhart model), but none of these models have seriously explored how temporal context is represented in the brain. It seems likely that prefrontal cortex (PFC) will play a key role in temporal context memory (by virtue of its ability to actively maintain patterns of neural firing over time). Other researchers have noted that the EC also has some intrinsic ability to maintain information over time. Future work using the CLS framework will explore the contributions of both PFC and EC to representing temporal context.

Key Challenges

Over the past several decades, a consensus has emerged among computational modelers regarding certain key aspects of memory functioning (e.g., how the hippocampus supports episodic memory). However, there is still extensive work to be done in specifying extant computational models of learning and memory. For example, while there is widespread agreement that cortical learning

is driven by a comparison of top-down expectations versus bottom-up inputs, there is still extensive debate concerning precisely how the brain implements this learning process. In addition, extant models have focused on specifying basic encoding and retrieval processes, and have not yet addressed fundamental issues with regard to strategic influences on memory (e.g., how much to rely on recall of specific details vs. familiarity when making recognition decisions; how to strategically construct retrieval cues during memory search). This latter issue might benefit from a normative approach (i.e., mathematically deriving how subjects should be cuing memory and making decisions in order to maximize performance, and then exploring whether subjects actually use these 'optimal' strategies).

Importantly, the models of episodic and semantic memory described above constitute only a small portion of the total space of memory models. Other models have been developed to account for data from other kinds of memory tasks, such as working memory tasks (which ask subjects to actively maintain stimulus information in the face of distraction), conditioning tasks, spatial learning tasks, and motor-learning tasks. These other models leverage some of the same computational principles and neural systems described above, but they also describe important ideas that were not reviewed in the preceding sections. For example, one topic that has received extensive attention in recent years is how the brain leverages simple reinforcement signals (rewards and punishments) to improve behavior. Another topic that has received extensive attention is the control of working memory (i.e., how does the brain learn when to 'gate' information into working memory and when to release it from working memory; see the work of Frank, O'Reilly, and colleagues).

The key challenge, moving forward, will be to integrate insights gleaned from all of these models while still keeping model complexity within manageable limits. Models like CLS are quite complex as they stand, and the extensions proposed above (e.g., adding a PFC network to CLS to help it maintain temporal context) will make the models even more complex. The saving grace here is that modern-day memory models can be used to address an enormous range of findings – using a complex model to explain a single result may not be all that meaningful, but simultaneously accounting for behavioral and neural data from multiple types of learning experiments is still a worthy challenge. So long as modelers continue to apply all available constraints to theory development, we should continue to see steady progress toward a complete computational account of learning and memory data.

Motor Learning in the Vestibulo-Ocular Reflex

D M Broussard, H K Titley, and R Heskin-Sweezie, University Health Network, Toronto, ON, Canada

© 2010 Elsevier Ltd. All rights reserved.

Glossary

AMPA receptor – A type of glutamate receptor containing a cation channel. α -Amino-3-hydroxy-5-methyl-4-isoxazole-propionate (AMPA) receptor current depolarizes the postsynaptic membrane, mediating most excitatory synaptic transmission in the brain.

Compensation – See the glossary entry ‘vestibular compensation.’

Consolidation – The conversion of a memory from a short-term, labile form to a long-term, more stable form.

Flocculus – A region of the cerebellar cortex that is reciprocally connected with the vestibular nuclei and which modulates the vestibulo-ocular reflex (VOR).

Flocculus target neurons – The neurons in the vestibular nuclei that receive direct input from the flocculus.

Gain – The ratio of output to input of a system; in the case of the VOR, the ratio of the eye velocity generated by the reflex to the head velocity that triggers it.

Inferior olive – A brainstem nucleus that projects to the cerebellar cortex and is the source of climbing fibers.

Long-term depression (LTD) – A persistent (45 min or more) decrease in the efficacy of transmission by a synapse.

Metabotropic glutamate receptors (mGluRs) – The glutamate receptors that do not contain ion channels, but interact with second-messenger systems through G proteins.

Motor learning – A change in the motor response to a sensory stimulus that is acquired by experience and that can be retained without further experience.

Parallel fibers – The long, unmyelinated axons of granule cells that make up the molecular layer of the cerebellar cortex, and that provide excitatory input to Purkinje cells.

Purkinje cells – Large inhibitory neurons, located in the cerebellar cortex, that project out of the cortex to the cerebellar nuclei and vestibular nuclei.

Retinal slip – The motion of an image with respect to the retina.

Vestibular compensation – The process by which vestibular function, including VOR function, is restored following damage to the vestibular sensory organ or vestibular nerve.

Vestibulo-ocular reflex (VOR) – A reflex that stabilizes gaze by moving the eyes in the opposite direction to the

head, and at the same speed, utilizing sensory signals that arise from the vestibular labyrinth.

VOR adaptation – A change in vestibulo-ocular reflex performance that occurs as a result of visual and vestibular experience and that persists in the absence of visual input.

The Vestibulo-Ocular Reflex

The vestibulo-ocular reflex (VOR) uses information from the vestibular labyrinth of the inner ear to generate eye movements that stabilize gaze during head movements. Without the VOR, when walking down the street, it is impossible to read signs or even recognize faces. Even an inaccurate VOR can cause the visual image to slip with respect to photoreceptors, blurring images. The VOR responds both to rotation and to translation, using signals arising from different receptors in the inner ear. During rotation, the VOR can stabilize the eyes accurately even at angular velocities of over 300° s^{-1} and frequencies above 20 Hz. This is because the VOR pathway is relatively short (see [Figure 1\(a\)](#)) and uses only vestibular sensory information to activate motoneurons. Precisely because it is so quick, the VOR must be intrinsically accurate; on this timescale, vision is too slow to be useful as a corrective mechanism.

Functional Significance of Learning in the VOR

Since vision cannot be used as feedback, how can the VOR ensure good visual stability? One solution is to calibrate the movement by trial and error, that is, by motor learning. Motor learning in the VOR is also called VOR adaptation or plasticity. [Figure 1\(b\)](#) shows an example of the VOR’s response to sinusoidal rotation in the horizontal plane. Although the VOR also responds to rotation in other planes as well as to translation and tilt, most studies of motor learning have been carried out using horizontal rotation. The eye movement generated by the VOR is opposite in direction and approximately equal in speed to the head movement. The ratio of eye to head speed is called the ‘gain’ of the reflex. A gain of 1.0 would describe a perfect VOR for rotation under normal conditions.

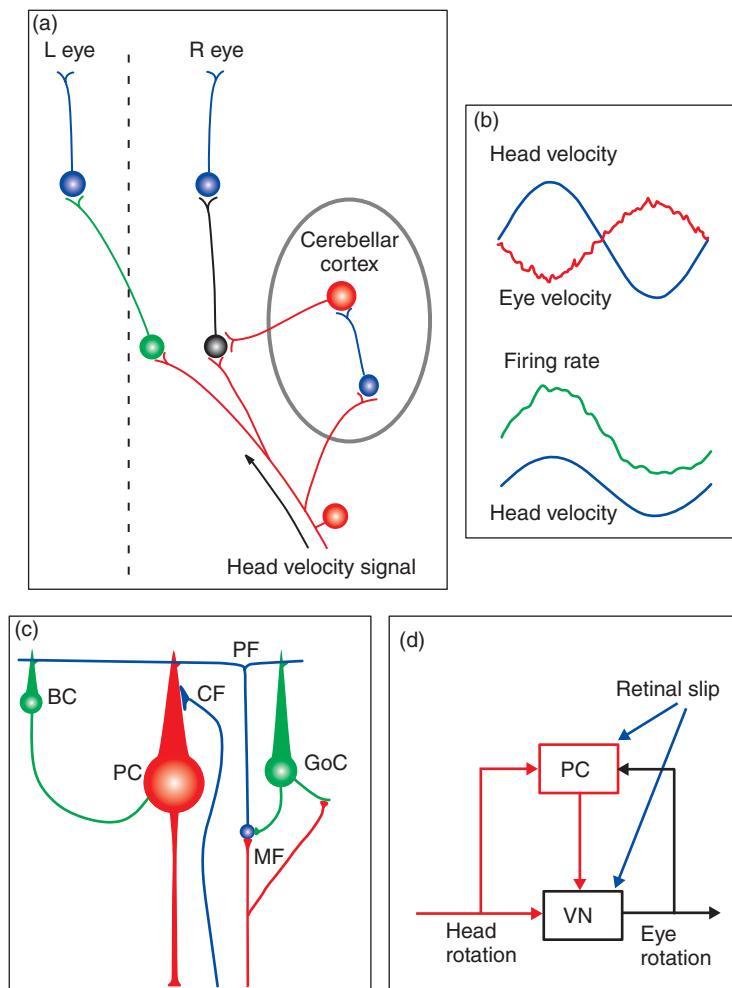

Figure 1 Anatomy of the vestibulo-ocular reflex. (a) Circuitry of the horizontal rotatory VOR. Primary afferents in the vestibular nerve (red) provide a head velocity signal to excitatory (green) and inhibitory (black) secondary vestibular neurons in the vestibular nuclei, which in turn project to motoneurons (blue) innervating the lateral rectus muscles. Because the axon of the excitatory interneuron crosses the midline (dashed line) to the contralateral side, the excitatory and inhibitory pathways are synergistic. Additional pathways (not shown) innervate the medial rectus muscles. An inhibitory side loop modulates the VOR in situations where its gain is too high or too low for perfect stabilization. The side loop includes granule cells (blue) and Purkinje cells (red) in the cerebellar cortex. The Purkinje cell output signal inhibits the inhibitory VOR interneuron. (b) Response of the VOR to rotation. Head (blue) and eye (red) movements are opposite in direction and approximately equal in velocity. Data from alert cat (gain = 0.8). The firing rate of a secondary neuron (green) closely follows head velocity. (c) Actual neural circuit of the cerebellar cortex. Input signals arrive in the cortex through mossy fibers (MF, red) and climbing fibers (CF, blue). Granule cell axons (blue, also called parallel fibers) excite dendritic spines of Purkinje cells (PC), Golgi cells (GoC), and inhibitory interneurons (BC or basket cell). Thus, excitatory inputs from climbing fibers and parallel fibers converge on the Purkinje cell dendrites. (d) Signal flow in the cerebellar cortex and the VOR. Primary afferent fibers from the semicircular canals send head velocity signals both to Purkinje cells and to VOR interneurons in the vestibular nuclei (VN). The Purkinje cell, in turn, inhibits the VOR interneuron. Climbing fibers (blue) carrying retinal slip signals excite Purkinje cells and send collaterals to the vestibular nuclei as well. Finally, an appropriate eye velocity signal is sent to the extraocular muscles. A feedback loop provides a copy of the eye velocity signal (through mossy fibers) to the Purkinje cells. Springer: Berlin.

If the VOR gain is inappropriate for the existing conditions, then learning is needed to improve its accuracy and, hence, visual stability. In everyday life, the VOR gain becomes inappropriate as we age and lose vestibular sensitivity, whenever we get a new pair of prescription glasses, and when we suffer from vestibular damage. Each of these situations provides a situation where motor learning is beneficial. For example, when a near-

sighted person puts on a new pair of glasses with a stronger prescription, the visual field is reduced and the eyes do not need to move as far or as fast to stabilize gaze. Initially, then, the VOR is inaccurate when wearing the new glasses. After wearing them for a while, motor learning reduces the VOR gain and gaze is stable again. In the lab, learning can be demonstrated by measuring the gain of the VOR in darkness after the subject has been exposed

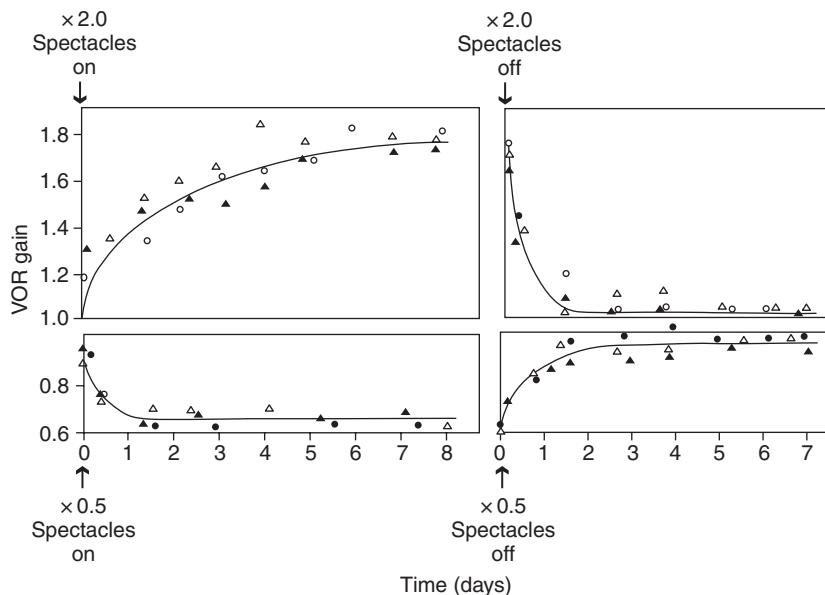

Figure 2 The time course of motor learning. Data are shown from monkeys wearing magnifying ($\times 2.0$, top two rectangles) or miniaturizing ($\times 0.5$, bottom two rectangles) telescopic spectacles. Head velocity was provided by the monkey's own movements. Different symbols are from different animals. The change in gain was fit by an exponential decay. In the right-hand panels, the spectacles were removed and the VOR gain was allowed to return to normal. The return to normal had a different time constant for high as compared to low gain. Reproduced with permission from Miles FA and Eighmy BB (1980) Long-term adaptive changes in primate vestibuloocular reflex. I. Behavioral observations. *Journal of Neuroscience* 43: 1406–1425, The American Physiological Society.

to particular combinations of visual magnification and head movement (see **Figure 2**).

In motor learning research, various reflexes and more complex systems are studied in the hope of defining the underlying principles and common mechanisms. The VOR is a popular choice because its short anatomical pathway means that the number of possible sites and mechanisms for learning is comparatively small. In addition, eye movements can be treated as pure rotations, which make them easy to describe quantitatively. As eye movements are kinematically simpler than limb movements, it is easier to establish a close correspondence between their parameters and neurophysiological measurements than it is for any other type of movement. The oculomotor system can be mathematically modeled as a simple linear control system, and the model is fairly accurate within a moderate range of stimulus parameters. The modeling approach has been used successfully to solve important problems in motor learning.

Anatomy and Physiology of the VOR

In **Figure 1(a)**, primary afferent fibers from the horizontal semicircular canal (shown in red) provide a signal, representing the angular speed of rotation, to secondary neurons in the vestibular nuclei. Majority of secondary

neurons increase their discharge rates as the head is rotated toward the side they are on (**Figure 1(b)**). Secondary neurons, also known as interneurons, project to the motoneurons, located in the abducens nuclei, which innervate the lateral rectus muscles. The direct projections are excitatory (green) to the contralateral and inhibitory (black) to the ipsilateral abducens. Therefore, the shortest VOR pathway is a three-neuron arc within the brainstem.

In addition to their excitatory inputs from the vestibular nerve, secondary neurons also receive both inhibitory and excitatory inputs from the vestibular commissure, which connects the vestibular nuclei on the two sides of the brainstem. Some secondary neurons also receive inhibitory inputs from Purkinje cells (PCs) in the cerebellar cortex (a region known as the 'flocculus') (**Figure 1(a)**). These secondary neurons are known as the 'flocculus target neurons.' Another vestibular pathway involves the circuitry of the flocculus itself, which receives vestibular input both from primary vestibular afferents and secondary vestibular neurons. **Figure 1(c)** illustrates the basic anatomy of the cerebellar cortex, consisting of mossy fiber (MF) and climbing fiber (CF) inputs, excitatory (granule cell, GrC) and inhibitory (basket cell, BC) interneurons, and PCs. PCs of the lateral vestibulocerebellum project directly back to the vestibular nuclei (**Figure 1(a)**), this simple arrangement reflecting the early phylogenetic origin of the VOR circuitry.

Sites and Mechanisms of Motor Learning

VOR motor learning is assumed to be due to some change in the VOR circuitry, either synaptic plasticity, a change in neuronal excitability, or another similar mechanism. In order to investigate this question using the techniques of neurophysiology and molecular biology, we first need to know where exactly the change occurs. The possibilities can be narrowed down by considering how and where the needed sensory information is transmitted. Signals encoding head speed and visual-image motion are clearly necessary for VOR motor learning, and ideally would converge on a common site so that they could interact directly. Such convergence actually occurs both in the cerebellar cortex and in the vestibular nuclei. The cerebellar cortical circuit is integrated into the VOR circuitry in a feedback arrangement similar to that shown in **Figure 1(d)**. Information about head velocity arrives at the vestibular nuclei from the vestibular primary afferents and at the cerebellar PCs by way of the MF/parallel fiber pathway. At the same time, the PCs receive CF input from the inferior olive nucleus that encodes retinal slip. Eye movement signals, including smooth pursuit and VOR-generated signals, return to the cerebellum by the feedback pathway (black), as shown in **Figure 1(d)**. These pathways provide information about ongoing eye movements, which could also participate in motor learning. The feedback signal arrives at the cerebellar cortex through MFs from the dorsolateral pontine and vestibular nuclei.

In the 1970s, Masao Ito proposed that during motor learning, CLs from the inferior olive provide a visual teacher signal that adjusts the sensitivity of PCs to particular inputs from parallel fibers. These fibers were assumed to provide a head velocity signal. In thinking about Ito's hypothesis it is important to keep in mind that the cerebellum is not the only site of convergence of visual and vestibular signals. However, leaving aside the possibility of other sites for now, according to Ito's hypothesis, the synapse between the parallel fiber and the PC becomes less effective in a process known as 'long-term depression,' or LTD. As PCs inhibit their target neurons in the VOR pathway, LTD of the synapses from parallel fibers firing preferentially for one direction of rotation would cause an increase in VOR gain for rotation in that direction. LTD of a different set of parallel fibers with different on-directions could decrease the gain. In this model, the reverse of LTD, LTP, is used strictly to adjust overall levels of activity. In a more recent theory of cerebellar motor learning, gain increases and decreases in the VOR rely on different plasticity mechanisms. While LTD is involved with learned gain increases of the VOR, LTP may be involved with learned gain decreases.

On the cellular level, the initial stages of cerebellar LTD and LTP are thought to be implemented by insertion and removal, respectively, of neurotransmitter receptor molecules in the postsynaptic membrane. Specifically, α -amino-3-hydroxy-5-methyl-4-isoxazole-propionate (AMPA)-type glutamate receptors are shifted in or out of the plasma membrane, depending on their phosphorylation state (**Figure 3**). The phosphorylation of AMPA receptors is thought to be regulated by the balance of activities of protein kinase C and various protein phosphatases. Protein kinase C, indirectly activated by mGluR1 receptors (metabotropic glutamate receptor 1, mGluR1), phosphorylates the AMPA receptor. At the same time, another pathway inhibits protein phosphatases, preventing them from dephosphorylating AMPA receptors. This kinase–phosphatase switch, in turn, is believed to be under the control of calcium levels. Thus, a high level of calcium in the PC flips the switch toward LTD, while a lower concentration of calcium results in LTP.

The strong depolarization evoked by CLs activates voltage-gated channels in the PC, increasing the influx of calcium, whereas parallel fibers are thought to activate AMPA and metabotropic glutamate receptors. Parallel-fiber stimulation alone can induce LTP. However, coactivation of parallel fibers and CLs is thought to be necessary to achieve the greater calcium threshold needed for the induction of LTD. The LTD mechanism is known to be dependent on both N-methyl-D-aspartic acid (NMDA) receptors and nitric oxide. Neither PCs nor parallel fibers express NMDA receptors in most species, but evidence suggests that these may be located on stellate and BCs.

In an experimental setting, learning can be imposed on the VOR by manipulating the visual image to induce apparent errors in the stabilization of gaze. Initially, reversing prisms were used as part of a portable headset. Reversal of vision induces tremendous image motion on the retina, which in turn provides a strong (and quite disorienting) stimulus for motor learning and induces learning rapidly and effectively. A less-disorienting visual stimulus is provided by miniaturizing and magnifying spectacles, or telescopes. **Figure 2** illustrates the exponential time course of motor learning. In monkeys wearing telescopic spectacles, the time constant of the exponential change in gain is different for increases (top left) and decreases in gain (bottom left), starting from the normal gain. This observation and others led to the consensus that learned increases in gain are fundamentally different from learned decreases.

Cerebellar and Brainstem Sites of Learning

In evaluating potential sites and mechanisms for VOR motor learning, it is helpful to remember a few principles that are generally agreed upon. These may be briefly

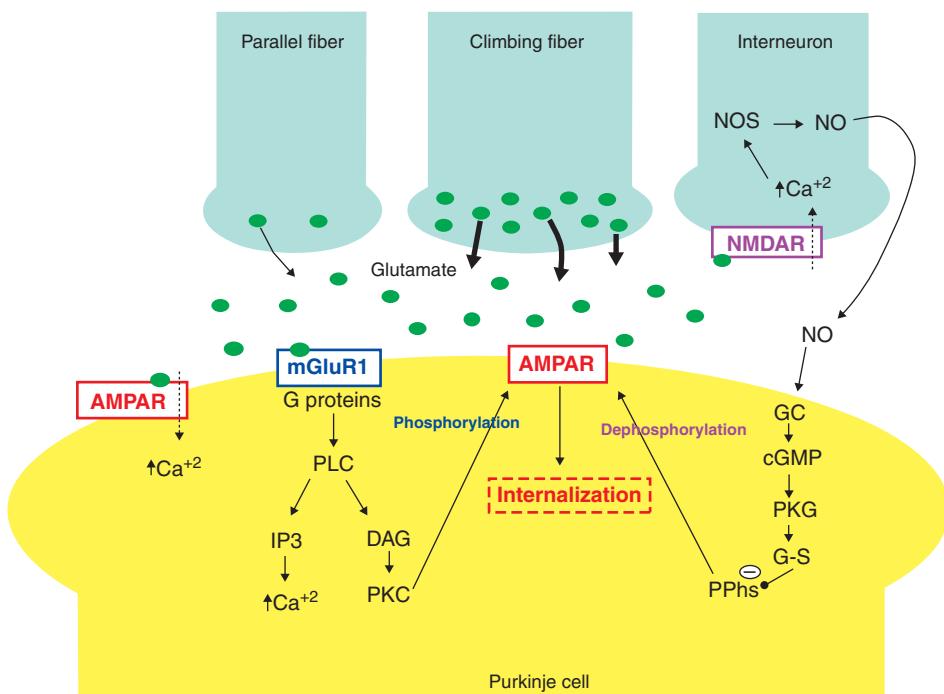

Figure 3 The cellular mechanisms of synaptic plasticity in the cerebellar cortex. During both long-term potentiation (LTP) and long-term depression (LTD), calcium enters the cell through AMPA receptors that are activated by glutamate from parallel fibers. During LTD, additional glutamate released from climbing fibers activates the metabotropic glutamate receptors (mGluR1), which cause calcium release from internal stores through phospholipase C (PLC) and inositol triphosphate (IP3). Protein kinase C (PKC) then phosphorylates the AMPA receptor and clathrin-mediated endocytosis removes phosphorylated AMPA receptors from the Purkinje cell membrane, depressing the postsynaptic response. Concurrently, another pathway inhibits protein phosphatases (PPhs) from dephosphorylating the AMPA receptors, under the control of both NMDA receptors and nitric oxide (NO) in local interneurons. Both the NO and the G-protein pathway must be active for LTD to occur. If the calcium concentration is too low because one of these pathways is inactivated, the phosphorylation balance shifts and more AMPA receptors become dephosphorylated. Then, they are actively inserted into the plasma membrane and LTP occurs instead.

summarized as follows: (1) an intact, functioning cerebellar cortex is required; (2) vision, in combination with another signal, is required; (3) the second signal can be either vestibular or oculomotor; and (4) both the lability and reversibility of VOR motor learning depend on the exact conditions and on the time course of learning and memory. VOR motor learning requires visual sensory input paired with either head or eye movement. Specifically, the gain of the VOR will be increased if either (1) the head movement and retinal slip are in opposite directions, or (2) the eye movement and retinal slip are in the same direction. In the reverse of each of these situations, the gain of the VOR will be decreased. This rule can be translated into specific pairings of pre- and postsynaptic activity that could occur either in the cerebellum or in the vestibular nuclei. The visual stimulus for learning need not be full-field retinal slip; smooth pursuit alone, in which a moving spot is tracked against a dark background, can change the gain of the VOR. Apparently, visual signals from the small pursuit target are adequate for motor learning. A strobe signal can even substitute for the pursuit target,

suggesting that visual motion *per se* is not necessary for learning.

Early lesion studies unequivocally showed that the flocculus and the nearby ventral paraflocculus are required for motor learning. A thorough investigation of ventral parafloccular PC responses to rotation concluded that although PCs do change their sensitivities when motor learning occurs, they change them in the wrong direction to support learning. In the long term, PCs decreased their sensitivity to rotation with a learned decrease in the VOR gain. This should have the effect of increasing the sensitivity of the VOR interneurons, which would be expected to lead to the opposite effect on VOR gain (i.e., an increase). This result led to the proposal by Fred Miles that the flocculus is not the site of learning; instead, the interneurons themselves (by default) are the sites where motor memory is stored. The Miles hypothesis introduced the idea that the cerebellar cortex, or the inferior olive, can provide a teacher signal to bring about modifications that are stored at a brainstem site. For example, direct transmission by the three-neuron arc is modified slightly during motor learning. The sensitivity of vestibular neurons to inputs from the vestibular

commissure, or to polysynaptic as well as monosynaptic inputs from the ipsilateral vestibular nerve, could also be altered by a Hebbian mechanism.

The flocculus target neurons in the brainstem modify their discharge patterns dramatically during motor learning; in fact, they change the polarity of their responses to rotation. In other words, when the VOR learns a lower gain, these neurons begin to increase their discharge rates during rotation away from the side they are on. Notably, this difference, similar to the difference in the VOR's response, is evident at short latencies after the start of a sudden rotation in contrast to the differences in PC responses, which are evident only at longer latencies. The flocculus target neurons are believed to be inhibitory VOR interneurons that project to the ipsilateral abducens nucleus (**Figure 1**). The excitatory, contralaterally projecting secondary neurons probably remain unmodified during motor learning.

Shifting Memory Storage and Consolidation

Why does VOR motor learning require the cerebellum, and yet apparently fail to encode the memory in the cerebellum? Why does the memory instead appear to be located in the brainstem? What, then, is the function of cerebellar plasticity mechanisms? Some results seem to indicate that the memory does initially form in the cerebellar cortex. In order to understand all of the apparently contradictory data, we must take into account the passage of time both during and after the learning process. In the VOR, if learning has occurred recently, it can be reversed by rotation in darkness alone, without any requirement for visual input. Over time, VOR memory becomes more resistant to disruption. The increased resistance to disruption indicates that VOR memory becomes consolidated. Consolidation over several days appears to coincide with a shift in storage the memory from the cerebellar cortex to a more distributed representation that includes the vestibular nuclei. However, compared with learning itself, the processes underlying consolidation of newly formed motor memories in the VOR are not well understood, and may (like learning) be different depending on the direction of the gain change.

So far, the results indicate that cerebellar plasticity processes are responsible for motor learning, and the brainstem becomes involved in long-term memory storage. In the case of learned gain decreases, existing evidence supports long-term synaptic potentiation as a likely mechanism and the cerebellar cortex as the initial site of learning. However, consolidation may also occur within the cerebellar cortex. Rapid consolidation of VOR motor memory requires just 1 h after the end of learning. Recent results suggest that rapid consolidation may

reinforce the memory trace at its original location, and the shift to the brainstem may occur subsequently. To understand this evidence, we must examine the way in which motor learning depends on the exact stimulus conditions, such as rotation frequency. VOR motor learning is selective for the particular rotation frequency that is used during training. This selectivity is thought to be conferred by the localization of changes to a particular set of synapses that are operational under the learning conditions, and cerebellar LTD and LTP could confer the necessary selectivity.

As described above, newly formed memory in the VOR can be reversed by rotation in darkness. Such disruption might reverse LTD or LTP that has not yet been stabilized. Disruption of gain decreases is most effective when measured at test frequencies that are different from the rotation frequency used during disruption. In contrast, gain-up learning is highly selective for the training frequency. Gain-up learning is, therefore, not a likely mechanism for disruption. However, these results would be expected if the rule during disruption is simply reversal, on the molecular level, of any changes that have recently occurred. Disruption in the VOR may be analogous to early extinction of fear memories, which has been attributed to depotentiation of recently potentiated synapses. Similarly, rapid consolidation does not show any frequency selectivity, suggesting that during rapid consolidation, synaptic changes that have recently occurred are simply converted to a more permanent form.

Motor Learning after Vestibular Damage

One situation in which motor learning might be useful is following the loss of peripheral vestibular function, for example, following damage to the inner ear. When this happens, the VOR gain is reduced due to the loss of part of the sensory signal, and a mechanism is needed for increasing the gain. Within hours after acute damage, VOR gain starts to increase by a process known as 'vestibular compensation' and, eventually, VOR gain reaches a near-normal value. In thinking about whether motor learning is responsible for this recovery, there is a major pitfall to be avoided. Compensation has several problems to solve, including the loss of balance, ongoing dizziness, and continuous eye movements (nystagmus). Some of these problems can be solved by changes in excitability or in tonic input to vestibular neurons, and such changes could even be under cerebellar control. As a result, we cannot simply compare changes (such as gene expression) during compensation and during motor learning, as two or more processes may be occurring simultaneously. Instead, we must attempt to sort out what affects VOR performance following vestibular damage. It is also helpful to look at studies where semicircular canals are plugged, since other symptoms are minimized in this situation.

Following a canal plug, the initial problem for the VOR may in fact be similar to what we would encounter when wearing magnifying lenses, and motor learning mechanisms should automatically be brought into play.

A few studies have specifically addressed the issue of motor learning during compensation (in all such studies, the changes in VOR function are long term, over days to weeks). Following ablation of the labyrinth, the flocculus is necessary for VOR recovery. Both the CF pathway to the cerebellar cortex and vision are necessary for compensation of VOR function. Following canal plugs, the excitatory commissural inputs to secondary vestibular neurons appear to be modified in a way that could account for the restoration of VOR gain. Flocculus target neurons (but not other secondary neurons) receive excitatory input from the commissure, suggesting that the commissural changes may be under cerebellar control, as we would expect in a motor-learning mechanism. On the other hand, cerebellar LTD does not seem to contribute to recovery of the VOR during compensation. Following compensation, the compensatory changes in the short brainstem pathway (the three-neuron arc) of the reflex are more significant than they are in long-term motor memory. These results suggest that brainstem sites may be more important in changing VOR gain if damage has occurred than if it has not.

To summarize the evidence so far, it appears that the mechanisms that allow VOR gain to recover following vestibular damage include, but are not restricted to, motor learning. The occurrence of damage may trigger mechanisms that are not available during motor learning in intact subjects. In particular, brainstem memory storage may take place without the necessity for cerebellar cortical plasticity, if damage has occurred. Since nystagmus, acute vertigo, and (in most cases) surgical stress are inextricably linked with vestibular damage, we must consider the possibility that stress following vestibular damage makes additional mechanisms available for brainstem plasticity. In support of this idea, stress hormones (corticosteroids) are known to act on vestibular neurons, and to contribute to some compensatory processes. In the absence of acute stress, when the damage occurs gradually (as it does during aging), these processes may not be available.

Summary

Several decades of research on motor learning in the VOR have yielded abundant information about the mechanisms

involved in motor learning and in long-term memory storage. As the rotatory VOR is so simple, it has been possible to localize the initial formation of the memory to the cerebellar cortex. Cellular mechanisms of plasticity in the cerebellar cortex are known to exist and appear likely to be a basis for the initial memory storage. In the long term, the exact mechanisms involved in memory storage are less clear but may include brainstem plasticity, which may also occur following vestibular damage.

Neural Plasticity of Spinal Reflexes

M M Patterson, Nova Southeastern University (Retired), FL, USA

© 2010 Elsevier Ltd. All rights reserved.

Introduction

The concept of neural plasticity has been studied for many years. Indeed, the concept of alterations of neural activity is recognized as the basis for learning and memory. The activity of the nervous system in both sensory and motor function is now known to be based partially on its past activity and sensory inputs. However, until about 25 years ago, the spinal cord was thought to play little to no part in this plasticity. It was thought of as a passive transmitter of impulses to and from the periphery and brainstem, the brain being the site where neural plasticity occurred. The reflex patterns that could be readily shown in the spinal cord were viewed as essentially hard-wired patterns of input/output relationships that served as the first line of defense against tissue damage, organizers of movement patterns, and visceral activity. This dogma was despite the fact that Sherrington, at the turn of the twentieth century, studied spinal reflex alterations such as sensitization and habituation extensively, as did his student, Eccles. As will be seen later, several lines of study in the mid-1900s showed that spinal circuits could undergo activity changes with various inputs and experiences, but the general thought in neurophysiology and neuropsychology was that spinal cord activity patterns did not show persistent or event-dependent alterations so characteristic of higher brain centers. This can be viewed as the first era of spinal cord research.

This view began to change with various demonstrations in the 1960s and 1970s from several laboratories that spinal reflex properties could be altered by several non-associative and associative paradigms that markedly resembled memory and simple learning well known in the intact organism. This second era of spinal research led to demonstrations of spinal excitability changes that mirrored associative conditioning, such as Pavlovian and instrumental learning, as well as nonassociative long-term activity changes that in many ways mirrored memory. Of course, the associative changes had to be underlain by memory-like changes as well.

The third era of spinal plasticity began in the 1980s with the application of model systems approaches to spinal plasticity and produced evidence that the spinal reflex pathways functioned in many ways like full-brain systems and could be used to identify underlying neural processes that might underlie similar whole animal learning and memory systems. The fourth era of spinal

plasticity developed from the third and entails employing many different technologies and behavioral techniques to define processes in the spinal cord that underlie processes of nociception (pain), locomotion, simple memory, and learning. This era has produced a wealth of information useful in understanding chronic pain, spinal cord injury rehabilitation, and even motor control. The spinal cord and its neural machinery are a very complex and plastic place, a far cry from the dogma of a simple hard-wired reflex machine and bundle of transmission lines.

Nonassociative Plasticity

Beginning with the studies by Sherrington and his students, short-term alterations of spinal reflex excitability have consistently shown that with repeated unaltered inputs, the output of a spinal reflex can either reliably increase or decrease. These changes are known as 'sensitization' if they increase and 'habituation' if they decrease. The behavioral properties of sensitization and habituation are well known in that these processes are relatively short lasting, appear quickly with stimulation, and are shown by almost all animals from simple, multicellular organisms to humans. In addition, many types of reflex patterns show both behavioral changes, with the exception in mammals of the stretch reflex, a monosynaptic reflex pattern from the muscle spindles to the motoneurons. Importantly, the spinal reflexes have been shown to undergo these alterations independent of the sensory receptors and that the changes are independent of muscle fatigue or spasticity. Thus, the phenomena of spinal sensitization and habituation are true properties of the spinal reflex circuits and dependent on the interposition of interneurons (small processing neurons) between the afferent inputs and the motoneurons (no sensitization or habituation in monosynaptic circuits), mainly in the dorsal horn of the spinal gray matter. The difference between the two alterations has to do primarily with stimulus intensity and frequency. With more intense and/or more frequent stimuli, sensitization is manifest and habituation is manifest with less intense and/or infrequent stimulation. One of the most used reflexes in studying these effects is the withdrawal or defensive reflex, which readily shows both changes. It appears that at least one of the underlying mechanisms for sensitization and habituation is an alteration in amount of

neurotransmitter released with each neural impulse at the primary afferent or input terminals from sensory neuron to interneuron. More transmitter release increases the probability of depolarization to threshold of the interneurons, hence a greater output to the motoneurons, and vice versa for habituation. The effect of stimulation in increasing the output of a simple reflex circuit can be seen in as little as one intense stimulus input, but usually shows increases over several seconds to minutes of stimulation, eventually reaching a plateau. Once the habituating or sensitizing stimulus is terminated, reflex excitability gradually returns to normal levels over several minutes.

A related phenomenon to sensitization is long-term sensitization, in which the increased response of the reflex circuit does not fall to its prestimulus levels for as long as 24 h. This longer-term excitability alteration is apparently due to alterations in the membranes of the interneurons that become more sensitive to transmitter released from the sensory input neurons. This effect has more in common with short-term memory phenomena than with the short-term effects of sensitization and habituation, and seems to increase with the length and, possibly, intensity of stimulation.

A longer-lasting alteration has been termed 'fixation' in the behavioral literature and central sensitization/excitation or long-term potentiation (LTP) and its analog, long-term depression (LTD). These changes have been extensively studied especially in the nociception (pain) literature and are thought to underlie altered pain states such as secondary hyperalgesia and allodynia. Fixation refers to an alteration of spinal reflex excitability that can be produced by things such as a cerebellar lesion, spinal cord partial transections, and direct peripheral stimulation, all of which cause a flexion usually of a hind limb. If the anesthetized animal is left in that position for 30–45 min, depending on amount of flexion and stimulus intensity, stopping the input to the spinal cord by spinal transection or stimulus cessation leaves the limb in an actively flexed posture. This effect can be shown to last for weeks. It is an active process in the spinal reflex centers that apparently causes sufficiently increased neural excitability such that impulses are spontaneously generated, causing the active motor activity without peripheral or descending inputs.

Fixation appears to be closely related to central sensitization or LTP. It is these long-term central excitatory states, especially LTP that are thought to be the basis for mammalian memory processes, having first been described in the hippocampus. A great deal of work has looked at these processes in the dorsal horn neurons of the spinal cord; in reality, the interneurons mentioned above, as a major site for alterations involved in nociceptive information processing. Primary nociceptive inputs, mainly unmyelinated C-fibers primarily subserving

deep pain senses, synapse on the dorsal horn interneurons and given appropriate circumstances, appear to alter, at times dramatically, the excitability characteristics of the nociceptive pathways underlying pain perception at cortical levels. Many of these studies have involved the induction of inflammation of a joint, such as a knee, and the effects of the resulting nociceptor inputs on the dorsal horn interneurons. While several types of interneurons have been identified, the production of a central excitatory state seems to involve the same basic processes such as sensitization, long-term sensitization, and fixation. Initially, an increase occurs in transmitter release, followed by an increase in membrane excitability of the interneurons. After continued C-fiber inputs, the interneurons begin to show an alteration in certain genetic functions, with genes such as *c-fos* being upregulated, resulting in an increased production of receptors on the cell surface. This produces an increased excitability of the interneuron even with a reduced amount of transmitter release. It seems that there are multiple neurotransmitters involved in the process, but N-methyl-D-aspartate (NMDA) and substance P seem central to the process. This process has been identified as one of the bases for the development of chronic and neuropathic pain states. It should be noted that C-fiber activation seems to be a central component of producing the central excitatory states, although some evidence suggests that fixation may be possible with lower-intensity stimuli, but then it is produced only by quite long stimulation periods.

There is some evidence to show that concurrent with the development of LTD or the central excitatory state, over a period of days, some interneurons in involved areas of the dorsal horn may actually die. These are apparently mainly inhibitory interneurons that would downregulate the total excitability of the reflex system. Inhibitory cell death would lead to an almost permanent change in excitability characteristics of a reflex pathway and potentially allow for sprouting of new connections from other healthy neurons, possibly from lower levels of the dorsal horn. Since the lower lamina inputs are primarily from mechano- and proprioceptors, sprouts from these areas connecting to nociceptive pathways would be expected to produce nociceptive inputs to the brainstem when movement occurred. Such a situation is often reported by chronic and neuropathic pain patients, and is a truly disabling and perhaps permanent situation.

In addition to importance for information processing and nociception, the nonassociative alterations described here are important for rehabilitation in spinal injuries and transactions. Ongoing studies on the effects of training on incomplete and even complete spinally transected animals and humans are showing often-dramatic improvements in functional capacity. Especially in incomplete spinal transactions, the individual can often regain a large degree of coordinated movement with

intensive training. These data suggest that signals from the brain that reach the spinal reflexes can be utilized to trigger motor patterns that are provided by the stepping movements during the rehabilitation periods. It appears that the proprioceptive inputs induced by the forced stepping or other exercises can reestablish sufficient background activity for the limited commands from the higher centers to use in coordinating movements. It seems likely that such training induces long-term excitability changes in interneurons involved in the activity patterns, allowing for new functional pathways to coordinate basic movement patterns. Thus, rehabilitation strategies for paralyzed patients can increasingly take advantage of spinal neural plasticity to enhance recovery after spinal injuries.

Associative Plasticity

The nonassociative changes in spinal reflexes reviewed above are obviously important in regulation of reflex excitability and in the processing of nociceptive and other sensory inputs to the spinal cord and ultimately to the brain. While some may call such changes a form of learning, they certainly represent a highly sophisticated form of short- and long-term memory. However, for most psychologists and neuroscientists, to be classified as learned alterations, behaviors must have an associative component.

The question of the capabilities of the spinal reflex circuits to learn began with the studies in the mid-1930s. It was generally assumed that learning was reserved for the cerebral cortex and perhaps subcortical regions of the mammalian system and that the spinal cord reflexes as hard-wired input–output relationships would not support such alterations as even the simplest of learning or associative changes. In fact, the progenitor of classical conditioning, Ivan Pavlov, assumed that the great cerebral cortices of the mammalian brain were the seat of all learning. However, studies in the late 1920s and 1930s strongly suggested that dogs could show behavioral changes consistent with learned behavior after complete or near-complete decerebration. The responses learned did not, however, show the fine-tuning associated with conditioning of motor responses in normal dogs. The question then became whether the neural organization at lower or spinal levels of the neuraxis could sustain any comparable behavioral changes that could be reasonably classed as learned or associative changes.

Classical Conditioning

Pavlovian classical conditioning procedures had become well known by the early 1930s, having been introduced by Ivan Pavlov in the late 1920s. The typical Pavlovian

conditioning or learning paradigm involved selecting an unconditioned stimulus (UCS), such as a paw shock that reliably and without training elicited an unconditioned response (UCR), such as a paw withdrawal. The UCS was then paired temporally with a conditioned stimulus (CS), which did not produce a response in the target motor system, such as a tone. After a variable number of pairings of the tone and shock (usually with the CS beginning 0.5–2 s prior to the UCS), the tone would begin to elicit a paw withdrawal (a conditioned response or CR) prior to the shock onset. If the same two stimuli were presented but not paired in time (e.g., CS presented 30 s before the UCS), no such response to the CS would develop. This type of learning is considered to be the simplest form of associative learning.

The first studies of classical conditioning in spinal reflex systems were performed in spinal dogs in late 1930s. The results suggested that a CR would develop to properly paired CS–UCS pairings and that the response declined when the CS was presented alone (extinction). However, the results were soon challenged with the argument from other studies that there had not been a new response formed, but only the modification of an existing one. By the mid-1960s, the question of spinal conditioning was an open one.

In the next set of studies, an appropriate control condition, the unpaired control group, was used in spinal cat preparations given a light-shock CS to the thigh and a UCS of a strong shock to the toe pads, producing a leg withdrawal. The results showed that there was no change in the response to the CS in the unpaired animals and a large increase in the paired group. Admittedly, no new response was formed, but the pairing had a definite effect on the response properties. In the late 1960s, spinal conditioning in cats was established as a model preparation for this type of associative learning. The preparation generally consisted of a spinalized animal with the CS delivered to the thigh skin and later to a toe sensory nerve directly, and the UCS delivered to the thigh skin. The CR was recorded from the deep peroneal motor nerve. This preparation provided for maximal stability of stimulus and response parameters, and also allowed for later neural studies within the spinal cord.

Over the 1970s and 1980s, several groups used this model to examine various aspects of classical conditioning in the spinal preparation and began examining the neural substrates of the process. In the behavioral studies, results showed that in many ways, the spinal conditioning preparation paralleled the findings in intact animal conditioning. For example, the optimal CS–UCS interval for conditioned increases in response during paired trials was found to be about 250 ms, with decreasing response increases with shorter or longer intervals. There was no response increase found with backward pairings (UCS–CS) or with CS-alone or unpaired trials. The CR

once established did not spontaneously decay, but showed the usual extinction decreases with CS-alone trials. Other findings showed that the usual discriminative or differential conditioning paradigm in which a CS⁺ is paired with a UCS and a CS⁻ is not paired in the same trials was not generally successful, suggesting that the behavioral parallels between spinal and intact animal conditioning could not be complete. It appeared that there was sufficient cross talk between the CS⁺ and CS⁻ neural pathways that robust differential conditioning was not possible. It remains to be seen whether the use of other CS inputs could show differential conditioning.

The neural underpinnings of spinal conditioning were examined in several studies. Here it was found that there was no change in afferent terminals of the CS input neurons in the dorsal horn during the conditioning process, suggesting that the changes were within the interneurons of the reflex pathways. Likewise, the motoneuron excitability was found to remain stable during conditioning procedures, although it was found that more motoneuron firings occurred as the CR increased. It was not possible to determine whether more motoneurons were recruited or there were more spikes from the same population of motoneurons. In either event, the data suggested an increased drive onto the involved motoneurons from the interneuron pools. Other work using a decerebrate cat suggested a form of unstable backward conditioning could occur, but that this was not a robust effect. It was also shown that the major pathways involved in the conditioning reflexes seemed to be disynaptic and that blocking the NMDA receptors of the interneurons during conditioning suppressed the CR increases. These data suggest that the spinal conditioning may be similar to LTP in the brain and other spinal areas. In addition, some data suggest that good conditioning occurs in acute preparations but not robustly in 2–3-week chronic spinal preparations, but reappears at chronicity of 3 months. This would suggest that as the cord undergoes changes and reorganization after injury, plasticity is decreased until a later time when the reorganization has taken place. These findings could have implication for rehabilitation of spinal-injured patients.

Other investigators have used rat models for classical conditioning, presenting the CS to the leg and the UCS to the tail. This preparation has shown that the CS–UCS pairing can produce less tail-flick habituation later. The implication is that the pairing strengthens the ability of the CS to cause a response, not unlike the results of the cat preparation.

Overall, the results of classical conditioning of spinal reflexes have shown remarkable similarities to classical conditioning in intact animals. However, as noted, there appears to be a limit to the amount of behavioral complexity available in the spinal cord, as would be expected from the relatively simple neural networks involved when

compared to the full brain. The changes during conditioning appear to occur in the interneuron pathways of the cord and not in the afferent terminals or motoneurons and may well involve neural mechanisms similar to LTP and other similar memory-like changes within the brain. Spinal conditioning serves as a well-controlled model for ongoing studies of simple behavioral plasticity.

Instrumental Conditioning

Instrumental conditioning utilizes a different paradigm from classical conditioning. Instrumental conditioning involves establishing a relationship between the response and an outcome. In the instrumental paradigm, the response thus generates some change in the situation that can be sensed by the organism and results in either an increase or decrease in response probability. In the 1960s, a behavioral paradigm was established in cockroaches that became known as the Horridge preparation. Headless cockroaches were suspended above a water dish and a hind leg was allowed to fall into the water. A shock was delivered by water contact and the leg would withdraw. The measure of learning was whether the leg learned to maintain withdrawal to avoid the shock. A yoked animal was used that received a shock whenever the master animal did, but the yoked shock was independent of leg position. The master headless animal learned to keep the leg flexed, whereas the yoked animal did not. This was taken as learning in the headless cockroach. While the paradigm generated controversy in the psychological learning community over what the appropriate control actually showed learning, the basic paradigm has become a very useful one in looking at various aspects of learning and now, neural mechanisms of behavioral change. In the 1970s, the paradigm was adapted to the spinal rat, and this is the paradigm generally currently in use. Here, the acute or chronic spinal rat is suspended with one hind leg over a dish of saline. A metal rod is anchored to the leg and the height of the water is raised to an appropriate level such that the rod is in the water. A record of shocks delivered through the water–rod interface, and of the number and durations of leg flexions is made. Learning is shown by an increase in the duration of time spent with the rod out of the water, the number of leg flexions, and the time of rod in the solution. Early results using the yoked control showed that the master animal reduced number of flexions, that is, had more time out of the saline, whereas the control did not. In addition, when control rats were given contingent shocks, they did not learn. In fact, if a noncontingent shock is delivered for a few minutes to a naive rat then the rat is put on a learning schedule, a severe deficit in learning results, much as if the rat had been a yoked control. Interestingly, a study of time between when the electrode

rod touched the water and the shock was given showed that if there was no delay, robust learning occurred, but decreased with intervals of 50, 100, and 200 m, a result indicating that strict contingency between response and outcome is best for this type of learning. In addition, exposure to continuous stimulation did not produce a deficit, whereas intermittent burst or single-pulse regular or irregular stimulation shocks did produce a deficit. These results suggest a sensitivity to temporal relations.

Subsequent studies have abundantly confirmed that this instrumental learning is robust in spinal rats and that it occurs fairly rapidly; does not spontaneously decay but is subject to the usual extinction procedures. In addition, data show that the effect transfers readily from the trained to the untrained leg, suggesting the possibility of common neural elements between the two sides.

Studies of the underlying neural mechanisms have shown that the effect is clearly dependent on spinal reflex pathways. In addition, studies have implicated NMDA in the formation of the effect, suggesting a link with LTP and central sensitization processes in the brain. There is also some evidence that there exists some dependency of this learning on *de novo* protein synthesis, suggesting a functional basis of neural development during learning. Other studies have suggested that spinal instrumental learning is impaired by neonatal hind-limb injury, possibly due to alterations in nociceptive processing in the cord. Recent studies have implicated neurokinin 1 and 2 receptors as important in the formation of the learning as well as the NMDA receptors and that γ -aminobutyric acid-A (GABA_A) receptors may be active in the inhibition produced by noncontingent shock that inhibits learning during contingent shock. Interestingly, the region of the rat cord involved in the hind-limb learning appears to be between L4 and S1. Relevant to human spinal cord injury, it has been found that neonatal spinal rats could alter the motion characteristics of walking imposed during treadmill exercise. Thus, the spinal cord could learn to respond adaptively to externally imposed forces.

These data suggest that the instrumental spinal learning is a very useful tool in elucidating the plasticity of spinal reflexes and ongoing work is uncovering many of the underlying neural mechanisms involved. It will continue to be useful in uncovering the inherent mechanisms and potentials of spinal reflexes.

Effects of Higher Centers on Spinal Plasticity

It is well known that the higher brain centers have profound effects on spinal reflex excitability and function. In fact, many of the effects seen in spinalized preparations are difficult, if not impossible, to observe in intact preparations due to these higher influences. Work has shown that higher centers can also cause spinal plasticity.

Examples of such plasticity are studies of the effects of higher centers on operant conditioning of the H-reflex that provide task-dependent changes from supraspinal centers onto the spinal stretch reflex or its analog, the H-reflex. If the mouse, rat, or monkey is rewarded for increasing the H-reflex amplitude, it reliably increases and if the reward is for lowering the amplitude, it goes down. The changes are slow compared with spinal conditioning, occurring over days, weeks, and months of training. The plasticity is formed in the cord by continuous control from the higher centers, not by direct stimulation of the spinal reflex. Since the reflex is a monosynaptic one, the influence must be either on the alpha motoneuron or on the 1a afferent terminal from the muscle spindle. In any event, the alteration is at the spinal level as it outlasts spinal transection. Recently, the effect has been shown in humans, indicating that the H-reflex can be altered by operant conditioning procedures.

These data, while not as advanced as the instrumental or classical conditioning data, suggest that long-term alterations of descending influences can alter spinal function independent of nociceptive inputs generally needed for the more rapid spinal reflex alterations. There are very important implications for human rehabilitation procedures in the discovery of higher-center-driven spinal plasticity that are only beginning to be recognized.

Summary

Neural plasticity is a fundamental process at all levels of the nervous system. While it is only recently that functional and perhaps structural plasticity have been widely recognized at the spinal level, such recognition opens a tremendous opportunity to develop new and exciting opportunities for rehabilitation of human spinal cord injuries and function. In addition, the deeper understanding of the plasticity involved in nociceptive processing in the dorsal horn is providing greater insights into chronic and neuropathic pain mechanisms and will ultimately provide new pathways to treat these devastating conditions. The spinal cord is a very active processor of information, and its effects on locomotion, visceral function, and pain are only beginning to be understood.

Glossary

Dendritic spines – Dendritic spines are contiguous with dendrites and continuously sense the local dendritic membrane potential. Majority of synapses in the central nervous system and almost all excitatory synapses in the hippocampus are at this specialized structure. These spines are small well-circumscribed biochemical compartments that localize proteins and signaling molecules to a specific postsynaptic compartment.

Hippocampal theta rhythm – The theta rhythm consists of regular, sinusoidal oscillations of waves in the range of 5–8 Hz that normally appear in the hippocampal electroencephalogram (EEG). The appearance of the hippocampal theta rhythm in the EEG is one of the most prominent electrophysiological characteristics of rapid eye movement (REM) sleep in mammals. Theta rhythm could also occur in the wake state when animals perform ecologically relevant species-specific behaviors. Theta waves are involved in the acquisition and processing of meaningful environmental information.

Learning – Learning is an altered behavioral and/or individual neuronal response produced by the individual's experience with a novel environmental stimulus. Normally, to assess learning, participants are exposed to repeated acquisition experiences and progressive changes in performance are observed. This activity provides an acquisition curve – an assessment of learning as a function of acquisition trials and time. Traditionally, measuring behavioral performance has been a gauge of learning. More recently, evaluation of learning has been possible by direct examination of physiological and cellular changes in the brain (neuronal plasticity). The term learning has thus taken on a broader meaning that now includes observed cellular changes that can also be used as indices of learning. Such changes include any number of cellular and/or subcellular neuronal alterations that result in improved performance.

Long-term potentiation (LTP) – LTP is an increase in synaptic excitability that persists for hours or more than days after the delivery of a few seconds of brief tetanic stimulus (100–500 Hz) to certain afferent pathways. LTP is now widely accepted as a neuronal model of memory.

Memory – In the experimental neuroscience literature, a concept related to learning is memory (the ability of the organism to retain acquired information over a period of

time). Learning is believed to include the process of forming memory (memory consolidation). Memory is believed to be a store of acquired information made more or less permanent by plastic changes in the brain's cellular structure at some level. In contrast, the philosopher and psychologist William James believed that there is a fine distinction between learning (explained as habits) and memory. He viewed memory as the conscious recollection of events and facts and this definition of memory still remains popular with many contemporary scientists and philosophers. There are different taxonomies for the classification of human and animal memory types. The most widely accepted taxonomy divides human memories first into declarative and nondeclarative, based on their accessibility to conscious recall, and then into finer and finer subdivisions of these categories.

Memory trace – A subset of neuronal elements that exhibit the learning-training-induced plasticity essential for such learned behavior.

P-wave generator – The P-wave generator is a collection of glutamatergic cells in the pons. P-wave generating cells discharge high-frequency (>500 Hz) spike bursts (3–5 spikes/burst) in the background of tonically increased firing rates (30–40 Hz) during the transition between nonrapid eye movement (NREM) and REM sleep. These cells remain silent during wake and NREM sleep. P-wave generating cells project to the hippocampus, amygdala, entorhinal cortex, visual cortex, and many other regions of the brain known to be involved in memory processing. The P-wave in the rat is equivalent to the pontine component of the ponto-geniculo-occipital (PGO) waves in other mammals.

Sleep Stages in Human and Other Mammals

Sleep in mammals is not a homogenous behavioral state; rather it is a continuum of mixed states that differ in their physiology, chemistry, and phenomenological experiences. The details of sleep–wake stages and their specific physiological, neurochemical, and phenomenological signatures are described below. Because some human sleep stages are named differently from those in animals, and since the present description on the

mechanisms of sleep stage-specific memory formation is based on both human and animal research, the following section describes the similarities and differences between human sleep stages and those of animals.

Using behavioral and physiological signs, sleep in mammals has been broadly divided into two major states: nonrapid eye movement (NREM) and rapid eye movement (REM) sleep. Human NREM and REM sleep alternate throughout each of the four to six sleep cycles that occur every night. The most common, and preferred, animal models for sleep research include the mouse, rat, and cat; in these animals, NREM–REM sleep cycles are much shorter than in human and nonhuman primates. These cyclic NREM–REM sleep epochs in rodents and cats continue throughout sleep during day and night, except when the animal is engaged in activities that require wakefulness. In a human, NREM sleep is further subdivided into four stages (I, II, III, and IV), each corresponding to an increasing depth of sleep. The deepest stages of NREM sleep, III and IV, are collectively called slow-wave sleep (SWS or delta sleep). Distinctions between stages of NREM sleep in animal models differ slightly from those in humans. In the aforementioned animals, NREM sleep is normally subdivided into two stages (SWS-I and SWS-II). SWS-I is identified by the presence of sleep spindles in the cortical EEG. SWS-II is considered deep sleep and is identified by the presence of high-amplitude, low-frequency waves in the cortical EEG (delta sleep). Human NREM-II sleep is comparable to mouse, rat, and cat SWS-I, whereas stages III and IV NREM sleep in humans are comparable to the animal SWS-II. Physiological signs of REM sleep in humans are comparable to physiological signs of REM sleep in the rat and cat. However, another sleep stage, one between SWS-II and REM sleep, is identified mainly in rats and cats and is called the transitional sleep stage (tS-R). During this transitional stage, the appearance of cortical EEG signs is similar to the cortical EEG of SWS-I and hippocampal and pontine EEG signs are similar in appearance to those during REM sleep, but with less intensity. Since most animal sleep and learning studies have not recorded hippocampal and/or pontine EEG, such studies have often considered this stage to be SWS-I. Similarly, in sleep studies of healthy humans, hippocampal and/or pontine EEG cannot be recorded to help identify sleep stages. Therefore, based on EEG signs in humans, this transitional sleep stage has always been identified as stage II NREM sleep. In reality, at least 80% of stage II NREM sleep periods in humans are the transitional sleep stage between SWS and REM sleep.

Stages of Memory Development

The development and maturation of memory is a complex process occurring in several distinct stages over time. The two major stages of memory formation are: (1) acquisition of information (learning or encoding) and (2) consolidation of memory trace. There is now evidence that the different stages of memory development are influenced by different stages of sleep. The first stage, acquisition, is when memories are initially formed or encoded by engaging with an object or performing an action, leading to the formation of a representation of the object or action within the brain. This initial encoding of a memory is a relatively rapid process requiring only a few milliseconds. At this stage, memory remains in a short-term store. This short-term memory store has very limited capacity and, in the absence of rehearsal, persists for only minutes at most. If this encoded information persists in the form of reverberating activity in the neuronal circuits, then another process transforms this short-term memory into an intermediate form. This intermediate form of memory is relatively more stable than the short-term memory and can last for several hours. However, at this stage, memory still remains sensitive to interference from competing or disrupting factors. Acquisition of information occurs only during the awake state, but the formation of the intermediate form of memory can occur during both waking and light sleep.

Following acquisition, the consolidation stage begins. The original definition of the term memory consolidation refers to a process whereby a memory trace, through the simple passage of time, becomes increasingly resistant to interference from competing or disrupting factors in the absence of further practice. At the end of the consolidation stage, a memory has become stable and resistant to even extreme disruptions, such as electroconvulsive shock or the application of neuronal gene and protein activation inhibitors. Following consolidation, a memory can be retained for days to years, during which time it can be recalled from long-term memory storage. But the act of memory recall itself is now suggested to destabilize the memory representation, making it again labile and subject to potential degradation. Subsequent to recall and destabilization of a memory, passage of time in a suitable neurochemical and molecular state of the brain can again consolidate this destabilized memory and return it to long-term memory storage. This process has been termed memory reconsolidation and is an automatic process that can occur without conscious awareness. This reconsolidated memory becomes more stable and easier to retrieve than was its original long-term memory trace. However, it is important to mention that, at this time,

some of the major cognitive neuroscientists do not believe that there exists such a stage as memory reconsolidation.

Sleep and Memory Encoding

At present, there are no physiological and/or structural measures that directly quantify or assess the levels of memory encoding. Normally, in animal studies, the level of memory encoding is measured by analyzing a learning acquisition curve over a training session. This method measures the rate of improvements in performance between individual trials within a single session of learning training. This method has also been used for measuring short-term memory. The optimal neurophysiological, neurochemical, and molecular conditions of the brain for memory encoding is illustrated in **Figure 1**.

Although there is no evidence to indicate that encoding of memory occurs during sleep, a number of recent human and animal studies have described the detrimental consequence of inadequate pretraining sleep on successful memory encoding. Human studies, using a variety of declarative memory paradigms (temporal, verbal, word association, episodic), have demonstrated that 24–36 h of pretraining sleep deprivation severely impairs the encoding of declarative memories, resulting in poor retention 24–48 h later. Such impairments have been demonstrated for both emotionally positive and neutral types of

declarative memory. Similarly, a number of animal studies have demonstrated that pretraining deprivation of total sleep or only REM sleep impairs encoding of memory in a variety of learning paradigms, including spatial, contextual, one-way and two-way active avoidance, taste aversion, and passive avoidance protocols. However, unlike encoding of emotionally positive and neutral stimuli, memory encoding of emotionally negative stimuli has been shown to be resistant to pretraining sleep deprivation in both humans and animals.

In addition to attention impairments resulting from sleep deprivation-induced physical and mental tiredness, there are additional physiological explanations as to why pretraining sleep deprivation is detrimental for the successful encoding of memory. Human brain imaging studies over the past decade have shown that baseline activity in the prefrontal cortex (PFC), hippocampus, and parahippocampal areas is significantly less following one night of sleep deprivation compared to that following a night with adequate sleep. Similarly, animal studies have shown that deprivation of total sleep or REM sleep only, over the range of 6–72 h, reduces the baseline excitability of dorsal hippocampal neurons. Thus, it appears that certain levels of baseline activity in the PFC, hippocampus, and parahippocampal areas are critical for memory encoding (**Figure 1**).

Neurophysiological and neurochemical evidence show that sleep provides a window of rest (reduced

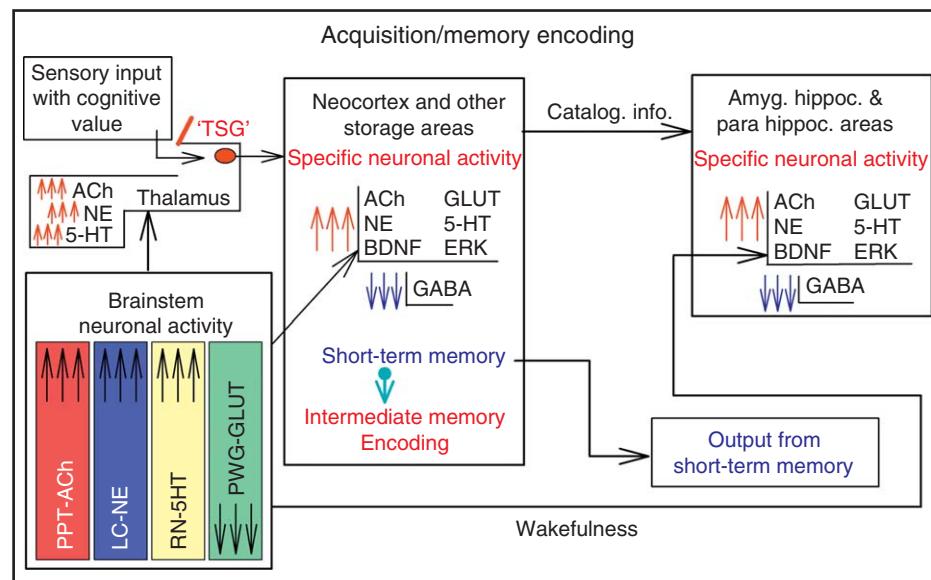

Figure 1 Physiological and biochemical conditions of the brain during wakefulness are conducive for memory encoding. Black arrows with solid lines between the blocks of brain structures: possible direction and flow of cognitive information and/or neurotransmitter; three upward arrows: highest levels of neuronal activity (PPT-ACh, LC-NE, and RN-5HT), extracellular level of neurotransmitters (ACh, NE, 5-HT, and GLUT), and intracellular proteins (BDNF and ERK); three downward arrows: lowest levels or absent of neuronal activity (PWG-GLUT) and extracellular level of neurotransmitter (GABA). 5-HT, 5-hydroxy tryptamine (serotonin); ACh, acetylcholine; BDNF, Brain-derived neurotrophic factor; ERK, extracellular signal regulated kinase; GABA, gamma amino butyric acid; GLUT, glutamate; LC-NE, noradrenergic cells in the locus coeruleus; NE, norepinephrine; PPT-ACh, cholinergic cells in the pedunculopontine tegmental nucleus; PWG-GLUT, glutamatergic cells in the pontine-wave generator; RN-5HT, serotonergic cells in the raphe nucleus; TSG, thalamic sensory gate.

neuronal activities and receptor sensitivities) to both aminergic (noradrenergic and serotonergic) and cholinergic neurons and their receptors in the brain. This well-deserved rest allows these neurons and their postsynaptic receptors to be optimally reenergized for activity during the subsequent waking period. A number of studies have shown that successful acquisition of information (a prerequisite of memory formation) requires that the aminergic and cholinergic postsynaptic receptors in the cerebral cortex, hippocampus, and amygdala are both optimally sensitive and surrounded by sufficient amounts of norepinephrine (NE), serotonin (5-HT), and acetylcholine (ACh). Thus, the memory encoding deficits resulting from inadequate amounts of sleep before training may result from altered sensitivities of postsynaptic aminergic and cholinergic receptors in the cerebral cortex, hippocampus, and amygdala and/or from neurochemical imbalances of aminergic and cholinergic neurotransmitters. Similar to brain-activity and neurotransmitter-release studies, molecular studies in animals have shown that 3–6 h of selective REM sleep deprivation reduces the levels of brain-derived neurotrophic factor (BDNF) and extracellular signal-regulated kinase (ERK) in the hippocampus. BDNF and ERK in the dorsal hippocampus are both involved in the development of memory. Thus, the memory encoding deficits in animals and humans with inadequate pretraining sleep may be due to altered baseline levels of BDNF and ERK. Based on this neurophysiological, neurochemical, and molecular evidence, it appears that adequate sleep during the pre-training period allows the brain to make the necessary physiological as well as chemical preparations for the successful encoding of memory during the subsequent wake period (**Figure 1**).

Sleep and Memory Consolidation

The current views of memory consolidation have their roots in the perseveration-consolidation hypothesis originally proposed by Mueller and Pilzecker in 1900. This hypothesis suggested that the neural processes underlying memory persevere in a labile form following an experience and subsequently become fixed or consolidated over passage of time. However, the past 50 years of sleep and memory research have revealed that not simply the passage of time, but also an adequate amount of sleep during this time is required for memory to successfully consolidate. Sleep and memory researcher Carlyle Smith has termed this time period the ‘REM sleep window’ for memory consolidation.

The hypothesis that sleep states play an important role in the consolidation of memory has had a long history even before scientists learned to record EEG activities to objectively identify sleep. Observational findings have

suggested that memory retention was better following a night of sleep than after an equivalent amount of time awake. Since the discovery of REM sleep, a huge number of human and animal studies have demonstrated that intact and/or undisturbed sleep following a learning session is critical for memory consolidation. Behavioral evidence that links sleep with consolidation of different categories of memories suggests that the specific homeostatic need for additional amounts of SWS, stage II NREM sleep, and/or REM sleep for the successful consolidation of both declarative and nondeclarative memory, depends mostly on the type of learning task. Contrary to those studies that have shown the beneficial role of sleep in learning and memory, there have been some animal, as well as human studies, that did not find any changes in amounts of sleep during the postraining sleep period. Normally, the results of those studies are interpreted to suggest that sleep may, in fact, not be involved in memory processing. If, however, the training has no effect on the amounts of sleep stage(s), one cannot necessarily conclude that the sleep stage(s) in question plays no role in processing of that type of memory. Indeed, some studies have also shown that normal and/or reduced duration of sleep stage(s) following training is sufficient for memory consolidation following many different types of tasks.

Mechanisms of Sleep Stage-Specific Memory Consolidation

Different parts of the brain are responsible for the formation of different categories of memory. Despite the differential role of distinct brain regions in different types of memory formation, recent experimental evidence suggests that all types of memory undergo a consolidation process in the period following training. The behavioral evidence on sleep and memory suggests that all four stages of sleep (animal/human: SWS-I/stage II NREM, SWS-II/SWS, tS-R/transitional stage II NREM, and REM sleep) are involved in consolidation of all types of memory.

Memory consolidation is not a single-step process; rather it is a multistep process and it occurs exclusively during periods of sleep. All of these processes occur over time, automatically, outside of awareness and without intent. Thus, they are specifically different from changes that result from conscious reminiscing or intentional rehearsal. Operationally, the cascade of memory consolidation processes can be divided into four stages: (1) search and readout of the intermediate form of memory; (2) elimination of unnecessary and/or redundant memory; (3) strengthening of cognitively relevant memory; and (4) transfer of stable memory to long-term storage. There is a clear consensus that neuronal plasticity (both

functional and structural changes in response to relevant stimuli/experiences) in the memory trace is the physical evidence of memory consolidation. Therefore, by quantifying those physiological and structural changes, one could measure the progress of each stage of the memory consolidation process.

Search and Readout of the Intermediate Form of Memory

The first stage of the memory consolidation process is the search and readout of the intermediate form of memory. In this stage, memory traces are sorted to identify memories that are to be stored and those that are to be deleted (or removed). For this particular step of memory consolidation, interference by sensory inflow to memory trace forming brain structures is blocked at the level of the thalamus (which normally remains open during the waking state). Yet, memory trace-forming brain structures are sufficiently conscious (active) to sort memory traces. By recording neuronal activity and measuring neurotransmitter release, researchers have shown that during the first part of NREM sleep (SWS I/stage II NREM sleep), brainstem cholinergic and glutamatergic cells are silent and stop releasing their neurotransmitters, ACh and glutamate (GLUT), in the thalamus, hippocampus, and cerebral cortex (Figure 2). Steriade and colleagues have

shown that the GABAergic cells (GABA – gamma aminobutyric acid) in the thalamus are activated when cholinergic and glutamatergic neurotransmitter levels are low in the thalamus. They have also shown that the activation of thalamic GABAergic cells generates sleep spindles that are normally recorded in the thalamus and cerebral cortex. An epiphenomenon of sleep spindle, called sharp-wave/ripple activity, could also be recorded in the hippocampus. It is known that this spindle activity prevents incoming sensory signals from reaching its targets in the cortical and subcortical structures by blocking them at the thalamus (Figure 2). Similar physiological studies have also shown that during this early part of NREM sleep (SWS-1/stage II NREM), the activities of the brainstem aminergic cells (noradrenergic cells in the locus coeruleus and serotonergic cells in the raphe nuclei) are reduced, but remain sufficiently active to release NE and 5-HT in the cerebral cortex, hippocampus, and amygdala. These reduced levels of NE and 5-HT are sufficient for maintaining neuronal activities at their targets in the cerebral cortex, dorsal hippocampus, and amygdala (Figure 2). Indeed, by recording neuronal activities in freely moving rats, Wilson and colleagues have shown that the pattern of cortical and hippocampal activities elicited while practicing a memory task is replayed in and around the time of hippocampal sharp-wave activity during this part of NREM sleep. These

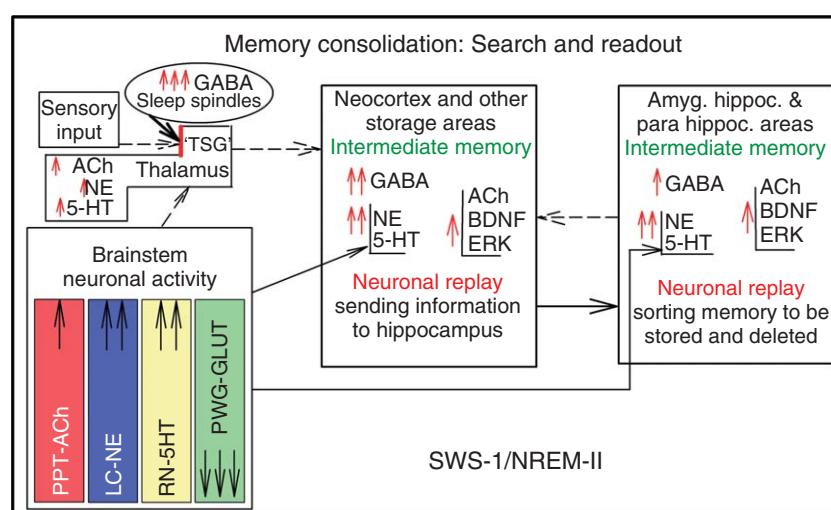

Figure 2 Physiological and biochemical conditions of the brain during SWS-1/NREM-II stage are conducive for the search and readout step of memory consolidation. Black arrows with solid lines between the blocks of brain structures: possible direction and flow of cognitive information and/or neurotransmitter; three upward arrows: highest levels of neuronal activity (PPT-ACh, LC-NE, and RN-5HT), extracellular level of neurotransmitters (ACh, NE, 5-HT, and GLUT), and intracellular proteins (BDNF and ERK); three downward arrows: lowest levels or absent of neuronal activity (PWG-GLUT) and extracellular level of neurotransmitter (GABA); black arrows with dashed lines between the blocks of brain structures: cognitive information and/or neurotransmitter flow in that direction is blocked; Arrows: levels of neuronal activity, extracellular levels of neurotransmitter, and intracellular levels of proteins: 3 arrows, highest; 2 arrows, medium; and one arrow, low. 5-HT, 5-hydroxy tryptamine (serotonin); ACh, acetylcholine; BDNF, Brain-derived neurotrophic factor; ERK, extracellular signal regulated kinase; GABA, gamma amino butyric acid; GLUT, glutamate; LC-NE, noradrenergic cells in the locus coeruleus; NE, norepinephrine; PPT-ACh, cholinergic cells in the pedunculopontine tegmental nucleus; PWG-GLUT, glutamatergic cells in the pontine-wave generator; RN-5HT, serotonergic cells in the raphe nucleus; TSG, thalamic sensory gate.

investigators have also shown that this type of learning-experience-induced off-line reactivation of a memory trace first begins in the cortex and then in the hippocampus, indicating that the cortex initiates this cortical-hippocampal interaction. Similarly, Peigneux and colleagues, using brain-imaging techniques in humans, have shown that the cortex and hippocampus are activated during the training session of spatial memory tasks, and are then reactivated during the early period of NREM sleep. These neuronal activity recordings and brain-imaging studies demonstrate that, during this early part of sleep, memory trace-forming structures are not only active, but are also replaying memory. Therefore, among all stages of the sleep-wake cycle, the early part of NREM sleep (light SWS) is the most conducive for the search and readout of the intermediate form of memory.

Elimination of Unnecessary and/or Redundant Memory

At this stage of memory consolidation, memories, which are identified as redundant, are deleted from the memory trace. Elimination of those redundant or irrelevant memory traces allows the brain to pay additional attention to memory traces that are more relevant for the next step of memory consolidation (increased signal-to-noise ratio). Since memories are stored as alterations in the strength

of synaptic connections, during this stage of the memory consolidation process, the number of synapse decreases, especially at the dendritic spines. This process is also known as synaptic pruning. Neuronal activity recording studies have shown that during the deepest part of the NREM sleep stage (SWS II/stages III and IV NREM, and deep SWS), the activities of brainstem cholinergic, and glutamatergic cells are at their lowest and that of aminergic cells is also very low (**Figure 3**). By measuring neurotransmitter release, studies have shown that the extracellular levels of NE, 5-HT, GLUT, and ACh in the cortex and in many other subcortical structures known to be involved in cognitive functions are very low during this deepest part of SWS. On the contrary, levels of inhibitory neurotransmitters, like GABA and adenosine, in the forebrain areas and cerebral cortex are at their highest level. This neurochemical state, with high levels of inhibitory neurotransmitters and low levels of excitatory neurotransmitters, is an inhibitory state of the brain. Indeed, brain-imaging and neuronal activity recording studies have shown that the deepest part of SWS is the most deactivated behavioral state of the brain. Recent molecular studies have shown that during the deepest part of SWS, hippocampal and cortical levels of immediate-early genes, early growth response 1 (Egr-1, also called zif-268, NGF1-A), and BDNF are at their lowest (**Figure 3**). Both conditions, either high levels of

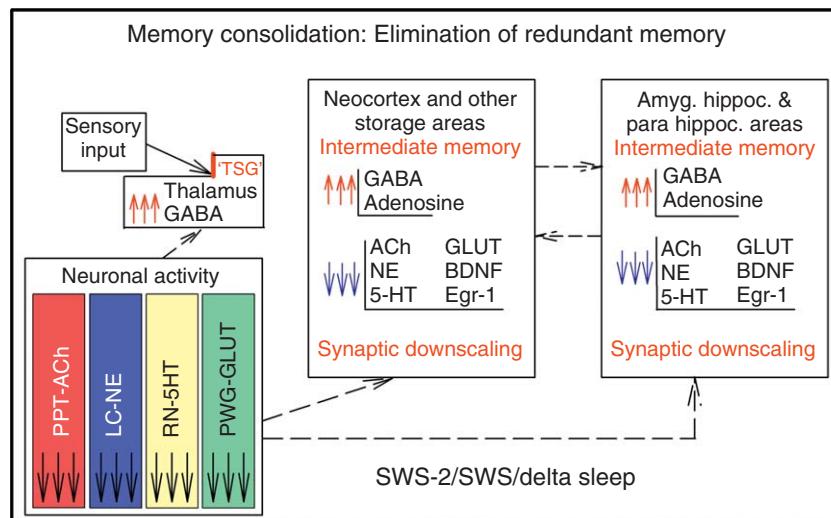

Figure 3 Physiological and biochemical conditions of the brain during the deep SWS stage are conducive for the elimination of redundant memory. Black arrows with solid lines between the blocks of brain structures: possible direction and flow of cognitive information and/or neurotransmitter; three upward arrows: highest levels of neuronal activity (PPT-ACh, LC-NE, and RN-5HT), extracellular level of neurotransmitters (ACh, NE, 5-HT, and GLUT), and intracellular proteins (BDNF and ERK); three downward arrows: lowest levels or absent of neuronal activity (PWG-GLUT) and extracellular level of neurotransmitter (GABA); black arrows with dashed lines between the blocks of brain structures: cognitive information and/or neurotransmitter flow in that direction is blocked; Arrows: levels of neuronal activity, extracellular levels of neurotransmitter, and intracellular levels of proteins: 3 arrows, highest; 2 arrows, medium; and one arrow, low. 5-HT, 5-hydroxy tryptamine (serotonin); ACh, acetylcholine; BDNF, Brain-derived neurotrophic factor; ERK, extracellular signal regulated kinase; GABA, gamma amino butyric acid; GLUT, glutamate; LC-NE, noradrenergic cells in the locus coeruleus; NE, norepinephrine; PPT-ACh, cholinergic cells in the pedunculopontine tegmental nucleus; PWG-GLUT, glutamatergic cells in the pontine-wave generator; RN-5HT, serotonergic cells in the raphe nucleus; TSG, thalamic sensory gate.

adenosine or low levels of BDNF and zif-268 are known for the reduction of dendritic spines and synaptic contacts (a process known as synaptic downscaling). Thus, the deepest part of SWS is the most conducive behavioral stage for the elimination of redundant memory.

Strengthening of Cognitively Relevant Memory

Physiologically, this is a process of synaptic strengthening in the memory trace. Over many years, pharmacological and biochemical research in cognitive neuroscience has shown that increased cholinergic and glutamatergic neurotransmission in the hippocampus, amygdala, and cerebral cortex improves this stage of the memory consolidation process. On the contrary, increased GABAergic and aminergic neurotransmissions in these areas attenuates this stage of the memory consolidation process. Studies of neuronal activity recordings in the brainstem and forebrain of rats and cats have shown that during REM sleep, cholinergic and glutamatergic neurons are very active but aminergic and GABAergic neurons are almost silent. Similarly, neurotransmitter release studies of Lydic, Baghdoyan, and many others have shown that, during REM sleep, the extracellular levels of ACh and GLUT are very high and at the same time extracellular

levels of NE, 5-HT, and GABA are very low in the hippocampus, amygdala, cerebral cortex, and many other areas of the forebrain. Thus, based on pharmacological and physiological evidence, only REM sleep neurochemistry could support this stage of memory consolidation (**Figure 4**).

Long-term potentiation (LTP) is hypothesized to be a neuronal model of learning and memory. LTP is also suggested to be the sign of synaptic strengthening in the memory trace. High-frequency (>200 Hz) electrical stimulation of an afferent pathway is important for inducing this type of LTP in the hippocampus, amygdala, and/or cerebral cortex. Datta and Hobson have identified a group of glutamatergic cells in the brainstem that discharge high-frequency (>500 Hz) spike bursts (3–5 spikes/burst) only during tS-R and REM sleep. They have also shown that the activation of these brainstem glutamatergic cells generates the pontine-wave (P-wave). Interestingly, activation of these cells facilitates hippocampal theta activity. Physiological evidence suggests that the hippocampal theta rhythm favors induction of LTP in the hippocampus as well as in many different parts of the cerebral cortex. Based upon physiological principles, neuronal reactivation is also critical for synaptic strengthening during sleep. Pioneering work by

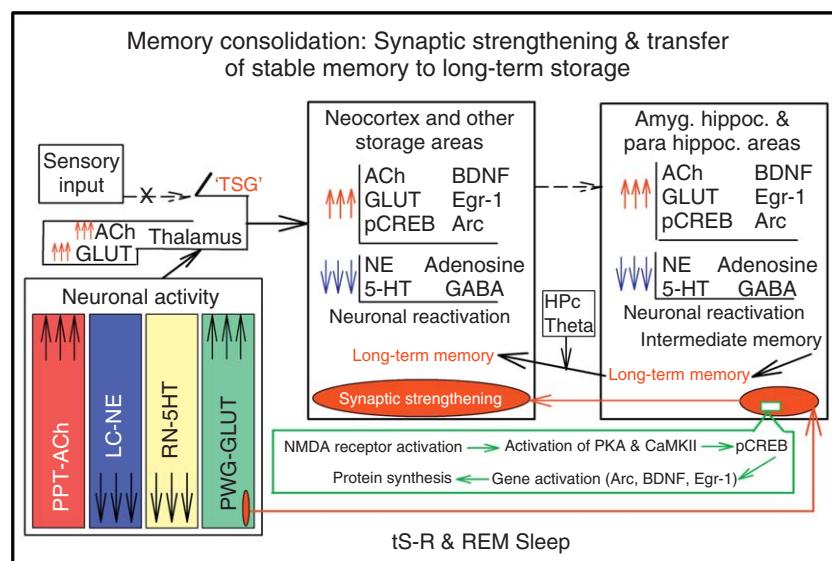

Figure 4 Physiological and biochemical conditions of the brain during tS-R and REM sleep stages are conducive for synaptic strengthening and transfer of stable memory to long-term storage. Black arrows with solid lines between the blocks of brain structures: possible direction and flow of cognitive information and/or neurotransmitter; three upward arrows: highest levels of neuronal activity (PPT-ACh, LC-NE, and RN-5HT), extracellular level of neurotransmitters (ACh, NE, 5-HT, and GLUT), and intracellular proteins (BDNF and ERK); three downward arrows: lowest levels or absent of neuronal activity (PWG-GLUT) and extracellular level of neurotransmitter (GABA); black arrows with dashed lines between the blocks of brain structures: cognitive information and/or neurotransmitter flow in that direction is blocked; Arrows: levels of neuronal activity, extracellular levels of neurotransmitter, and intracellular levels of proteins: 3 arrows, highest; 2 arrows, medium; and one arrow, low. 5-HT, 5-hydroxy tryptamine (serotonin); ACh, acetylcholine; BDNF, Brain-derived neurotrophic factor; ERK, extracellular signal regulated kinase; GABA, gamma amino butyric acid; GLUT, glutamate; LC-NE, noradrenergic cells in the locus coeruleus; NE, norepinephrine; PPT-ACh, cholinergic cells in the pedunculopontine tegmental nucleus; PWG-GLUT, glutamatergic cells in the pontine-wave generator; RN-5HT, serotonergic cells in the raphe nucleus; TSG, thalamic sensory gate.

Pavlides and Winson and, more recently, by Louie and Wilson has demonstrated that hippocampal neuronal activity expressed in place cells (neurons that fire in response to encountering specific locations) during waking is re-played (expressed as neuronal reactivation) during subsequent REM sleep. Moreover, Poe and colleagues have shown that this hippocampal place cell replay occurs at the positive phase (peak) of theta rhythm during REM sleep. Pavlides and colleagues and a number of other investigators have shown that the LTP-inducing tetanic stimuli are most effective at the positive phase of theta rhythm. Thus, the activation of P-wave generating cells during tS-R and REM sleep is capable of inducing physiological LTP in the hippocampus and amygdala. Similarly to neuronal recording in animals, in human subjects, using brain imaging, Maquet and colleagues have shown that patterns of brain activity expressed during training on a serial reaction time motor task reappear during subsequent REM sleep. Collectively, these physiological data suggest that REM sleep provides the ideal physiological environment for synaptic strengthening in the neuronal circuits of memory storage.

Over the last 25 years, cellular and molecular studies have demonstrated that *N*-methyl-D-aspartate (NMDA) glutamate receptor activation-induced, neuronal activation-dependent gene expression and protein synthesis in the dorsal hippocampus, amygdala, and cortex are necessary for synaptic plasticity and memory consolidation. However, such cellular and molecular studies have ignored the possibility that postlearning-training sleep could also positively (or negatively) influence learning-induced cellular and molecular changes. Using combinations of anatomical, physiological, pharmacological, and molecular techniques in the rat model, Datta and colleagues, during the last 10 years, have shown that the sleep stages, tS-R and REM sleep, tightly regulate this cellular and molecular cascade of memory formation. These studies have shown that after a session of learning training, P-wave generating cells increase their activity during the tS-R and REM sleep periods. Furthermore, the level of memory retention during the subsequent test session exhibited a positive relationship to the level of P-wave generating cell activation during REM sleep. They have shown that the activation of P-wave generating glutamatergic cells increases glutamate release in the dorsal hippocampus. This learning-training-induced increase in glutamate release during REM sleep in turn activates NMDA receptors in the hippocampus and amygdala. Activation of these postsynaptic NMDA receptors then activates intracellular signal transduction cascades, such as the cyclic AMP-dependent protein kinase-A (cAMP-PKA). Learning-training-induced P-wave generator activation-mediated activation of this cAMP-PKA then increases phosphorylation of cAMP response element binding protein (pCREB). This transcription factor

pCREB then increases the expression of Egr-1, activity-regulated cytoskeletal-associated protein (Arc), and BDNF messenger ribonucleic acid (mRNA) and proteins in the dorsal hippocampus and amygdala. More interestingly, they have shown that the increased REM sleep P-wave density during the posttraining sleep period is positively correlated with the increased levels of pCREB, BDNF, and Arc in the dorsal hippocampus. Collectively, these multidisciplinary studies of Datta and colleagues provided evidences to suggest that glutamate release by the activation of P-wave generating cells during tS-R and REM sleep is necessary for NMDA receptor-activation-mediated synaptic plasticity-related genes activation and protein synthesis in the hippocampus and amygdala (**Figure 4**). Thus, the above neurochemical, physiological, and molecular evidence suggests that tS-R and REM sleep stages provide a unique brain environment that is ideal for synaptic strengthening in memory-trace-forming structures of the brain.

Transfer of Stable Memory to Long-Term Storage

The last step of memory consolidation is to transfer stable memory traces to their long-term storage areas in the cerebral cortex. Based on memory testing in both hippocampus-lesioned patients and in experimental hippocampal- and amygdala-lesioned animals, it is now clear that once memory is processed in memory trace-forming structures (hippocampus, amygdala, PFC, cerebellum, and elsewhere), processed memories are then shifted from those structures to a permanent storage in the cerebral cortex. Louie and Wilson showed that, during REM sleep, the time frame of correlations between activities in different hippocampal neurons expands by two orders of magnitude resulting in the replay of waking activity patterns spanning seconds or even minutes. Such REM-related temporal expansion, relative to their original waking activity, in the time course of correlations between firing of different neurons is suggested to be the physiological sign of memory transfer from the hippocampus to its long-term storage in the cerebral cortex. Indeed, Pavlides and Ribeiro have shown that, during REM sleep but not other behavioral states, memory-consolidation-specific zif-268 activation begins in the hippocampus and then activation spreads into the cerebral cortex. Thus, this memory transfer occurs only during REM sleep.

The collective evidence from all sleep and memory studies suggests that all stages of sleep are equally important for the consolidation of all types of memory. Based on the type and amount of information to be processed and also the environment in which information was acquired, homeostatic demands for specific stages of sleep are readjusted for the completion of the memory consolidation process.

Glossary

Attractor networks – Recurrent networks with persistent states toward which the activity state of the network is attracted; persistent states are called fixed points.

Composite action command – Command refers to the output of a motor area, action commands include commands for plans and commands for movements, and a composite command generated by a mesoscopic module refers to a set of elemental commands generated by microscopic modules.

Distributed processing module (DPM) – One motor area together with its subcortical loops through the basal ganglia and through the cerebellum forms a distributed processing module.

Microscopic versus mesoscopic modules – DPMs are mesoscopic modules because they are composed of sets of microscopic modules; the microscopic modules have essentially the same computational architecture as do mesoscopic modules.

Training signal – For supervised learning the training signal specifies how the network can improve its response whereas for reinforcement learning the training signal simply evaluates whether performance is better (reward) or worse (punishment) than previously.

synapses at one site in the brain to synapses at other sites. For example, during practice of a particular program, planning operations tend to migrate from subcortical sites to cortical sites and then from PM areas of the cortex to M1. These migrations permit more rapid and accurate implementation of automatic movements. Neural signals returning from subcortical loops regulate the process of migration.

The learning rules that mediate synaptic plasticity at different sites in the brain differ (see **Table 1** for a summary of the sites highlighted in this article). In the cerebral cortex, plasticity at excitatory synapses onto pyramidal cells utilizes a Hebb-like rule for the detection of coincidence between input and output. In the BG, plasticity at spiny neuron synapses from cortical afferents uses a trace of coincidence detection that is trained by reward signals; this learning rule is called reinforcement learning. In the cerebellum, plasticity at Purkinje cell synapses formed by parallel fiber afferents also uses a trace of coincidence detection, but in this case depressions in synaptic weight are trained (instantiated) by errors in performance; the learning rule is akin to supervised learning. Diffuse synaptic inputs modulate the above learning rules; they function as permissive factors that gate the intensity of learning. Distributed processing modules composed of one area of cerebral cortex, together with its loops through the BG and cerebellum, benefit from all of these mechanisms operating in combination. In this article, motor learning in the cerebral cortex, the BG, and the cerebellum are each treated individually; following this, the benefits of coordinated learning in entire distributed processing modules (DPMs) are discussed.

Motor programs involve both the planning and the execution of movements. For voluntary movements of the limbs, these functions are distributed among several cortical motor areas. Generally speaking, planning operations are controlled by premotor areas (PMs in **Figure 1**) whereas execution is controlled by the primary motor cortex (M1 in **Figure 1**). Although not specifically illustrated in **Figure 1**, each of these motor areas is regulated by relatively private subcortical loops through the basal ganglia (BG) and the cerebellum (CB). These subcortical loops are specialized for learning from training signals. In contrast, the cortical motor areas are specialized for learning from practice.

Cellular and molecular processes at specific synaptic sites underlie the learning and memory of motor programs. Learning modifies the weights of specific synaptic inputs to specific neurons and the persistence of these weight changes represents one form of memory. Migration is a process that transfers memories from

Hebbian Learning of Motor Programs in Cortical Motor Areas

The learning of motor skills over extended periods of practice results in enlargement of motor and sensory representations in the cerebral cortex. Initial learning relies on long-term potentiation (LTP); this Hebbian learning rule enhances the strength of synapses that participate in practice. Projections from the BG and the cerebellum force their targeted cortical neurons to practice particular firing patterns until more direct inputs from other cortical areas are strengthened enough to generate similar firing patterns without guidance from the BG and/or cerebellum. Cholinergic neuromodulatory

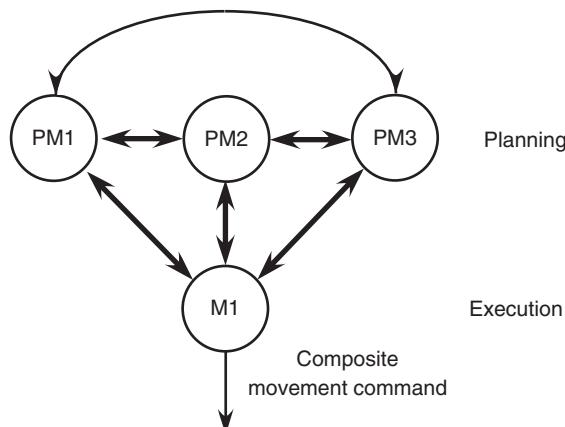

Figure 1 Cortical motor areas. M1 = primary motor cortex; PM1 = premotor area 1; PM2 = premotor area 2; PM3 = premotor area 3.

input from the nucleus basalis is a permissive factor related to attention. It permits the consolidation of cortical memories through synaptogenesis and cytogenesis. This scenario is especially important for crystallizing automatic movements.

BG Loops for the Selection of Ballpark Motor Programs

The cortical motor system's loops through the BG learn to regulate the selection of motor plans and movement commands – operations collectively referred to as action selection. The learning rule given in **Table 1** includes both coincidence detection, as in the cortex, and also training information transmitted by dopamine neurons. Brief bursts of dopamine-neuron firing signal the likelihood of future reward; these neural signals serve well as training signals for reinforcement learning. Next, we consider just what is being learned and why it is a difficult learning problem. The left side of **Figure 2** is a simplified schematic of one mesoscopic loop through the BG; it is comprised of thousands of microscopic loops originating from the same area of the cerebral cortex.

We discuss the coarse selection of a ballpark action since a small set of potential actions is selected rather than

an individual action. This imprecision results from cortex-to-striatum connections: any given spiny neuron (in the input stage of BG, called the striatum) receives a very large array of afferents from neurons in the cerebral cortex. Among several areas sending inputs, one forms a recurrent loop or module. Neighboring spiny neurons representing alternative actions thus receive a very similar, but slightly different, array of potential inputs. Spiny neurons compete with each other via prominent recurrent collaterals of their inhibitory γ -aminobutyric acid (GABA)ergic axons; the winners of this competition transmit their decisions to the next stage of BG processing. This pattern-classification operation by spiny neurons effectively decides on the relative merits of alternative actions based on the synaptic weights of its cortical inputs. These cortical-striatal synapses are trained by the dopamine input that signals the likelihood of future reward. Dopamine signals also function as a permissive factor that enhances the excitability of activated spiny neurons. The result is a powerful pattern classification operation that selects ballpark actions from thousands of alternative actions.

How do the inhibitory GABAergic outputs from selected spiny neurons instantiate their coarse decisions? This question is complicated by multiple stages of inhibition and by the presence of multiple pathways through the BG. Direct pathways learn to select context-dependent desired actions by disinhibiting positive feedback loops between the thalamus and cortex. These operations yield bursts of output from selected cortical neurons. Indirect pathways are tuned to deselect undesired actions by disinhibiting BG output neurons so that they can inhibit activity in inappropriate loops between the thalamus and cortical neurons.

To summarize, a large array of spiny neurons in the striatum receives a diverse convergent input from the area of the cerebral cortex that participates in any given mesoscopic loop. The array of spiny neurons performs a pattern-classification operation that is made competitive by the presence of collateral inhibition. Competition is biophysically mediated by both presynaptic and postsynaptic collaterals of the GABAergic spiny neurons. The superior performance of the presynaptic inhibitory mechanism appears to be augmented in phylogeny, and

Table 1 Different learning rules in the cerebral cortex, basal ganglia, and cerebellum

Brain site	Cerebral cortex	Basal ganglia striatum	Cerebellar cortex
Cellular Site	Excitatory afferents Onto pyramidal cells	Cortical afferents Onto spiny neurons	Parallel fibers Onto Purkinje cells
Learning rule Operation	Hebbian Coincidence	Reinforcement Coincidence • reward	'Supervised' Coincidence • error
Permissive factors	Cholinergic+	Dopaminergic+	Noradrenergic+

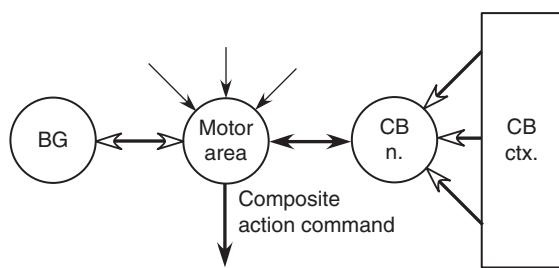

Figure 2 Subcortical loops. BG = basal ganglia; CB n. = cerebellar nucleus; CB ctx. = cerebellar cortex.

its occasional disruption associated with unfavorable epigenetic expression might help to explain schizophrenia. The selection of potential actions (by individual microscopic loops) from thousands of alternative actions is a very difficult pattern-classification task, which probably explains why it typically yields only a coarse selection of ballpark actions. The amplification and refinement of these ballpark actions into a precise action is attributed to the loop through the cerebellum.

Cerebellar Loops for the Amplification and Refinement of Motor Programs

The motor system's loops through the cerebellum (right side of **Figure 2**) are needed to amplify and refine potential action – ones that are promoted by synaptic input from other areas of the cerebral cortex and selected by loops through the BG. Amplification is mediated by positive feedback in an array of microscopic loops between a given area of the cerebral cortex and the corresponding division of a cerebellar nucleus. These loops form attractor networks that facilitate the planning and execution of motor programs. Purkinje cells in the cerebellar cortex control the fixed points of these attractor networks and, in doing so, create spatiotemporal patterns of cortical output that represent refined motor plans and motor commands. Sets of microscopic loops between primary motor cortex and cerebellum are forced by Purkinje cell inhibition to coordinate their activities in order to command movement at a selected velocity to a desired endpoint in space and time. The complete array of microscopic loops forms the composite action command for any given mesoscopic loop. The loops with the cortex thus generate composite motor plans and movement commands that control accurate movements.

Motor learning in Purkinje cells is guided by error-driven feedback from climbing fibers. These training signals signify punishment when an error is made. They instantiate long-term depression (LTD) – the ‘supervised’ form of learning in the cerebellum (**Table 1**). If, for example, a movement stops short of the target, a

corrective movement toward the target fires climbing fibers. LTD is then instantiated, and this delays the time at which Purkinje cells fire to terminate the next movement in the same direction. As a permissive factor, noradrenergic fiber discharge has two modes of action. Phasic discharge signals good outcomes and helps to consolidate LTD. Tonic discharge signals poor outcome and facilitates alternative actions. Another permissive factor, serotonergic discharge, signals the opposite of urgency; thus, pauses in discharge facilitate faster actions.

To summarize, composite action commands are initiated in loops through the cerebellar nucleus (CB n. in **Figure 2**), and they are then shaped and ultimately are terminated by prominent inhibitory input from the cerebellar cortex (CB ctx.). Arrays of Purkinje cells learn to detect input patterns signifying that the time has come to terminate elements of action plans and/or movement commands. Microscopic loops generate elemental commands and mesoscopic loops generate the several composite action commands in different motor areas. The overall result is a well-coordinated and precise composite movement command.

Coordination of Eyeblink Conditioning

Eyeblink conditioning is given special treatment here, since so much is known about how the cerebellum participates in the generation of eyeblink motor commands. The core of **Figure 3** is the same as **Figure 2**, except that the ‘red’ nucleus replaces the general label ‘motor area’ because it constitutes the main output for conditioned reflex (CR) motor commands. Conditioned stimulus (CS) signifies all of the variety of sensory inputs that can be used by the other four structures. The brainstem circuitry that mediates an unconditioned response (UR)

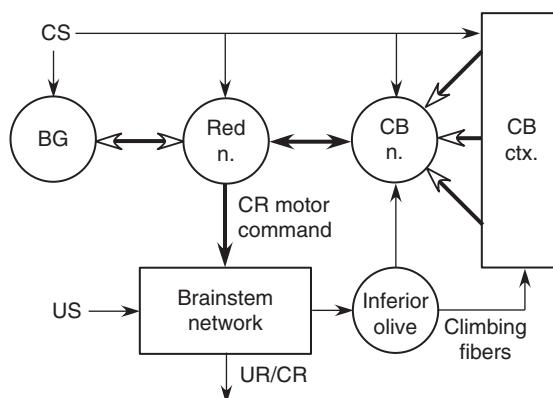

Figure 3 Eyeblink conditioning. BG = basal ganglia; CB n. = cerebellar nucleus; CB ctx. = cerebellar cortex; CR = conditioned reflex; CS = conditioned stimulus; Red n. = red nucleus; UR = unconditioned reflex; US = unconditioned stimulus.

to an unconditioned stimulus (US) and sends climbing-fiber input to CB cortex is shown at the bottom. This network also generates a CR in response to a CR motor command.

Much of the research in this field has focused on the association between a CS and the initiation of the eyeblink CR. While the BG is likely to be crucial in the discovery of potential stimuli that might fulfill a CS role, until recently the emphasis has been on where the associative link is actually made with the cerebellar circuitry that is required for CR responding. The most prominent link appears to be formed at CS synapses onto neurons in a CB nucleus – the interpositus nucleus. Once formed, this associative link is responsible for initiating positive feedback in the reciprocal loop between the red nucleus and the cerebellar nucleus. This loop forms CB modules that are analogous to the CB modules formed with motor cortex. The CB cortex then refines the amplitude and timing of the CR motor command so that it closes the eyelid in time to protect the cornea from the US.

Note that synapses at any site along the reciprocal pathway between the red nucleus and CB nucleus can fulfill the associative role ascribed to the interpositus nucleus for CRs. Viewed in this manner, eyeblink conditioning provides an excellent model system for studying learning mechanisms for motor control. The learning rule in the loop between CB nucleus and red nucleus is Hebbian as in the cerebral cortex, whereas the learning rule in CB cortex is supervised.

Coordinated Operation of DPMs

All of the operations outlined above occur in parallel in our brain, resulting in a high level of performance. Sensory and other inputs to the cerebral cortex begin the process of initiating actions. Inputs from BG regulate this process through the selection of ballpark actions and reinforcement learning that homes in on promising actions. Once competitive interactions within BG produce a ‘winner,’ that tentative action is selected and loops through cerebellum amplify and refine it into a precise composite action. Training signals from climbing fibers allow the cerebellum to optimize the action, permitting us to hit a desired endpoint with precision in both space and time. As the motor areas of the cerebral cortex practice controlling these actions, their signal-processing activities become consolidated into long-term memories, and eventually even the most elegant of actions becomes almost automatic.

Note that many factors influence motor learning. One can think of these diverse factors as different constraints on the evolutionary process that fine-tunes the

mechanisms used by the motor system. Since we live in an uncertain world, any given action may have many possible outcomes. Decision theory provides an approach to motor learning and control that can yield compact assessments of outcomes. Combining the various types of knowledge outlined in this article should help us to fathom the complexity of motor control and learning.

Glossary

Enhancer trap – The insertion of a P-element carrying the GAL4 coding region, resulting in GAL4 expression in a spatially and temporally defined pattern determined by a nearby enhancer.

Forward genetics – Random mutagenesis and screening (e.g., behavioral screens) to identify individuals with a phenotype of interest as a means of gene discovery.

Mushroom body – Bilateral neural structures in the insect brain required for olfactory memory functionally analogous in some ways to the vertebrate hippocampus.

Mutagenesis – The use of chemical mutagens, irradiation, or insertion of novel DNA to introduce random genomic mutations into a population of organisms to produce variant mutant alleles.

Neurogenetics – The study of genes involved in the structure and function of the nervous system.

P-element – A transposable DNA element in *Drosophila* that is flanked by inverted repeats recognized by a transposase. P-elements are often manipulated in *Drosophila* to introduce transgenes or produce mutations by disrupting endogenous genes.

Reverse genetics – The manipulation of identified genes (often as transgenes) in a system in order to test a hypothesis about the function of the gene.

Temperature-sensitive mutation – A mutation identified in a screen using temperature variations to increase detection of the mutant phenotype. Typically such mutants appear normal at the lower, permissive, temperature; a shift to an elevated, nonpermissive, temperature causes the mutant gene product to become unstable producing a change in phenotype.

neurogenetics – that complex behaviors might be genetically tractable, and in the model organism *Drosophila melanogaster*, no less – met with general skepticism and disbelief. Since then, *Drosophila* neurogenetics has resulted in pioneering studies that have elucidated the fundamentals of circadian rhythms at both the cellular and molecular levels, and has contributed significantly to greater understanding of learning and memory formation and sexual behaviors. As new tools are applied to these complex biological problems, the tiny fruit fly seems poised to bridge molecular genetics with a more systemic understanding of how neural circuits are formed and maintained in memory.

Not long after single gene mutants in phototactic and circadian behavior were isolated in Benzer's lab, confirming the promise of a neurogenetic approach, Quinn, Harris, and Benzer demonstrated that *Drosophila* could be conditioned using an operant conditioning paradigm. In this negatively reinforced assay, flies learn to avoid an odor paired with electric footshock. A forward genetic screen using this assay rapidly yielded mutants in which learning and memory was defective. The subsequent 30 years have seen the isolation and identification of numerous such mutants, some of which have been molecularly identified and examined. Many of these mutants are in highly studied cellular signaling pathways, and this has contributed to studies on learning and memory formation in other organisms.

In addition to these classical forward-genetics screens, sophisticated transgenic tools have contributed to contemporary studies. Indeed, memory research has driven the development of technology that limits transgene induction and repression both spatially and temporally. Progress has also been made in the ability to image and record neural activity in specific neurons. Most recently, it has been shown that heterologous channels can be expressed in defined neurons, allowing rapid, temporal control over their depolarization or hyperpolarization. The application of these tools to memory research will allow *Drosophila* neurobiologists to tackle heretofore unanswerable questions about neural circuitry and cellular connectivity, as well as when and where specific molecules are required for memory formation. These tools – combined with some of the genes that have been discovered – should facilitate the move from neurogenetics to the neurobiology of memory formation.

Introduction

In the postgenomic age, where the idea of genes underlying virtually every aspect of human health and function has gained wide acceptance, it can be difficult to comprehend how revolutionary neurogenetics once was. Yet when Seymour Benzer's laboratory began their pioneering work in the 1960s, the principle of

The Neurogenetics of *Drosophila* Memory Formation – the First 35 Years

Learning and Memory Paradigms in *Drosophila*

Olfactory memory paradigms have dominated *Drosophila* memory research since its inception. Tully and Quinn developed a more robust, negatively reinforced, Pavlovian (classical) conditioning assay in 1985. This olfactory classical conditioning (OCC) assay has largely replaced the original operant conditioning paradigm. In this assay, one of two odors is paired with footshock, while the other odor is unpaired. Following training, flies must choose between the paired and unpaired odors. Varying the number of training trials and their spacing produces different phases of memory analogous to those in other learning and memory models: short-term memory (STM), which is independent of transcription and translation and decays within 1 h; middle-term memory (MTM), which requires translation but not transcription and decays within 1–4 h; anesthesia-resistant memory (ARM), which is independent of translation and decays after 96 h; and long-term memory (LTM), which requires transcription and translation and lasts for at least 7 days. Single-trial or repetitive massed training (where trials are performed sequentially) produce the first three of these phases but only repetitive spaced training, where a rest period follows each training trial, produces LTM.

The other most common assay of learning and memory is an operant conditioning paradigm in which courtship is suppressed. Mated females paired with virgin males will induce courtship but reject attempts at copulation. Single, short-term exposure to mated females prevents males from subsequently courting virgin females (for 2–3 h) and fertilized females (for up to 24 h). Extended exposure to mated females (presumably resulting in many spaced rejections) results in a conditioned courtship suppression (CCS) lasting at least 9 days. While this paradigm integrates multiple sensory pathways and is based on a highly biologically relevant behavior, the underlying circuitry may be more complex due to the multimodal nature of the stimuli.

Flies are able to distinguish similar abstract visual patterns, and recall the position of items no longer present in an environment. These abilities have been exploited in a number of lesser-used memory paradigms, including appetitive sucrose-based (i.e., positively reinforced) conditioning, conditioned place-preference assays, and a disappearing-visual-landmark paradigm. Despite these alternative paradigms, the bulk of what has been learned concerning *Drosophila* memory has come from employing the OCC and CCS paradigms. Through the combined application of forward and reverse genetics, the various memory phases have been outlined, and a large number of genes that contribute to one or more of these processes

have been identified (see below). In addition, the forward genetic screens – especially those performed by Heisenberg and colleagues – identified the mushroom bodies (MBs) and central complex (CC) as key structures in olfactory memory. These discoveries have been critical in mapping the olfactory circuitry and driving recent experiments. Contemporary experimental strategies rely heavily upon the enhancer-trap screens that owed their genesis to these early screens, which identified mutations affecting the neuroanatomical architecture required for olfactory memory. The complexity of the circuitry underlying behavior is generally appreciated, but its details remain unclear, both within and outside of the MB. Recent work using temperature-sensitive dynamin (*shibire^{ts1}*) has revealed complex circuitry even for short-lived memories, providing a glimpse of the likely minimum complexity that underlies LTMs. In addition to molecular, cellular, and neurobiological issues, the first 30+ years of neurogenetics has also provided a neurocognitive perspective. Flies are able to generalize visual stimuli, and this cognitive process requires an intact MB. Prior to turning to the next 30 years of fly-memory research, we summarize some of the important genes that have been identified during the ‘golden’ years of gene discovery.

Gene Discovery in *Drosophila*

The first and best-characterized molecular pathway of memory in *Drosophila* is the cyclic adenosine monophosphate (cAMP) signaling pathway. Quinn and colleagues' original screen yielded two mutants in this pathway – *dunce* (*dnc*) and *rutabaga* (*rut*) – encoding a cAMP phosphodiesterase and a calcium ion (Ca^{2+})/calmodulin-regulated adenylate cyclase (AC). These mutants are poor learners in the operant, OCC and CCS behavioral paradigms. Subsequent experiments have shown that dysregulation of cAMP levels severely inhibits learning in OCC, indicating the cAMP signaling cascade must be intact for learning and memory to occur. Whether these genes played an architectural or acute role in memory formation, however, was unclear. For the *rut* product, temporally and spatially limited expression of the wild-type *rutabaga* in adult MB neurons rescues the learning deficit, thus demonstrating an acute requirement for *rut*. The *amnesiac* (*amn*) mutant, identified in the same screen, has recently been shown to encode a neuropeptide resembling pituitary AC-activating peptide (PACAP). Identification of the *amn* product provided an intriguing clue about the cellular connectivity of the cAMP pathway, as the gene is strongly expressed in the dorsal paired medial (DPM) neurons, which synapse onto the MB neurons and are believed to release their neurotransmitters onto the MB neurons, potentially activating the AC in the MBs.

Two other genes in the cAMP signaling cascade have been examined for their role in learning and memory: protein kinase A (PKA), a cAMP-stimulated kinase, and the transcription factor cAMP response-element-binding protein (CREB), which lies downstream of PKA activation. PKA is the principal effector of the cAMP cascade, and has been shown to up- and downregulate synaptic strength in central synapses. PKA-mediated regulation of synaptic strength can be phenocopied by *rut* expression in the postsynaptic cell. Overexpression of a regulatory subunit of PKA – creating, in effect, a dominant-negative PKA – also impairs olfactory learning and MTM, but only MTM in CCS suppression. Mutations in the catalytic domain of PKA, including *DCO*⁵⁸¹, can reduce PKA activity by 80%, and substantially impair memory. The PKA catalytic subunit is enriched in the MBs, as are the *dnc* and *rut* products; hence three principal cAMP cascade components colocalize to essential olfactory memory structures. This emphasizes the centrality of cAMP signaling in the biochemical pathways underlying learning and memory.

The role of CREB is somewhat more complex. As a transcription factor, CREB acts as a bottleneck upon which many different signaling pathways converge. This means that altering its expression is highly likely to have pleiotropic effects. In addition, it is differentially spliced in fly brains, with at least seven isoforms with presumably distinct coactivators and therefore differential transcriptional activity. In 1995, we reported that the acute expression prior to training of two different splice isoforms had opposite effects on memory: dCREB2-b, the ‘blocker’ isoform, was sufficient to prevent LTM formation following spaced training in OCC. The overexpression of dCREB2-b was also later found to selectively block LTM in CCS, illustrating the specificity of this dominant negative for consolidated memory. The expression of another isoform, dubbed dCREB2-a, was sufficient to produce enhanced memory formation following a single training trial – which would normally produce only STM and ARM. A point mutation encoding an early stop codon in dCREB2-a was discovered some years later. It has only recently become apparent that the isoform of dCREB2 responsible for memory enhancement is one whose expression is tightly regulated, in part in a circadian manner, suggesting another level of regulation in how different isoforms of CREB enact their transcriptional programs. These findings have been echoed by a report in mice that there are circadian oscillations in cAMP levels and CREB phosphorylation states and that disruption of these oscillations results in memory deficiencies. This suggests that assessing molecular components of memory pathways may require strict control of transgene expression, particularly for transcription factors.

Other Cell Signaling Molecules Implicated in Learning and Memory

The neurofibromatosis I (NF1) gene encodes a *ras* inactivating, GTPase-activating protein (GAP) and mutations in human NF1 produce a disorder marked by learning defects and benign tumors throughout the nervous system. In flies, loss of the *Drosophila* *NF1* ortholog leads to defects in learning and all later forms of memory. While dysfunctional regulation of Ras activity is the most likely cause of these deficits, *NF1* is necessary in *Drosophila* for stimulation of the *rut*-encoded AC by PACAP-like peptides. *Drosophila* *NF1* mutants display deficits in STM rescued by acute expression of a wild-type *NF1* transgene or by expression of a constitutively active PKA catalytic subunit, implying that the learning deficits in *NF1* mutants are in part related to defects in cAMP signaling. The LTM defect in *dNF1* mutants has been shown to be specifically the result of altered Ras activity, and LTM is rescued by overexpression of the GAP domain of *NF1* alone, suggesting an important role for Ras inactivation in consolidated memory. Hence, a single protein appears to be involved in mediating both learning and later forms of memory.

Two other kinases have been shown to affect learning, and indeed, to enhance some forms of memory in the fly. Temporally restricted expression of a PKC-inhibiting peptide results in normal learning but failure to suppress courtship in CCS after training – indicating a role for PKC in longer-lasting forms of memory. Based on mammalian work in hippocampal slices, we tested the atypical subfamily of PKC in learning and memory formation. The induction of a partially activated isoform of the murine or fly aPKC ζ gene, aPKM ζ or DaPKM, in a small post training window, was sufficient to selectively enhance ARM in OCC. Expression of a dominant negative form of DaPKM or use of the PKM inhibitor chelerythrine was sufficient to block ARM. Again, subsequent studies in vertebrate mammals have underscored the importance of aPKM ζ in learning and memory, confirming that such cellular signaling pathways are highly conserved.

The calcium/calmodulin-dependent protein kinase II (CaMKII) has received a great deal of attention among molecular neurobiologists. It is enriched at synapses, suggesting it may be a key player in responding to neuronal stimulation, and is capable of autophosphorylation, leading to rapid changes in its activity, and the ability maintain persistent activation. The expression of a CaMKII peptide inhibitor throughout the fly impairs learning and memory in CCS. Conversely, the expression of a constitutively active CaMKII in MB neurons and the antennal lobes – components of the olfactory learning circuitry – results in enhanced learning in the same assay.

RNA Transport and Translation Mutants

Tully, Dubnau, and colleagues paired a transposon-insertion screen for LTM-specific mutants with a DNA microarray performed in wild-type flies following spaced training. These complementary screens yielded seven genes involved in control of subcellular mRNA localization and translation. Among the mutants identified by the behavioral screen were mutations in eIF-5C, a translation initiation factor; *oskar*, a known requirement for *staufen*-mediated RNA transport; and *pumilio* (*pum*), a repressor of translation. *Pum* was also identified in the DNA microarray as a gene whose expression is increased during LTM formation. Other genes whose expression was significantly altered in the DNA microarray include *staufen* (*stau*), involved in mRNA transport within the cell; *moesin* (*moe*), an actin-binding protein that mediates *stau*-bound mRNP translocation; *orb*, the fly cytoplasmic polyadenylation element binding protein (CPEB) homolog, which is required for local translation in oocytes and presumably at synapses; and eIF-2G, another translation initiation factor. As a validation of the DNA microarray results, a temperature-sensitive *stau* mutant was used to demonstrate that learning was intact but 1-day memory specifically disrupted when flies were maintained at the elevated, nonpermissive temperature following assessment of learning. The identification of multiple genes in the well-studied messenger RNA (mRNA) transport and translation pathway provides support for the idea that LTM formation requires the transport of newly transcribed, synaptically localized mRNAs, and that local translational control is key to LTM formation.

The cytoplasmic poly(A) polymerase GLD-2, similarly to CPEB, enhances translation of its target mRNAs by extending their poly(A) tails when the polymerase is activated. *Drosophila* GLD-2 interacts with *dfmr1*, *pum*, and *eIF-4E*, placing it at the heart of the translation-regulatory machinery. Acute overexpression of a dominant-negative *Drosophila* GLD-2 prior to training has recently been shown to specifically inhibit LTM but not learning or STM, in the classical olfactory conditioning paradigm. This lends additional support to the notion that local translational activation at the time of memory formation is essential for consolidating memory.

Another gene in the translation pathway with an effect on memory is the *Drosophila* ortholog of *FMR1* in humans. Defects in *FMR1* result in fragile X mental retardation syndrome (FXS) or in fragile X tremor/ataxia syndrome, a progressive neurodegenerative disorder. *FMR1* and its orthologs normally function in the micro-RNA (miRNA) pathway, where it participates in translational repression; *fmr1* knockout models have elevated levels of mGluR activity as well. *dfmr1* mutants replicate many salient features of FXS, including memory impairment; they exhibit normal learning but defective memory in the

CCS-suppression paradigm. This memory defect is rescued by several metabotropic glutamate receptor (mGluR) antagonists, confirming that mGluR dysregulation in *dfmr1* mutants is in part responsible for the impairment of memory. More recently, *dfmr1* expression was shown to be elevated in wild-type MBs following spaced training. Overexpression of wild-type *dfmr1* following spaced training was shown to impair 1-day memory in the classical olfactory conditioning paradigm, as did a *dfmr1*-directed RNA interference (RNAi) transgene is driven in the MBs. Impairments were specific for 1-day memory after spaced training and had no effect on 1-day memory after massed training, confirming the role of *dfmr1* in consolidated memory. Notably, protein-synthesis inhibitors at low concentrations rescued the 1-day memory deficit in *dfmr1* mutants without effect on wild-type fly performance, suggesting that *dfmr1* participation in translational repression is important to its normal function in memory.

The increased expression of translational repressors *pum* and *dfmr1* after spaced training is, at first glance, counterintuitive: if local translation is required for consolidated memory, which it almost assuredly is, why then are translational repressors required as well? One possibility is that while LTM formation appears to require ongoing local translation following training in LTM formation, the mRNAs being translated likely vary at different stages of consolidation and eventual transfer of memory. If ongoing, synaptically localized translation of specific subsets of mRNAs is required, translational repressors can be thought of as essential in maintaining mRNAs in an inactive state as they are transported to distal locations in the cell, where the mRNAs may be activated and translated. One advantage of allowing the products of transcription to be delivered in a relatively defined manner would be the selective, local production of specific proteins.

Other Classes of Genes Affecting Learning and Memory in *Drosophila*

Two different genes that participate in a common pathway during neuronal development affect memory formation. Notch (N) receptors are single transmembrane proteins primarily studied in developmental cell-fate determination. Temperature-sensitive mutations in N, as well as transgenic flies carrying dominant-negative constructs, are selectively defective in LTM but not ARM in OCC. Expression of a Notch-directed RNAi transgene in the MBs alone specifically impairs LTM, demonstrating how new tools can be directed to determine the spatial requirement for genes involved in learning and memory. Overexpression of N after a single training trial enhances 1-day memory, and this enhancement is protein-synthesis-dependent.

The highly conserved E3 ubiquitin-ligase encoded by Neuralized (*neur*) enhances Notch-mediated transcription during development by ubiquitinating the Notch ligand. A recent report demonstrates that loss of a single copy of *neur* significantly reduced LTM in the OCC paradigm, whereas overexpression of wild-type *neur* in peripheral MB neurons resulted in a dosage-dependent enhancement of LTM. In neither case was learning, STM, MTM, or ARM affected. This selective effect on LTM is part of the evidence for a *neur* role in LTM formation; the requirement for *neur* in the peripheral MB neurons suggests a role in formation as opposed to consolidation as these neurons are thought to be involved in the early stages of memory.

In our discussion of genes of learning and memory in *Drosophila*, we have presented only some of the better-studied genes and pathways. This is neither an exhaustive presentation of genes implicated in learning and memory, nor a complete history of every behavioral result obtained with every gene mentioned. These represent only a fraction of the mutants, however, and many remain unidentified. Likewise, many of the mutants affect learning and STM rather than longer-lasting forms of memory. A principal challenge for *Drosophila* neurogeneticists in the future is the identification of molecules participating in the maintenance and retrieval of memory.

Novel Tools

The principal novel transgenic tools available to *Drosophila* neurogeneticists are all derived from the binary Upstream Activation Sequence (UAS)-GAL4 expression system developed by Norbert Perrimon's laboratory. This system exploits a yeast transcriptional activator (GAL4) inserted at random within the fly genome to drive the expression of transgenes that carry tandemly arranged GAL4 binding sites (the Upstream Activation Sequence, or UAS). Cell-type restriction of GAL4 permits localized expression of the transgene. Using a tyrosine hydroxylase promoter to drive GAL4 expression, for example, restricts UAS-transgene expression to dopaminergic neurons. Variants on GAL4 permit further modulation of expression, including repression or induction of GAL4 activity; such variants (GAL80^{ts} and GeneSwitch, doxycycline) give a temporal, user-controlled dimension to GAL4-UAS transgene expression. UAS-driven fluorescent reporters of intracellular Ca²⁺ activity (UAS-Cameleon, UAS-GCaMP) and synaptic transmission (synaptopHluorin) provide the means of tracking activation of defined cellular populations. Other UAS-driven tools of special interest in learning and memory include: UAS-*sbire*^{ts1} – an inducible blocker of synaptic vesicle release; UAS-ChR2 – a blue-light-activated ion channel permitting direct photostimulation of neurons; and UAS-PAC α – a photoactivatable AC

allowing direct stimulation of the cAMP pathway in neurons. The astute combination of these tools with simple behaviors in the fly has the obvious potential to answer a host of questions about learning and memory.

The size of the *Drosophila* brain is often considered a disadvantage, as it limits the use of electrophysiology. The relatively small number (approximately 100 000) neurons in the fly brain and their stereotyped nature, however, make elucidation of the circuits underlying specific behaviors an attainable goal. Resolution of neural memory circuits requires the following: (1) a defined behavior, (2) identification of the cells participating in that behavior, (3) determining how these cells are activated and how that activation is transferred or communicated throughout the circuit, and (4) finally determining what cellular and molecular mechanisms underlie the inter- and intracellular communications producing the behavior. The dissection of olfactory memory structures using genetic tools has advanced rapidly in the last decade and the gross architecture of the olfactory system circuit is now understood as are the functional roles of subsets of neurons within the circuit. Future challenges in this area include understanding just how stimuli are encoded and transformed in the circuit and how effector neurons downstream of the MBs elicit the behaviors themselves.

Summary: Tools and Genes and the New Neurobiology of Memory Formation

The last 30 years of *Drosophila* neurogenetics have revolutionized the way we understand learning and memory, forging an appreciation of single-gene function in complex behaviors and identifying biochemical pathways that have proven to be essential for many types of mammalian memory. Given the array of genetic technology now available to manipulate and dissect memory, perhaps the major challenge for the next 30 years is more conceptual than technological.

A sizable collection of memory mutants now exists, and multiple genes have been identified. Rather than striving to identify additional genes, effort might be more effectively expended in bringing coherence to those already known. The tools available to test the function of these genes in memory are formidable, but by no means have simpler assays been exhausted. The classical genetics approach of using double mutants to assess whether the mutations are in the same pathway, for example, could determine whether existing mutations represent interdependent effects on memory. A variant of this approach using the circadian clock gene period (*per*) is instructive: *Per*-null mutants are selectively impaired in LTM. The inducible expression of a wild-type *per* transgene rescued the LTM deficit when

expressed before OCC, suggesting *per* is required for LTM formation. Surprisingly, overexpression of this *per* transgene in a wild-type fly prior to conditioning produced LTM from training conditions that normal induce only STM. LTM enhancement was maintained when dCREB2-b and *per* were overexpressed simultaneously prior to training, suggesting that *per* is downstream of dCREB2.

One principle that is needed is the development of new concepts guiding the field out of the age of gene discovery. The formulation of clear hypotheses about the roles of these genes in specific aspects of learning and memory is essential; equally important is the expansion of our view of the cognitive abilities and range of experience of the organism. For example, the role that non neuronal cells play in memory formation is unclear, even though studies on the cathepsin-encoding crammer (*cer*) mutant, for example, suggest a glial role in modulating early stages of LTM. In addition, the use of UAS-*shibire^{ts1}* has already established that dopaminergic and octopaminergic neurons mediate negatively and positively reinforced behaviors, respectively. Other contributory processes, such as the behavioral or circadian state of the flies, synaptic scaling, and other neuromodulatory factors are uniquely tractable in the fly. Despite the stereotyped nature of *Drosophila* neurons, the fly-brain need not be thought of as entirely hard-wired: there is evidence that activity-dependent plasticity exists at a cellular level, and flies exhibit behavioral plasticity – modifying courtship and fighting strategies based on experience. Expanding the repertoire of behavior in *Drosophila* will provide us with a richer understanding of learning and memory in a model that has already altered the landscape of learning. The power to answer virtually any defined question about *Drosophila* learning and memory is now limited principally by the hypotheses directing the work. During the next few decades, *Drosophila* should transition from a primarily neurogenetic system to one that is fully neurobiological.

Mechanisms of Memory Formation and Storage in *Hermisenda*

T Crow, L-M Tian, and J-J Xue-Bian, University of Texas Medical School, Houston, TX, USA

© 2010 Elsevier Ltd. All rights reserved.

Glossary

Actin – A protein filament that is a major constituent of the cytoskeleton of all eucaryotic cells.

Cytoskeleton – The system of protein filaments in the cytoplasm of a eucaryotic cell.

ERK (Extracellular signal-regulated kinase) – A component of the signal transduction pathway that couples intracellular responses to the binding of growth factors to surface receptors.

GABA (Gamma aminobutyric acid) – An inhibitory neurotransmitter.

G protein – One of a large family of GTP-binding proteins that are important intermediaries in signaling pathways.

Hermisenda – A carnivorous nudibranch mollusk found along the Pacific coast of North America used in the studies of learning and memory.

5-HT (5-hydroxytryptamine (serotonin)) – A neurotransmitter.

Phosphorylate – The process of adding a covalently linked phosphate group to a small molecule or protein.

PKC (Protein kinase C) – A family of enzymes that control the function of other proteins by phosphorylation

Protein kinase – An enzyme that transfers a phosphate group from adenosine triphosphate to a specific amino acid of a target protein.

formation. The marine mollusk *Hermisenda crassicornis* is one preparation that has contributed to an understanding of Pavlovian conditioning at the cellular, molecular, and system levels. Classical conditioning of *Hermisenda* is well documented and follows the Pavlovian tradition where the conditioned stimulus (CS) and unconditioned stimulus (US) elicit different responses prior to training. Before conditioning light, the CS does not elicit either of the unconditioned responses (UCRs) that have been studied in *Hermisenda*: muscular foot-shortening and inhibition of forward ciliary locomotion. Stimulation of statocyst hair cells of the graviceptive system using rotation or orbital shaking as the US elicits foot-shortening and inhibition of locomotion or a reduced rate of forward ciliary locomotion. Pavlovian conditioning produces two conditioned responses (CRs): light-elicited inhibition of ciliary locomotion which results in a suppression of *Hermisenda*'s normal positive phototaxis and CS-elicited foot shortening (see **Figure 1**). In both of the CRs, a new response emerges to the CS and the response-evoking properties of the US transfer to the CS. The formation of memory in *Hermisenda* involves changes in both intrinsic cellular excitability and synaptic strength at multiple sites within the neural circuit supporting the generation of CR (see **Figure 2**). The modifications produced by Pavlovian conditioning involve the engagement of multiple cellular mechanisms that are expressed by alterations in the properties of channels in excitable membranes within identified sensory neurons and interneurons. Initial acquisition and long-term retention involve both presynaptic and postsynaptic mechanisms. The actions of several second-messenger pathways contribute to both acquisition and retention of associative memory. Short-term memory involves posttranslational modifications of proteins supported by the activation of several signaling pathways and is expressed by changes in both the strength of synaptic connections and intrinsic excitability. Intermediate-term memory requires translation and post-translational modifications, but not transcription. Long-term memory requires posttranslational modifications, new messenger ribonucleic acid (mRNA) and protein synthesis, structural modifications, and is expressed by long-term changes in intrinsic cellular excitability and the strength of synaptic connections.

Introduction

A central focus of studies on nervous system function is on how basic associations are formed and retained in memory. Pavlovian conditioning paradigms have provided the opportunity to study mechanisms underlying the formation of basic associations in memory at cellular, synaptic, and molecular levels. There is now an extensive database on Pavlovian conditioning generated from diverse species that represents sufficient complexity characteristic of the different forms of memory. The mechanistic analysis of Pavlovian conditioning has been effectively addressed in the less-complex nervous systems of higher invertebrates and has been useful in identifying cellular and molecular mechanisms underlying different stages of memory

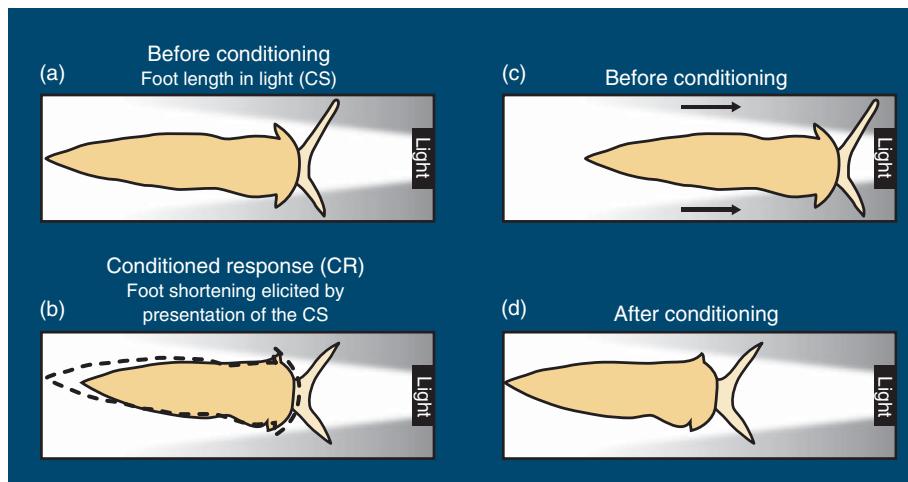

Figure 1 Pavlovian conditioning produces two CRs in *Hermissenda*: foot shortening and inhibition of locomotion. (a) Foot length measured during the presentation of the CS (light) before conditioning; (b) foot-shortening CR elicited by the CS after conditioning. The black dashed line indicates foot length measured during the presentation of the CS before conditioning; and (c) light-elicited locomotion assessed before conditioning; and (d) inhibition of light-elicited locomotion measured after Pavlovian conditioning. Random or pseudorandom presentations of the CS and US do not produce either light-elicited inhibition of locomotion or CS-elicited foot shortening. Cellular and Molecular Mechanisms Underlying Short-, Intermediate-, and Long-Term Memory Formation

Contemporary views of memory and its formation over time indicate that both declarative and nondeclarative (procedural) forms of memory involve multiple stages with different underlying mechanistic requirements. Several *in vivo* and *in vitro* procedures involving one or a few conditioning trials have been used in Pavlovian conditioning studies of *Hermissenda* to examine the initial events supporting the formation of short-, intermediate-, and long-term memory. The different protocols involving one or several conditioning trials produce behavioral changes and physiological modifications that can be detected within minutes following training. *In vitro* Pavlovian conditioning procedures can be applied to the isolated circumesophageal nervous system since the two sensory pathways mediating the CS and US are totally intact in the isolated nervous system. Pairing the CS (light) with either mechanical perturbations of the statocyst or rotation of the isolated nervous system sufficient to depolarize hair cells (US) produces electrophysiological modifications in sensory neurons that are similar to changes produced by multitrial *in vivo* procedures. In addition, a multitrial *in vitro* procedure involving pairing the CS with extrinsic current depolarization of identified statocyst hair cells (nominal US) produces modifications in sensory neurons. The relevance of these investigations to the formation of different stages of memory depends upon the different conditioning protocols, the efficacy of the US,

the number of conditioning trials, and the duration of CS-US stimulation.

One-Trial Conditioning

A one-trial *in vivo* conditioning procedure was developed to more precisely control when initial learning occurs and to not confound time after conditioning, when memory is tested, with different numbers of conditioning trials. One conditioning trial consisting of pairing the CS (light) with the direct application of one of the proposed transmitters of the US pathway (5-hydroxytryptamine (5-HT), nominal US) to the exposed nervous system of the otherwise intact *Hermissenda* produces a long-term inhibition of light-elicited ciliary locomotion (CR). An *in vitro* analog of the one-trial procedure that consists of pairing the CS (light) with the application of 5-HT to the isolated circumesophageal nervous system has been used to examine mechanisms underlying the development of short-, intermediate-, and long-term memory. The *in vitro* analog of one-trial conditioning generates a time-dependent enhancement of intrinsic excitability in sensory neurons and regulates the phosphorylation of proteins associated with memory formation (see the section titled ‘Proteins regulated by Pavlovian conditioning’ below). A variation of the one-trial *in vitro* procedure consisting of pairing the CS with mechanical perturbation of the statocyst (US) also produces a significant Ca^{2+} -dependent increase in input resistance, a correlate of enhanced excitability of sensory neurons, which is expressed within minutes postconditioning. In addition, a one-trial

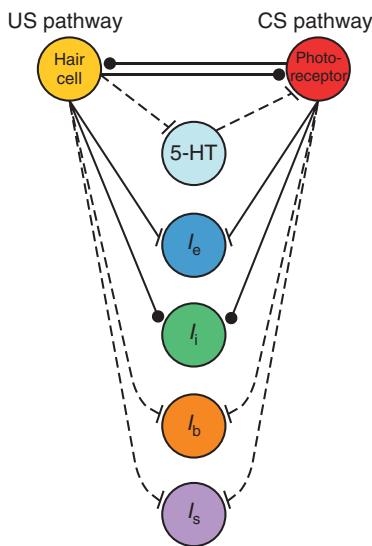

Figure 2 Diagram showing sites of synaptic convergence between identified neurons of the CS and US pathways. The formation of intrinsic enhanced cellular excitability and changes in the strength of synaptic connections between sensory neurons (photoreceptors) and sensory neurons and type I interneurons support the generation of light-evoked inhibition of locomotion. Proposed modifications in type I_b and I_s interneurons may also contribute to the development of the foot-shortening CR. Statocyst hair cells form monosynaptic GABAergic and putative polysynaptic serotonergic projections to identified sensory neurons (photoreceptors). Caudal hair cells inhibit photoreceptors and cephalic hair cells are inhibited by type B photoreceptors. Hair cells of the graviceptive system and photoreceptors of the visual system form monosynaptic connections with identified type I interneurons and polysynaptic connections with identified type I_b and I_s interneurons. (●) Inhibitory synaptic connections; (↑) excitatory synaptic connections. The neural circuit shows solid lines that represent established monosynaptic connections and dashed lines indicating polysynaptic connections to identified I_b and I_s interneurons that may involve potential interneurons not yet identified.

in vitro procedure involving gamma aminobutyric acid (GABA) application to the region of the sensory neuron terminal branches (nominal US) paired with a 10-s depolarization of the sensory neuron (nominal CS) produces an increase in the input resistance of the sensory neurons that persists for at least 10 min. These studies indicate that the application of a neurotransmitter (nominal US) when paired with depolarization (nominal CS), resulting in a brief period of Ca^{2+} elevation, is sufficient to produce short-term enhanced excitability in sensory neurons.

Multitrial Conditioning

The analysis of electrophysiological and biophysical modifications detected following multitrial Pavlovian conditioning has focused upon two sites of convergence

between the CS and US pathways (see **Figure 2**). The first site is in the sensory neurons (type A and B photoreceptors) of the pathway mediating the CS. Modifications in the sensory neurons of conditioned animals involve both intrinsic enhanced excitability and facilitation of synaptic connections between identified sensory neurons, and between identified sensory neurons and interneurons. The intrinsic modifications in sensory neurons are expressed by enhancement of the amplitude of CS-elicited generator potentials, a concomitant increase in CS-elicited spike frequency, increased spike activity evoked by depolarizing extrinsic current, decreased spike frequency accommodation, and a reduction in the peak amplitude of voltage-dependent (I_A, I_{Ca}) and Ca^{2+} -dependent ($I_{\text{K(Ca)}}$) membrane currents.

The increase in the amplitude of CS-elicited generator potentials is, in part, the result of a reduction in both I_A and $I_{\text{K(Ca)}}$. In sensory neurons of conditioned animals, the peak amplitude of I_A is significantly reduced and exhibits more rapid inactivation as compared to controls. However, both the delayed rectifier (I_K) and inward rectifier (I_h) may also play a role in conditioning-dependent enhanced excitability. The application of 5-HT to the isolated nervous system enhances the peak amplitude of I_h and decreases the peak amplitude of I_K and I_A in sensory neurons. In addition, 5-HT reduces the amplitude of $I_{\text{K(Ca)}}$ and decreases I_{Ca} in sensory neurons. The reduction in $I_{\text{K(Ca)}}$ produced by 5-HT is a consequence of the decrease in I_{Ca} by 5-HT rather than a direct effect of 5-HT on $I_{\text{K(Ca)}}$. In addition to intrinsic enhanced excitability in sensory neurons produced by multitrial conditioning, changes in the strength of synaptic connections between identified sensory neurons and interneurons occur following conditioning. The amplitude of the monosynaptic inhibitory postsynaptic potential (IPSP) between the medial type B photoreceptor and medial type A photoreceptor is significantly enhanced in conditioned animals. The second convergence site between the CS and US pathways is the monosynaptic connection between identified sensory neurons and type I interneurons (**Figure 2**). Multitrial conditioning produces facilitation of monosynaptic and complex PSPs in identified type I_e and I_i interneurons. In addition to conditioning-dependent synaptic facilitation, type I interneurons also express intrinsic enhanced excitability with conditioning. Extrinsic current pulses elicit significantly more spikes in type I_e interneurons of conditioned animals as compared to pseudorandom controls. Therefore, long-term memory in *Hermisenda* involves both presynaptic and postsynaptic modifications. The enhanced excitability of sensory neurons, expressed by an increase in both the amplitude of CS-elicited generator potentials and the number of action potentials elicited by the CS, may be a major contributor to changes in the duration and amplitude of CS-elicited complex PSPs and

increased CS-elicited spike activity in type I interneurons of conditioned animals. However, facilitation of the amplitude of the monosynaptic IPSP between sensory neurons and type I_i interneurons, and the monosynaptic EPSP between sensory neurons and type I_e interneurons of conditioned animals may involve both pre- and post-synaptic mechanisms.

Second Messengers

Studies of diverse species have shown that many different second-messenger systems are activated by procedures that produce cellular and synaptic plasticity. Multiple pathways exhibit convergence and divergence when activated and specific second-messenger cascades express both positive and negative regulation by cross talk with other pathways. Therefore, it is unlikely that a single second-messenger supports the formation of memory in the nervous system.

Protein Kinase C

Protein kinase C (PKC) activation contributes to enhanced excitability and synaptic facilitation underlying the formation of short- and long-term memory in *Hermissenda*. PKC is translocated from the cytosol to the membrane in the nervous system of *Hermissenda* by treatment with a phorbol ester (12-O-tetradecanoylphorbol-13-acetate (TPA)). The bath application of a phorbol ester (phorbol 12,13-dibutyrate (PDB)), or injection of PKC into sensory neurons, results in a reduction in the peak amplitude of two K^+ currents contributing to enhanced excitability, I_A and $I_{K,(Ca)}$.

PKC activation contributes to the development of cellular and synaptic modifications supporting both of the CRs that have been examined with Pavlovian conditioning (see **Figure 1**). Nine conditioning trials produce a foot-shortening CR elicited by the CS that is detected within minutes after the last conditioning trial. An *in vitro* conditioning procedure consisting of nine training trials of the CS paired with rotation of the isolated nervous system (US) enhances sensory neurons excitability. The *in vitro* conditioning-dependent change in the excitability of sensory neurons is blocked by the broad-spectrum kinase inhibitor H-7. A second *in vitro* procedure involving pairing the CS with extrinsic current depolarization of the sensory neurons (nominal US) produces enhanced excitability which is also blocked by the preconditioning application of the kinase inhibitors H-7 or sphingosine. One-trial *in vivo* conditioning consisting of pairing the CS with the application of 5-HT to the exposed, but otherwise intact, nervous system produces short-, intermediate-, and long-term enhanced excitability of sensory neurons. The induction of short-term enhanced excitability following one-trial conditioning is blocked by

H-7 and sphingosine, and by the downregulation of PKC produced by pretreatment with TPA. However, while H-7, sphingosine, or the downregulation of PKC by TPA blocks short-term enhanced excitability, the same treatments do not block long-term enhanced excitability produced by one-trial conditioning. The expression of long-term memory produced by one-trial conditioning does not depend upon the induction of short-term memory. Therefore short- and long-term enhanced excitability produced by one-trial *in vivo* conditioning involves independent or parallel processes and differential contributions of second messengers. Consistent with previous studies, the induction of enhanced excitability in sensory neurons produced by five *in vitro* conditioning trials involving the CS paired with depolarizing current stimulation of a statocyst hair cell is blocked by pretreatment with PKC inhibitors. However, the contribution of PKC to the expression of long-term enhanced excitability depends upon the conditioning protocol and the number of conditioning trials. Previously established long-term enhanced excitability produced by one-trial *in vivo* conditioning is not reversed by the broad spectrum kinase inhibitor H-7, or the PKC inhibitors sphingosine or staurosporine. In contrast, long-term enhanced excitability in sensory neurons produced by multitrail Pavlovian conditioning is attenuated by H-7, or sphingosine, suggesting that it is dependent upon persistent kinase activity. Moreover, injection of the PKC inhibitor peptide PKC(19–36) into sensory neurons 24–48 h following multitrail conditioning reverses enhanced excitability within 16 min postinjection, suggesting that either a long-lived activator or a constitutively active kinase contributes to the expression of enhanced excitability. Injection of the control noninhibitory peptide [glu²⁷] PKC(19–36) does not reverse enhanced excitability in the sensory neurons of conditioned animals. PKC activation also contributes to the induction of 5-HT-dependent synaptic facilitation, but persistent PKC activity is not required for the maintenance of long-term synaptic facilitation. Short-term synaptic facilitation of the connection between identified sensory neurons (type B and type A photoreceptors) is produced by the bath application of 5-HT. Injection of the PKC inhibitor peptide PKC(19–36) into medial type B photoreceptors blocks 5-HT-induced short-term synaptic facilitation of the IPSP recorded in the medial type A photoreceptor. However, injection of PKC(19–36) into medial type B photoreceptors following multitrail Pavlovian conditioning does not reduce or reverse established synaptic facilitation of the IPSP recorded in the medial type A photoreceptors.

Extracellular Signal-Regulated Protein Kinase

One trial *in vitro* conditioning of the isolated nervous system involving the CS paired with 5-HT results in the

increased ^{32}P labeling of a protein with an apparent molecular weight consistent with extracellular signal-regulated kinase (ERK). The increased phosphorylation of the protein following one-trial conditioning is blocked by pretreatment with the map kinase kinase (MEK1) inhibitor PD098059. Assays of ERK activity with the brain myelin basic protein as a substrate show greater ERK activity for nervous systems from one-trial *in vitro* conditioned animals as compared to unpaired controls. In addition, western blot analysis of phosphorylated ERK with a phospho ERK antibody showed a significant increase in ERK phosphorylation after one-trial conditioning as compared with unpaired controls. The increased phosphorylation is blocked by pretreatment with a MEK1 inhibitor PD098059. Following a multitrial conditioning procedure consisting of 10–15 trials, nervous systems from conditioned animals exhibited significantly greater ERK phosphorylation as compared with pseudorandom controls. PKC contributes to the 5-HT-dependent activation of the ERK pathway. The phorbol ester TPA increases ERK phosphorylation that is blocked by pretreatment with PKC inhibitors. TPA-dependent ERK phosphorylation is also blocked by the MEK1 inhibitors PD0988059 or U0126. The increased phosphorylation of ERK by 5-HT is attenuated, but not blocked, by pretreatment with the Ca^{2+} chelator 1,2-bis-(*o*-Aminophenoxy)-ethane-N,N,N',N'-tetracetic acid, tetraacetoxy methyl ester (BAPTA-AM) or pretreatment with PKC inhibitors Gö6976 or GF109203X. This suggests that Ca^{2+} -dependent PKC activation contributes to ERK phosphorylation, although a PKC-independent pathway also contributes to 5-HT-dependent ERK phosphorylation.

Ca^{2+}

The sensory neurons (photoreceptors) in the eyes of *Hermisenda* exhibit a spatial segregation of function. Phototransduction takes place in the apical region where the rhabdomere abuts the lens and spike generation occurs near the distal end of the axon close to the location of synapses on the terminal processes. Therefore, the CS (light) and the US (rotation) have spatially separated physiological consequences in photoreceptors. Both light and depolarization increase cytosolic Ca^{2+} levels in photoreceptors. Light activates phospholipase C (PLC) to produce an increase in inositol trisphosphate (IP_3) and diacylglycerol (DAG). IP_3 opens rhabdomeric Na^+ and Ca^{2+} channels which result in a depolarizing generator potential and Ca^{2+} influx. IP_3 also binds to its receptor (IP_3R), which triggers Ca^{2+} release from the endoplasmic reticulum (ER). The Ca^{2+} influx from the rhabdomere and the IP_3R -gated storage compartment can cause Ca^{2+} release from the ryanodine receptor (RyR)-gated compartment. Rotation (US) produces a depolarizing generator potential in identified statocyst hair cells and

elicits a monosynaptic GABAergic IPSP in the sensory neurons. The US is also proposed to activate a polysynaptic serotonergic pathway that projects to the sensory neurons (see Figure 2). Both 5-HT and GABA are linked to a pertussis-toxin sensitive G protein. These proteins can activate second-messenger systems that contribute to memory formation underlying one- and multitrial classical conditioning (see Figure 3). The induction of 5-HT-dependent enhanced excitability in sensory neurons is Ca^{2+} dependent since BAPTA loading before 5-HT application blocks the induction of enhanced excitability. In addition, 5-HT has been shown to modulate several membrane conductances contributing to enhanced excitability in sensory neurons (see ‘Multitrial conditioning’). With regard to the second neurotransmitter in the US pathway, it is proposed that GABA binding to G-protein-coupled receptors on sensory neurons activates phospholipase A₂ (PLA₂) to liberate arachidonic acid (AA) that interacts with Ca^{2+} to synergistically stimulate PKC and create a back-propagating wave of Ca^{2+} released from intracellular stores. When the CS and US are repeatedly paired, the Ca^{2+} influx due to light, IP_3R stores, RyR stores, and voltage-gated Ca^{2+} channels sums together. The large increase in cytosolic Ca^{2+} combined with DAG and AA acts to synergistically activate PKC by translocating it to the membrane. Each pairing of the CS and US has been proposed to incrementally increase the proportion of PKC translocated to the membrane that would contribute to the phosphorylation of K^+ channels.

Long-Term Memory Depends upon Translation and Transcription

Mechanistic differences between short- and long-term enhanced excitability are illustrated by studies showing that the inhibition of protein synthesis during one-trial *in vivo* conditioning blocks long-term enhanced excitability without affecting the induction or expression of short-term enhanced excitability. Moreover, long-term enhanced excitability produced by one-trial conditioning is blocked by the inhibition of mRNA synthesis which does not affect the induction of short-term enhanced excitability. This indicates that long-term memory following one-trial *in vivo* conditioning is dependent upon both translation and transcription.

The time-dependent development of enhanced excitability in sensory neurons following one-trial conditioning is biphasic; enhancement reaches a peak at 3 h postconditioning, decreases toward baseline control levels at 5–6 h, and increases to a plateau at 16–24 h postconditioning. Enhanced excitability following one-trial conditioning also involves an intermediate phase of memory consolidation that requires protein synthesis, but not mRNA synthesis.

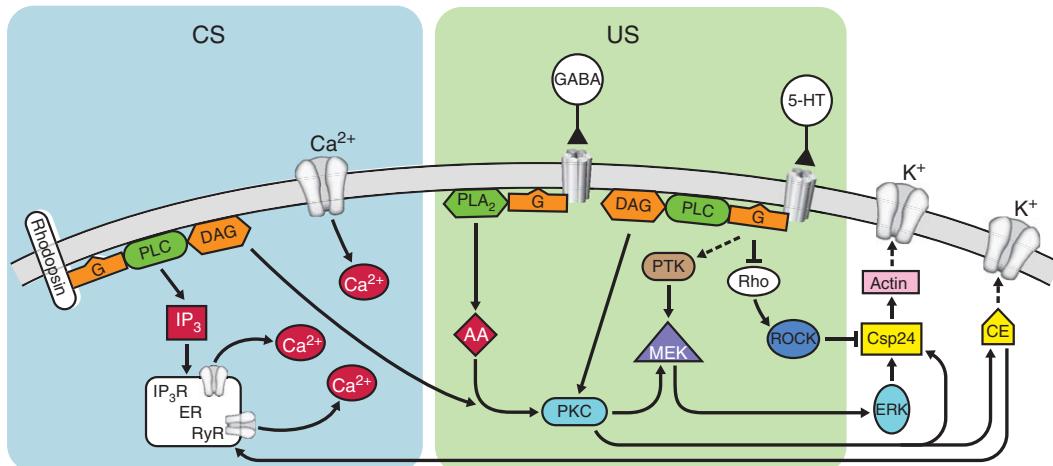

Figure 3 Mechanisms of memory formation produced by Pavlovian conditioning in *Hermisenda*. Acquisition involves the interaction of Ca^{2+} with second-messenger pathways regulated by neurotransmitter release in the US pathway. Light (CS) activates phospholipase C (PLC) to produce and increase inositol triphosphate (IP_3) and diacylglycerol (DAG). The depolarizing generator potential and IP_3 effects on endoplasmic reticulum (ER) result in an increase in intracellular Ca^{2+} . Transmitters in the US pathway bind to G-protein-coupled receptors (G) to activate phospholipase A₂ (PLA₂); increase arachidonic acid (AA); and activate protein kinase C (PKC), nonreceptor protein tyrosine kinases (PTK), extracellular signal-regulated kinase (ERK), and the Rho/ROCK pathway. The PKC pathway can couple directly to Raf that leads to the phosphorylation and activation of MEK and ERK. Two phosphoproteins that have been characterized are regulated by the second-messenger pathways. Csp24 phosphorylation is regulated by PKC, ERK, and the Rho/ROCK pathway. CE phosphorylation is regulated by the PKC pathway. Csp24 binds actin and may support cytoskeletal reorganization underlying the formation of long-term memory in sensory neurons and interneurons. Enhanced excitability is a consequence of the long-term modification of K^+ channels (dashed lines) by CE and Csp24. Adapted with permission from Crow et al. (2008) Molecular mechanisms of associative learning in *Hermisenda*. In: David Sweatt J (ed.) *Molecular Mechanisms of Memory*, vol. 4, pp. 119–132. Oxford: Elsevier, copyright 2008 by Elsevier.

The conditioned foot contraction CR is expressed at a retention interval of 5 min following two or nine conditioning trials. However, nine conditioning trials are required for 90-min retention. *In vivo* incubation of animals with the protein synthesis inhibitor anisomycin during conditioning does not affect the expression of the CR at the 5-min retention interval, but attenuates conditioning assessed at the 90-min interval for the group that received nine conditioning trials. A protocol involving *in vitro* conditioning of the isolated nervous system produces similar results to the effects of anisomycin on conditioned behavior. Two conditioning trials produce a short-term protein synthesis-independent increase in excitability that decrements within 45 min and nine conditioning trials produces a persistent protein synthesis-dependent increase in sensory neuron excitability detected at 90 min. Applying anisomycin 5 min after the ninth conditioning trial does not affect the retention of enhanced excitability.

However, under some experimental conditions, protein synthesis occurring during or shortly after learning is not necessary for the formation of long-term memory. PKC activation produced by a potent agonist of PKC, bryostatin, on days before conditioning leads to the expression of proteins that can support long-term

memory produced by later Pavlovian conditioning. Two conditioning trials typically result in a short-term (~7 min) foot-shortening CR. A 4-h exposure to bryostatin on 2 days preceding conditioning results in a long-term (>1 week) CR produced by two conditioning trials that is not blocked by anisomycin.

Proteins Regulated by Pavlovian Conditioning

Different *in vivo* and *in vitro* conditioning protocols have been used to study proteins regulated by conditioning. Multitrial conditioning produces posttranslational modifications in a number of proteins; however, only a few of the full-length complementary deoxyribonucleic acids (cDNAs) have been cloned and the phosphoproteins fully characterized. Calexcitin (CE) is a GTP- and Ca^{2+} -binding protein found in *Hermisenda* photoreceptors. CE is activated by elevated Ca^{2+} and binds to the RyR to increase cytosolic Ca^{2+} concentrations. CE is phosphorylated by PKC, which results in the translocation of CE to membrane compartments, where it modulates K^+ currents. Phosphorylation of CE also results in binding to the Ca^{2+} -ATPase transporter to increase the rate of Ca^{2+} removal from the cytosol.

Multitrial conditioning increases the phosphorylation of CE, and increases CE in B photoreceptors, specifically in Ca^{2+} sequestering organelles such as ER and within mitochondria and photopigments. The increased CE levels in B photoreceptors of conditioned animals result in increased excitability via K^+ -channel inactivation and internal Ca^{2+} release from ER due to increased CE binding to RyRs.

One- and multitrial conditioning regulate other proteins found in the CS pathway and nervous system. The phosphorylation of CS pathway protein 24 (Csp24) is regulated by Pavlovian conditioning and contributes to the formation of both intermediate- and long-term memory. One- and multitrial conditioning result in a significant increase in the phosphorylation of Csp24 that can be detected at times associated with the intermediate- and long-term phase of memory formation, but not the short-term phase. Modifying the efficacy of the US by reducing the concentration of 5-HT used in one-trial conditioning produces a short-term (<1 h) associative enhancement of sensory neuron excitability that does not result in phosphorylation of Csp24. Csp24 is a cytoskeleton-related protein that is homologous to members of the family of multirepeat β -thymosins that contain multiple actin-binding domains. Actin co-immunoprecipitates with Csp24 and is co-localized with Csp24 in the cytosol of sensory neuron cell bodies. In addition, recombinant Csp24 binds to and sequesters G actin *in vitro*, and phosphorylation of Csp24 by one-trial *in vitro* conditioning increases the co-immunoprecipitation of actin with anti-Csp24. Mass spectrometric analysis of Csp24 has identified phosphorylation sites at Ser-49 and Ser-122. One-trial *in vitro* conditioning results in an increase in the phosphorylation of Ser-122, but not Ser-49 of Csp24. Several signaling pathways regulate Csp24 phosphorylation; thus, it can integrate a number of signals that contribute to cytoskeletal remodeling. Inhibitors of PKC and MEK1 reduce Csp24 phosphorylation produced by *in vitro* conditioning. In addition to PKC and ERK regulation of Csp24, Rho GTPase activity and its downstream target ROCK contribute to the posttranslational regulation Csp24 through an inhibitory pathway. The ROCK inhibitor Y-27632 significantly increases Csp24 phosphorylation and the Rho activator lysophosphatidic acid decreases Csp24 phosphorylation. In addition, the application of 5-HT to the isolated nervous system decreases Rho activity and increases the phosphorylation of Csp24. The inhibition of cyclin-dependent kinase 5 by butyrolactone also reduces Csp24 phosphorylation. The incubation of isolated *Hermisenda* nervous systems with *Csp* antisense oligonucleotides decreases Csp24 expression, and treatment with antisense oligonucleotides before one-trial *in vitro* conditioning blocks intermediate-term enhanced excitability without affecting the induction of short-term

enhanced excitability. Since Csp24 is associated with the actin cytoskeleton, its regulation by conditioning may influence K^+ -channel activity by the spatial and temporal control of actin dynamics. One-trial *in vitro* conditioning of isolated sensory neurons produces a significant reduction in the amplitude of I_A and a depolarized shift in the steady-state activation curve of I_A without altering the inactivation curve. The conditioning-dependent changes in I_A are blocked by incubation of the isolated sensory neurons with *Csp* antisense oligonucleotide. Therefore, Csp24 contributes to the regulation of voltage-gated channels associated with the development of intrinsic enhanced excitability underlying Pavlovian conditioning in *Hermisenda*.

Overview and Discussion

Pavlovian conditioning in *Hermisenda* results in both intrinsic enhanced cellular excitability and modifications in the strength of synaptic connections at multiple sites within the neural circuit responsible for the generation of the CR. The first site of storage for the memory of the associate experience is in the sensory neurons of the CS pathway. The modifications in the sensory neurons are spatially segregated. There are alterations in the properties of K^+ channels in the soma that result in an enhancement of the amplitude of the CS-elicited generator potential, a change in the biophysical properties of channels in the spike-generating zone that results in a decrease in spike-frequency accommodation, and a concomitant enhancement of intrinsic excitability. In addition, changes in synaptic strength result in facilitation of the monosynaptic connections between identified sensory neurons (type B and type A photoreceptors) and between identified sensory neurons and interneurons. Memory produced by Pavlovian conditioning involves both pre- and postsynaptic mechanisms since the second site of memory formation and storage is in type I interneurons.

Conventional mechanistic views of memory formation have proposed that (1) the short-term phase involves posttranslational modifications of existing cellular proteins; (2) the intermediate phase is dependent on translation, but not transcription; and (3) the long-term phase is dependent upon protein synthesis, gene transcription, and the synthesis of new mRNA. Collectively, short-, intermediate-, and long-term memory produced by Pavlovian conditioning in *Hermisenda* involves the activation of several second-messenger cascades, post-translational modification of proteins, the synthesis of proteins, transcription, and the synthesis of mRNA. However, increased phosphorylation of proteins associated with the different phases of memory may occur several hours or 24 h postconditioning. This suggests that

posttranslational modifications may contribute to the maintenance or expression of translation-transcription-dependent long-term memory. The activation of several signaling cascades that express cross talk and convergent interactions contributes to all phases of memory formation. Second-messenger pathways may exhibit differential contributions to memory formation involving enhanced excitability and changes in the strength of synaptic connections. Therefore, the mechanism(s) for intrinsic enhanced excitability may be different from the mechanisms supporting modifications in the strength of synaptic connections.

Two proteins that have been fully characterized, and are regulated by Pavlovian conditioning, are CE and Csp24. The binding of CE to the plasma membrane decreases K⁺ conductances and releases Ca²⁺ from internal stores. Csp24 phosphorylation is regulated by one and multi-trial conditioning, is associated with actin, and contributes to long-term intrinsic enhanced excitability produced by the depolarized shift in the steady-state activation of I_A and the concomitant reduction in peak I_A. Therefore, the expression of Csp24 is important in both intermediate- and long-term memory involving intrinsic enhanced excitability.

The analysis of mechanisms of memory in *Hermissenda* raises a number of questions that are important for an understanding of memory produced by Pavlovian conditioning. How are posttranslational modifications in proteins supporting short-term memory transformed into long-term memory involving both intrinsic enhanced excitability and changes in the strength of synaptic connections? What are the contributions of pre- and postsynaptic modifications to short-, intermediate-, and long-term memory? How does the regulation of CE and Csp24 by conditioning result in an alteration in the properties of K⁺ channels in excitable membranes? Finally, how are modifications in intrinsic excitability and synaptic strength at several loci integrated within a neural circuit to reconfigure the circuit and support the generation of the CR?

Glossary

Anisomycin (ANI) – A protein-synthesis inhibitor that has been widely used in studies of learning and memory. Anisomycin prevents translation of new protein by interfering with ribosomal subunits. This drug also has several important side effects that are not directly related to inhibition of translation.

Consolidation – It generally refers to the time-dependent process through which new memories become increasingly resistant to disruption. At the cellular level, consolidation describes the development of stable synaptic plasticity which persists indefinitely in the absence of stimulation. At the systems level, consolidation can refer to the time-limited role of certain structures such as the hippocampus as a memory ‘matures.’

Immediate early gene (IEG) – These genes are rapidly activated by stimulation and contribute to multiple cellular responses including transcriptional regulation during the formation of memory. Because they are often strongly expressed in active neurons, they can also serve as a cellular marker of recent neural activity.

Reconsolidation – When a stable long-term memory is recalled it will sometimes require *de novo* protein synthesis to persist normally after retrieval. Evidence for reconsolidation comes from the observation that post-recall administration of protein-synthesis inhibitors can selectively disrupt memory at subsequent tests.

Transcription – The process through which genetic information contained in DNA in a cell’s nucleus is copied onto a complementary strand of messenger RNA (mRNA). The mRNA strands contain the information required to make a specific protein.

Translation – The process through which amino acids are assembled into proteins. Translation occurs in the cytoplasm within ribosomes and is controlled by information contained in mRNA.

system. While this conclusion is logical, the huge number of possible underlying cellular and molecular mechanisms of change provide a real challenge to any complete understanding. Consequently, researchers have tended to look for classes of cellular events that might serve as mechanisms for synaptic plasticity and memory storage.

As our understanding of how genetic information is encoded and used within cells increased during the mid-twentieth century, the idea that newly synthesized protein might be important for forming specific ‘memory traces’ gained currency. Protein synthesis triggered by experience could provide new raw material or modify the regulation of a number of processes that determine how the functional connections between neurons can be changed.

Early studies using systemic injections of drugs that interfere with the synthesis of protein – mostly by preventing its translation from messenger RNA – supported the importance of new protein in memory formation. Generally speaking, applying broad-spectrum translation inhibitors like cycloheximide or anisomycin (ANI) around the time of training would result in severely impaired behavioral retention during a drug-free test of long-term memory. Furthermore, memory impairments were sometimes seen even when the drug was given immediately after the training experience making it much less likely that sensory/motor impairments or other unintended consequences of drug administration were responsible for the apparent effects on memory. Importantly, the effects of protein-synthesis inhibitors tended to develop only when testing of the memory was temporally separated from the training session. These drugs tended not to affect short-term forms of plasticity.

These early studies on protein synthesis and memory were not without significant confounds and conflicting results. Not surprisingly, given that protein synthesis is such a critical process for many aspects in cell biology, injections of large systemic doses of translation inhibitors would be expected to have multiple important effects on an organism beyond any direct influence on activity-dependent synaptic plasticity. Nonetheless, the overall conclusion seemed to be that *de novo* protein synthesis is important for new learning to occur.

Background and Early Studies

Scientists interested in understanding the biological substrates of memory have traditionally understood that the formation of long-lasting memories must somehow involve modification of the physical properties of the nervous

Current Working Model

More recent experimental work in the neurobiology of memory has continued to support the basic idea that *de novo* protein synthesis is a required step in the formation

of new memories. The thinking here, as well as the general approach used to investigate these issues in whole animal behavioral studies, relies heavily on pioneering work in reduced preparations like the *Aplysia* abdominal ganglion and hippocampal slice long-term potentiation (LTP) showing that short- and long-term plasticity can be separated based on the requirement for macromolecular synthesis. A very general framework linking the exposure of an organism to some environmental event to the protein-synthesis-dependent modification of synapses is given in **Figure 1**. The event to be remembered generates increased activity within populations of cells within neural circuits appropriate to the particular stimuli being used. This increased neural activity gives rise to alterations in intracellular calcium ion (Ca^{2+}) and initiation of several classes of Ca^{2+} -dependent signaling mechanisms. Some of these result in posttranslational modifications responsible for short-term changes in synaptic excitability while other consequences of elevated Ca^{2+} include the activation of transcription factors which promote the synthesis of new messenger RNA (mRNA) which interacts with ribosomal proteins outside the nucleus to enable the translation of new target protein. These new proteins are thought to make a critical contribution to synaptic plasticity by functioning as structural proteins, transcription factors, biosynthetic enzymes, ion channels, neurotransmitter receptors, etc. The creation and stabilization of memory is thus a time-dependent process that relies on a series of related intracellular events. Preventing any step in the sequence would be expected to impact the behavioral evidence for memory.

It is also important to note that protein synthesis is always occurring, even in the absence of the type of stimulation that forms a new memory. Proteins are constantly being ‘turned over’ – broken down and replaced – at synapses and elsewhere in the cell. Many manipulations applied to the question of protein synthesis and memory can affect constitutive as well as learning-evoked protein expression.

Memory and Alterations in Gene Expression

One general prediction of this model is that when animals are in the process of forming a new memory, one should be able to find new protein within appropriate brain areas. More specifically, the identity and/or quantity of these gene products should specifically relate to the learning process and not be similar in animals exposed to similar stimuli in control conditions that do not result in learning. A large number of studies conducted over the last several years have supported this basic idea.

The first studies of this type tended to focus on immediate early genes (IEGs) whose expression had previously been shown to be rapidly and strongly induced by seizure activity or intense electrical stimulation. Many IEGs function as transcriptional regulators while others can have more direct effects on plasticity through interactions with other proteins that regulate synaptic physiology (such as glutamate receptors). Other IEGs have a less well-described role in learning or plasticity

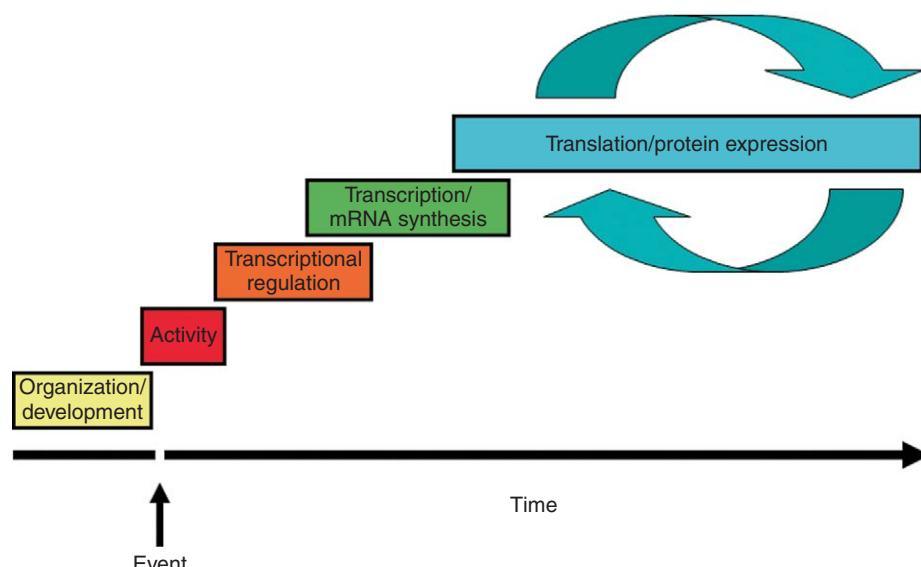

Figure 1 The formation of memory is a time-dependent process that includes multiple steps. Short-term memory and neural plasticity can rely on rapidly induced activity-dependent posttranslational modifications at synapses. Long-term memory, on the other hand, normally requires the transcription of new mRNA and the translation of these messages into new protein. Preventing either transcription or translation often results in a selective deficit in long-term memory.

per se but are often still useful as a cellular marker of neural activity.

Zif268/Egr1 is a mammalian zinc-finger transcription factor that regulates the expression of several groups of target genes and has been closely linked to learning and memory in rodents. Exposing rats or mice to standard behavioral tasks in which new memory is formed often results in increased levels of Zif268 mRNA as well as increased expression of the protein itself within brain regions known to be important for the particular task being used (e.g., the hippocampus for spatial memory or the amygdala for Pavlovian fear conditioning). Importantly, if one prevents the translation of Zif268 protein by introducing antisense oligonucleotides to critical brain areas around the time of learning this can disrupt behavioral performance in a manner consistent with a critical role for Zif-regulated proteins in memory formation. Similarly, mice lacking the Zif268 gene are selectively impaired on tests of long-term memory while general behavioral competence and tests of short-term memory appear intact. Complementary data from *in vivo* LTP studies in the hippocampus show that Zif268 may be critical for long-term (i.e., days) changes in synaptic efficacy but not baseline synaptic transmission or for short-term changes thought to require posttranslational modifications of existing proteins.

Another IEG that is closely linked to memory is the activity-regulated cytoskeletal associated protein (Arc/Arg3.1). Arc mRNA is very rapidly expressed in hippocampal neurons around the time animals are learning. A series of elegant experiments conducted by John Guzowski and his colleagues showed that Arc mRNA is induced by behavioral experience (e.g., exposure to a novel environment) in the cell's nucleus almost immediately, but after about 20 min is largely localized in the surrounding cytoplasm. This pattern of mRNA expression allowed Guzowski to identify individual hippocampal neurons that were active at two different time points in the same animal. Subsequent work by several groups has focused on how Arc protein resulting from this mRNA contributes to long-term neural plasticity and memory.

At the protein level, Arc expression also changes in a time-dependent manner in the hippocampus after learning. **Figure 2** shows the results of an experiment in which rats were exposed to a novel environment that was paired with mild shock. Animals will remember this experience and behave accordingly when tested the next day, and prior studies have shown that plasticity in hippocampal neurons is required for this form of memory. The amount of Arc protein in the dorsal hippocampus increases during the period in which the memory is consolidated and peaks at approximately 90 min after training. Other studies have shown that preventing the translation of Arc mRNA can disrupt the consolidation of some forms of memory and

that Arc protein can play an important role in regulating the function of α -amino-3-hydroxy-5-methyl-4-isoxazole-propionate (AMPA)-type glutamate receptors at synapses.

A number of other converging lines of evidence support the idea that new protein is being produced in neurons during the process of forming new long-term memories. The transcription factor cAMP-dependent-element binding protein (CREB) influences the expression of multiple genes related to neural plasticity. Behavioral training in several different memory tasks results in the time-dependent phosphorylation of CREB. At the level of translational control, recent evidence indicates that learning results in the activation of various enzymes that facilitate the synthesis of new protein from existing mRNAs. One example of this is the mammalian target of rapamycin (mTOR) kinase which, when activated, increases the rate at which new proteins are translated at ribosomes. **Figure 3** shows the phosphorylation of p70s6k, a downstream target of mTOR, in rat lateral amygdala neurons 1 h after training in a fear-conditioning experiment. Animals given a control treatment that did not result in new learning did not show increased translation of new protein.

Current technology offers many options for the quantification and localization of gene-expression changes related to learning and memory. One major conceptual advance has been the increased understanding that altered protein synthesis – and by inference altered synaptic plasticity – can occur throughout multiple brain regions around the time of learning even when a restricted number of structures may be considered essential for learning or behavioral performance to occur. Of course, our ability to observe changes in gene expression as they consistently co-vary with learning tells us little about the degree to which these proteins are actually required for the formation of new memories.

Manipulating Protein Synthesis *in vivo*

There are a variety of interventional strategies that more directly address the issue of whether or not a given protein or regulatory pathway is required for normal learning to occur. Transgenic approaches allow for the conditional deletion of specific genes or the targeted overexpression of selected gene products. At the transcriptional level, the literature on CREB contains numerous examples of converging approaches with multiple species and behavioral endpoints all supporting a general role for this molecule in the formation of long-term memory. While other similar examples of the systematic analysis of single molecules exist, scientists concerned with the more general question of whether or

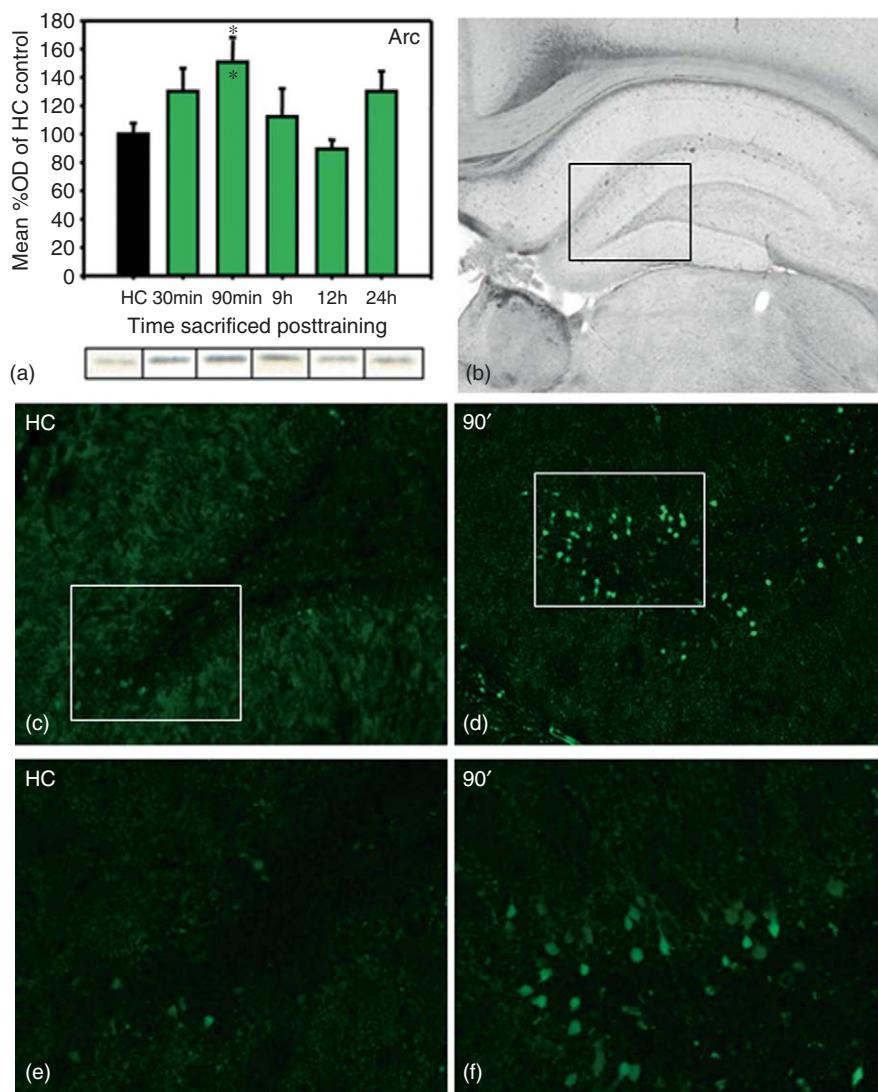

Figure 2 Immediate early genes (IEGs) were some of the first proteins to be studied during memory formation because they are rapidly induced by training and expressed at fairly high levels within key brain regions. In this experiment rats were trained by pairing a distinctive environment with shock and levels of the IEG Arc were measured. (a) Arc-protein levels in the hippocampus as measured by Western blots peaked at 90 min after training. (b–f) Arc-positive cell bodies were seen in many regions of the hippocampus including the dentate gyrus. HC = homecage control; 90' = tissue processed 90 min after training. Data are taken from a recent study by Mary Lonergan.

not new memory requires new protein have tended to employ more general manipulations.

A trend in recent behavioral studies has been to apply broad-spectrum macromolecular synthesis-inhibitors locally to target brain areas that are selected based on systems-level analysis within a particular learning paradigm. These drugs may target transcription, interfering with the synthesis of mRNA at one of several steps in the process, or may target protein translation from intact message. Using this general approach, a very large number of papers have been published all lending support to the idea that new protein is important for new learning. This conclusion appears to hold for multiple vertebrate

and invertebrate species as well as for multiple forms of memory including taste aversion, eye blink conditioning, spatial learning, fear conditioning, avoidance learning, conditioned drug seeking, and others.

Of course, using a rather nonspecific translation inhibitor like ANI (probably the most popular choice in recent studies on general requirements for protein synthesis) leaves one open to many of the same criticisms directed at the protein-synthesis-inhibition studies of the 1960s and 1970s. At doses that block memory, ANI can reduce local protein synthesis by as much as 70%. Even when small volumes are injected into restricted brain sites this level of suppression is likely to produce

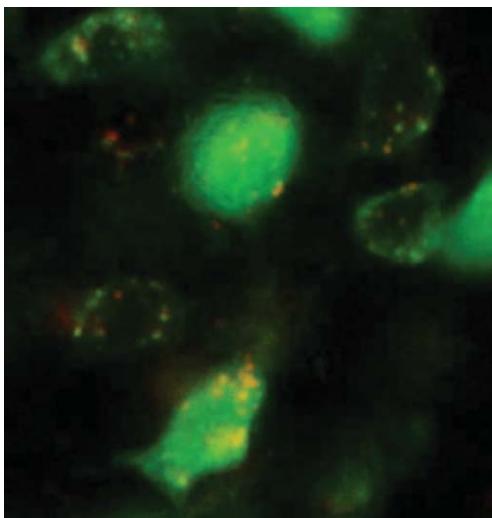

Figure 3 mTOR-dependent translation of new proteins occurs in amygdalar neurons during the period when memory is being formed. This photomicrograph shows cells in the lateral nucleus of the amygdala of a rat. The animal's brain was removed shortly after training and processed for immunohistochemistry. Neurons are shown in green through staining with the DNA-binding protein NeuN. Red immunofluorescence reflects the phosphorylation of p70s6k, a downstream target of mTOR that is activated during protein translation.

effects beyond those directly related to memory formation. Furthermore, ANI by itself will tend to ‘superinduce’ or dramatically increase the level of expression of certain IEGs as well as promote phosphorylation of at least one major protein kinase known to be involved in neural plasticity. Recently, Gold and colleagues have quantified some rather dramatic alterations in local catecholamine concentration following the application of ANI and once again called into question specific conclusions about protein synthesis made when using this drug.

While ANI may be an imperfect tool, the conclusions reached by studies that have used it may still have some merit. One alternate approach is to use inhibitors that are linked to more specific translational control pathways and that are likely to have fewer nonspecific effects when compared to ANI. Recent studies from the author's laboratory have used rapamycin (RAP) which selectively targets the mammalian target of rapamycin (mTOR) pathway. RAP prevents the phosphorylation of mTOR and its downstream targets which results in suppressed translation of some, but not all, mRNAs. **Figure 4** depicts some of the results from a recent study by Parsons and colleagues showing that RAP applied to the amygdala at a dose that results in significant memory impairment produced an ~10% reduction in local protein synthesis. For comparison, the commonly used behaviorally effective dose of ANI produced a nearly 60% decrease in protein synthesis. This observation suggests that only a small fraction of the proteins affected by ANI are actually

related to the formation of memory. It also provides a slightly more subtle demonstration of the importance of translational control and *de novo* protein synthesis in new learning.

Protein Synthesis and Memory Stability

One of the more exciting recent lines of work on protein synthesis and memory has grown out of some observations made nearly 10 years ago by Karim Nader and colleagues. They showed that ANI was effective at disrupting the storage of a memory not only when the drug was given after the initial learning, but also when it was given following the retrieval of the memory. This effect, which they termed ‘reconsolidation,’ implied that new protein synthesis is required every time a memory is brought from storage into an active state. It also suggests that some of the same mechanisms used to form a memory are also used to maintain the stability of that memory over time.

A number of studies have since replicated Nader's observation and added to our understanding of how the cellular events that follow the use or retrieval of a memory correspond to those that participate in its original formation and storage. Many of the same pathways and regulatory processes appear to be involved. It is important to note that protein synthesis at the time of retrieval does not appear to be required for the behavioral expression of a previously established memory, but rather relates to a process by which that memory is preserved and stabilized after use. Theoretically, the ‘reconsolidation’ of memory provides a mechanism through which information can be updated and new elements incorporated into particular representations.

Figure 5 illustrates how retrieval of a specific memory triggers the translation of new protein in hippocampal neurons. In this study conducted by Gafford and colleagues rats were trained to recognize a distinctive environment that was paired with shock. After this memory had been established, the animals were either returned to the original environment (where they showed behavioral evidence of retention) or to a different environment not related to shock (where they did not show any memory). Animals that retrieved and expressed the memory showed significantly higher levels of phosphorylation of two downstream targets of mTOR: p70s6k and 4E-BP1. These findings indicate that memory retrieval activated a period of protein translation that was similar in many respects to that normally seen after original training. These retrieval-induced proteins are presumably what is affected by ANI or other manipulations in reconsolidation experiments.

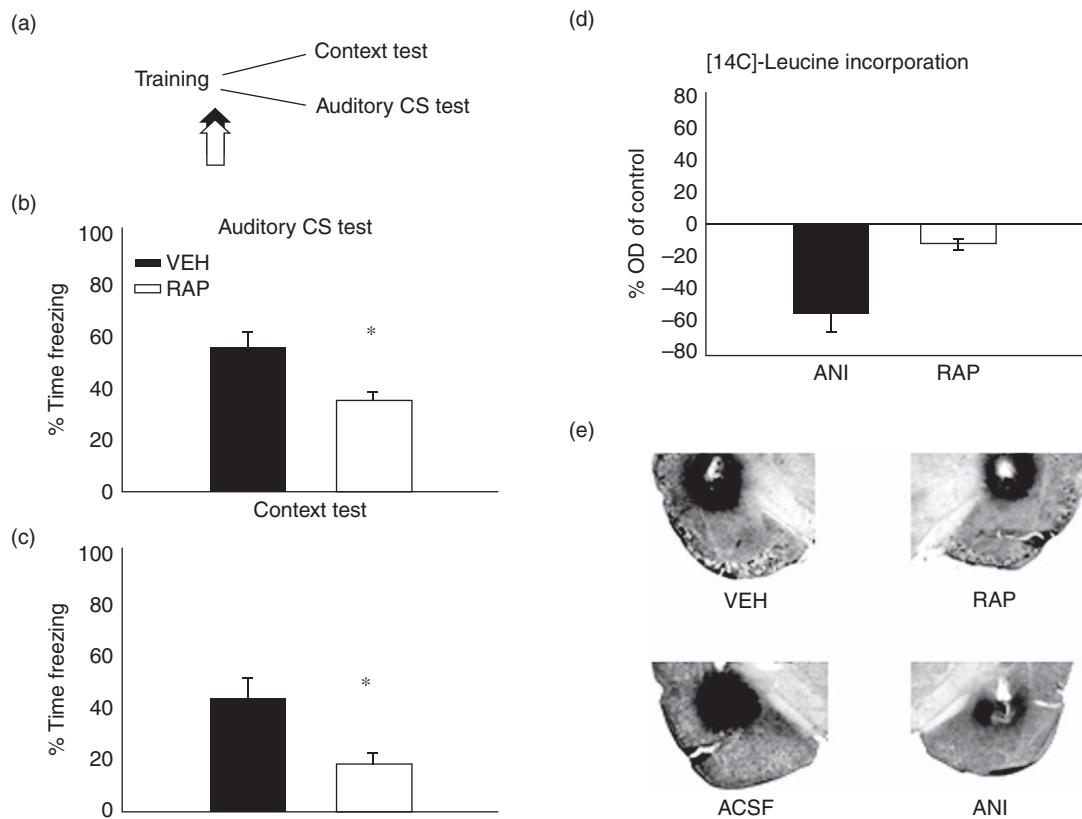

Figure 4 While translation inhibitors like anisomycin can produce large decreases in local protein synthesis along with several unintended effects, other related approaches are less affected by these limitations. Rapamycin (RAP) is a selective inhibitor of protein translation. (a) RAP was injected into the amygdala immediately after auditory fear conditioning. One day later, RAP-treated animals showed impaired memory for the (b) tone paired with shock as well as for the (c) environment in which training took place. (d) Even though RAP was effective in disrupting memory for the training experience, injections into the amygdala result in a relatively modest decrease in local protein synthesis when compared to ANI. (e) Three-dimensional reconstructions of the area using autoradiographs made with [¹⁴C]-leucine give an estimate of the area in and around the amygdala that is affected. Data are redrawn from Parsons RG, Gafford GM, and Helmstetter FJ (2006) Translational control via the mammalian target of rapamycin pathway is critical for the formation and stability of long-term fear memory in amygdala neurons. *Journal of Neuroscience*, 26:12977–12983.

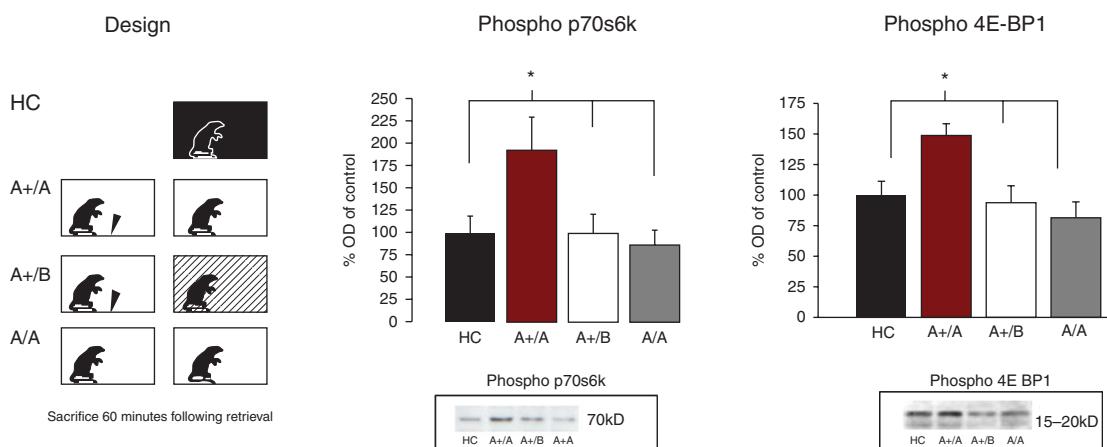

Figure 5 The retrieval of an established memory triggers a new wave of protein synthesis. Rats trained to associate shock with a distinctive environment were re-exposed to that environment or to one of several control conditions. Increased protein translation, as indicated by increased phosphorylation of p70s6k and 4E-BP1, was only seen in the group in which the original memory was retrieved. These data add support to the idea that protein synthesis is required for multiple aspects of memory encoding and maintenance. Data are taken from a recent study by Georgette Gafford.

Glossary

Acute hippocampal slice preparation – An experimental preparation wherein the living hippocampus is rapidly removed from the brain and sectioned perpendicular to its long axis to create 300–400- μ m thick slices containing a great proportion of the intrinsic hippocampal circuitry within the plane of the slice. The slices are maintained in a heated, oxygenated, artificial cerebral spinal fluid bath and can be used for electrophysiological analysis of synaptic responses for hours after preparation. Such slices can subsequently be harvested for biochemical, immunocytochemical, or ultrastructural analyses of effects of stimulation or drug treatment.

Theta burst stimulation (TBS) – Patterned electrical stimulation of axonal systems designed to simulate the naturally occurring hippocampal theta rhythm. The conventionally used pattern of theta burst stimulation involves application of a train of 10 theta bursts with each burst containing four stimulation pulses applied at 100 Hz and a 200-ms interburst interval. TBS is particularly effective for inducing enduring NMDA-receptor-dependent long-term potentiation (LTP) within the hippocampus.

Theta rhythm – A spontaneous 4–8-Hz rhythm of synchronous neuronal firing typically recorded from the hippocampus, and the associated limbic regions, in freely moving animals during particular behaviors (e.g., exploratory behavior). The appearance of theta rhythm firing during what are considered learning episodes raised interest in the possibility that this firing frequency was significant for cellular mechanisms of learning and memory. Although the source of the theta rhythm generator has been a topic of debate, recent studies of hippocampal slices have shown that epochs of theta rhythm activity can arise from intrinsic activities within the hippocampus.

occurred in the nineteenth century. In his 1882 analysis of memory disorders, Ribot had a very specific argument for this conclusion and Cajal, writing at the beginning of the twentieth century, ascribed the hypothesis to earlier researchers. The arguments, then, as now, center on the immense capacity of memory: How else could the brain encode and organize the vast amount of information accumulated during even a single day other than by changing some small fraction of the trillions of connections between cortical neurons?

This point was appreciated by several prominent investigators in the middle part of the last century who used some of the better understood synaptic systems of the time (e.g., spinal cord and neuromuscular junction) to ask if protracted periods of afferent stimulation cause lasting changes in postsynaptic responses. The early results, while often intriguing, failed to meet the basic requirements of a memory mechanism. Modification of this approach by Thompson and Spencer in the 1960s resulted in the discovery that synapses in the more evolutionarily conserved parts of the nervous system do in fact possess the necessary and sufficient machinery for generating two fundamental forms of learning. Depending on the temporal patterns used, they found that repetitive presentation of a stimulus to animals results in either a gradual enhancement (sensitization) or reduction (habituation) of physiological and behavioral responses. Detailed analyses led to an extended list of features that define these opposing forms of learning and to evidence that these items are present in the synapses related to the production of the behaviors. Independent studies by Kandel and co-workers showed that invertebrate synapses also exhibit phenomena that are isomorphic with habituation and sensitization. These landmark studies, and the large literature that grew around them, provided the first descriptions of synaptic memory mechanisms.

Synaptic parallels to more elaborate forms of memory were revealed suddenly with the discovery by Bliss and Lomo of hippocampal long-term potentiation (LTP). Following on the lines of older tradition of using repetitive stimulation as a tool for engaging synaptic plasticity, these investigators found that short (20 s) trains of high-frequency afferent stimulation induced a large, and remarkably stable, enhancement of excitatory postsynaptic potentials (EPSPs) in the cortical inputs to the dentate gyrus. LTP at its introduction thus satisfied two very demanding requirements of memory: Rapid onset and extreme persistence.

Introduction: Memory Research Turns Back to the Synapse

The idea that memory is encoded by changes in the strength of synaptic connections between cortical neurons is one result of the explosion of scientific information that

Evolution of LTP research, and the search for the synaptic substrates of memory, was greatly accelerated by the introduction of the acute hippocampal slice technique in the early 1970s. This *in vitro* preparation has many advantages (e.g., ability to directly apply drugs/reagents and to visualize cell layers and afferent lamina) that vastly simplifies analysis of the cellular processes underlying the potentiation effect. Slice research from a large number of laboratories gradually led to something like a standard model for LTP and with it the detailed proposals about the synaptic chemistry of commonplace forms of memory. This material constitutes the subject of the present discussion. The size of the pertinent literature makes it necessary to restrict the discussion to events occurring during the first hour following the induction of LTP, a period during which major steps in the initial consolidation of potentiation, and memory, take place.

Induction of LTP and the Encoding of Memory

LTP is Induced by Theta Activity

LTP can be seen as involving sequential stages of induction, expression, and stabilization. Induction is probably the best understood, and least controversial, phase in the sequence leading to stable potentiation. A high-frequency burst of afferent activity produces a profound depolarization of postsynaptic spines via activation of synaptic AMPA-type glutamate receptors and spatiotemporal summation of EPSPs. Depolarization of sufficient degree and duration unblocks voltage-sensitive *N*-methyl-D-aspartic acid (NMDA)-type glutamate receptors, which then pass calcium into the spine. Calcium, acting with other factors to be discussed, then sets in motion the steps that lead to LTP expression and consolidation.

A more precise description of the triggering events for LTP became available after the discovery that the induction process has a deep relationship with theta (5 Hz)-patterned neuronal activity that naturally occurs during learning and other behaviors. Specifically, delivery of a short train of high-frequency stimulation bursts (4 pulses per 30-ms burst) induces LTP when the bursts are separated by the 200-ms period of the theta wave (theta burst stimulation, TBS; see **Figure 1(a)**). Deviations from this pattern reduce the amount of potentiation. The peculiar efficiency of theta bursts has been traced to the feedforward GABAergic inhibition that accompanies excitatory (glutamatergic) transmission in the cortical telencephalon. Afferent fibers not only innervate principal cells (e.g., cortical and hippocampal pyramidal neurons) but, via collateral branches, contact a broad array of inhibitory, GABAergic interneurons with axonal projections to the same targets. Input activation, as expected from these

anatomical arrangements, generates a biphasic response consisting of an EPSP followed quickly by an inhibitory postsynaptic potential (IPSP) that shunts the excitatory currents. The latter event prevents a single theta burst from producing the depolarization needed to engage NMDA receptors. However, a second burst following at 200 ms results in the normal depolarizing drive but in much reduced inhibition and so leads to greater depolarization (**Figure 1(b)**) and a measurable influx of current through the NMDA receptors. This occurs because the interneuron terminals enter a refractory period, mediated by presynaptic autoreceptors, after being activated by the first burst, and this refractory state reaches its maximum at approximately 200 ms.

In all, the temporal parameters of IPSP suppression, along with other features, generate greater postsynaptic depolarization than that obtained with a continuous 100-Hz train (**Figure 2(b)**) and tune the theta burst pattern so as to maximize NMDA-receptor responses. These observations show how ubiquitous local network designs and a battery of physiological (and biophysical) properties act in concert over a 1-s period to initiate lasting changes to synapses. Beyond this, they make a strong case for the idea that LTP is a naturally occurring phenomenon – an argument that is further strengthened by studies showing that theta rhythm bursting occurs during learning.

Induction and Organizational Aspects of Learning

The above results provided some of the first insights derived from mechanisms of LTP into the cellular and neurochemical mechanisms of learning and memory. It has long been recognized that electrographic 4–8 Hz theta rhythms are intimately connected to learning, a relationship that is usually assumed to reflect a need for synchronizing brain contents that are about to be associated. This of course does not explain the particulars of the rhythm – its period, duration of bouts, etc. – or the import of the short bursts of neuronal firing that ride upon it. From studies of LTP we now see that all of these features are uniquely associated with the engagement of peculiar network properties and synaptic mechanisms that collectively produce time-locked calcium pulses in dendritic spines. The theta rhythm–LTP connection also helps explain the powerful role of temporal contiguity in learning. In the simplest sense, inputs arriving on successive peaks of the rhythm have a greater chance of being associated via LTP than those spaces apart by other intervals. Contiguity relationships based on subtler aspects of the induction process have also been found. One experiment entailed asynchronous theta burst stimulation of three afferents (#1, #2, and #3) to the same neuron with the drive from each, by itself, being too

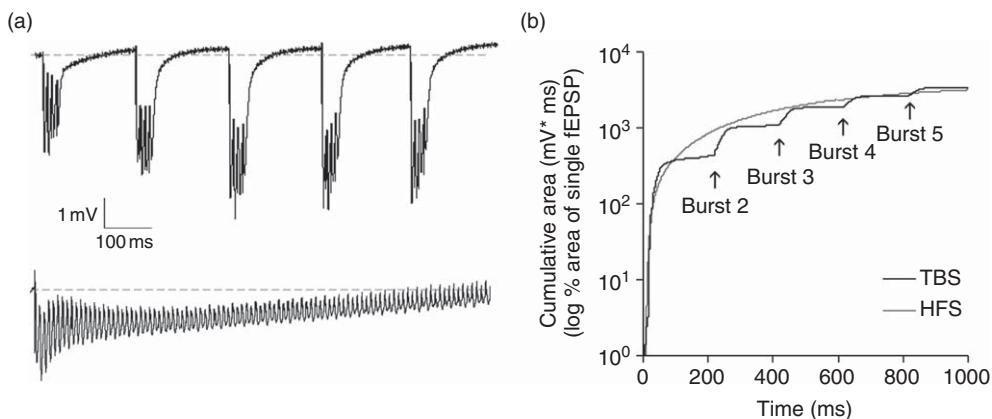

Figure 1 Theta burst stimulation is particularly effective for eliciting postsynaptic depolarization. Recordings of field excitatory postsynaptic potentials (fEPSPs) elicited by stimulation of Schaffer collateral-commissural afferents to field CA1 (adult rat hippocampal slices) illustrate differences in the magnitude of responses generated by the same period of stimulation applied as theta bursts (4-pulse 100-Hz bursts separated by 200 ms) or as a continuous 100-Hz high-frequency stimulation (HFS) train. Panel (a) shows representative responses to 1-s TBS (upper trace) and HFS (lower trace). With TBS the magnitude of the responses builds after the first burst, peaking at burst 3 or 4. In contrast, with HFS there is an initial facilitation (through 30–40 ms) followed by depression for the remainder of the train. (b) To assess the overall depolarization generated by the different forms of stimulation, the mean cumulative area under the response curve was plotted for four sets of responses to 1 s of TBS (black line) and HFS (gray line). Values were normalized to the area of a single test pulse that preceded the train and plotted as log values. Contributions of each theta burst are evident in the TBS curve (burst 2–5). As shown, despite the HFS train containing 5 times the number of pulses, the cumulative area, denoting the magnitude of the postsynaptic response, is nearly identical.

weak (i.e., engaging too few synapses) to trigger the depolarization needed to activate NMDA receptors and set the LTP-induction process in motion. However, serial activation of the inputs (#1>#2>#3) with bursts resulted in robust potentiation in the first member of the sequence (input #1) but not in the third member (input #3) when each episode of sequential activation was separated by the period of the theta wave. Thus, the order in which information arrives during theta activity dictates the strength for encoding the individual elements in the sequence.

Biologically realistic computer simulations confirm the suspicion that the order phenomenon just described results in a system that can learn to recognize complex cues according to the sequence of the elements within the cue (e.g., the words ‘raw’ and ‘war’); they also show that such a system has remarkable storage capacity. More broadly, the theta rhythm–LTP findings constitute the first steps toward the identification of synaptic learning rules that may determine how and why the cortical telencephalon organizes its representations of the world in the way that it does. This, of course, is not the end of the story. The vast networks in associational cortex, with their apparent lack of detailed topographic anatomy, are likely to represent a programmable system that allows the brain to escape from narrow synaptic rules. However, one suspects that even here, at the remote frontiers of neuroscience, LTP-induction mechanisms will influence the efficacy and organization of information storage.

Expression of LTP and Memory

Expression is Largely Postsynaptic

Theta burst stimulation is followed within 5–10 s by a marked increase in the size of EPSPs that is restricted to stimulated connections (i.e., it is synapse specific). This indicates that some form of potentiation is expressed almost immediately after the induction events, but it is unclear if this is supported by the same postsynaptic processes responsible for LTP. Indeed, the critically important question of when LTP expression first occurs remains a little-studied issue. A cleverly designed experiment by Gustafsson and colleagues led to the conclusion that the changes underlying LTP expression begin within seconds of induction and are fully realized 30 s later. Such extremely rapid expression would place a strong constraint on hypotheses about the nature of the modification that actually enhances synaptic currents. However, as discussed below, there are reasons to suspect that the synapse passes through multiple stages before a final stage of LTP expression is realized.

The discovery that NMDA receptors and increases in spine calcium content are required for the induction of LTP led to the early assumption that LTP expression also involves postsynaptic changes. Striking support for this came from studies showing that, within hippocampus, robust LTP is associated with changes in the magnitude of those components of the postsynaptic response mediated by the AMPA class, but not the NMDA class, glutamate receptors. In the absence of a set of unlikely assumptions, it is

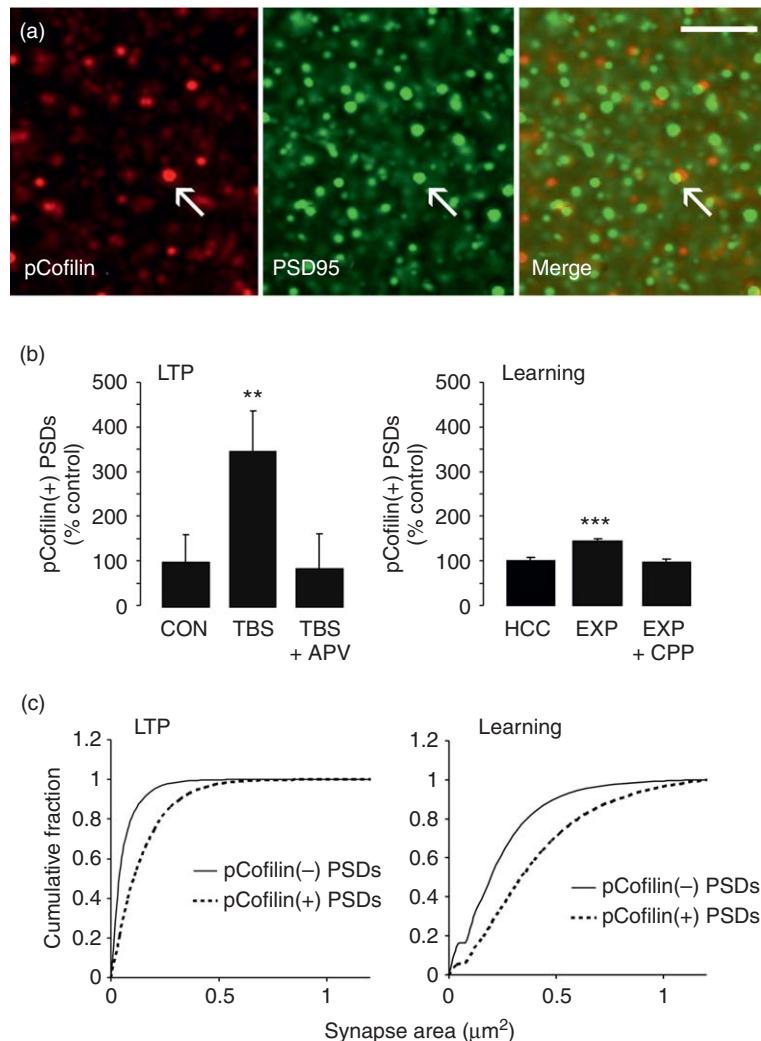

Figure 2 LTP and learning induce spine cytoskeletal remodeling and changes in synapse size. Immunofluorescent labeling for the actin regulatory protein cofilin and the postsynaptic density marker protein PSD95 was used to identify spines engaged in cytoskeletal remodeling and to measure the size of associated PSDs. Photomicrographs in (a) show double immunofluorescent localization of phosphorylated (p) cofilin and PSD95 in dendritic spines in hippocampal field CA1 of an acute slice: pCofilin labeling is reliably localized to a subset of spines with PSD95+ synapses (arrow indicates one double-labeled profile; iterative deconvolution images from CA1 str. radiatum; Scale = 5 μm). (b) The graph on the left shows that the induction of LTP by theta burst stimulation (TBS) produced a significant, three to fourfold increase in numbers of spines containing pCofilin [pCofilin(+)] PSDs ($**p < 0.01$; a two-tailed *t*-test) and that this effect was completely blocked by stimulation in the presence of the NMDA receptor antagonist APV. Similarly, unsupervised learning increased numbers of spines containing pCofilin (b, right); the graph shows counts of pCofilin+ spines (i.e., spine-like profiles associated with PSD95) in hippocampal CA1 str. radiatum in rats (1) maintained in their home cage (HCC), (2) engaged in 30 min unsupervised learning just before sacrifice (EXP), and (3) engaged in 30 min unsupervised learning under treatment with the NMDA receptor antagonist CPP (EXP+ CPP). The unsupervised learning group had 40% more pCofilin+ spines than did the home cage controls ($***p < 0.001$) and this effect of unsupervised learning was blocked by CPP (10 mg kg^{-1}). (c) To evaluate the effects of LTP, and learning, on synapse size, the areas of PSD95+ elements were measured for profiles immunolabeled in experiments illustrated in panel (b). Graphs in (c) show size-frequency distributions for PSDs associated with (dashed line) or not associated with (solid line) dense pCofilin; these distributions show that with both LTP (left) and learning (right) pCofilin-containing spines are associated with larger synapses.

difficult to see how a presynaptic increase in neurotransmitter release could act on just one subset of glutamate receptors co-localized at the synapse. Moreover, LTP is not accompanied by changes in paired-pulse facilitation of EPSPs, an effect that is sensitive to altered neurotransmitter release probabilities. Despite these points, the

above results opened one of the more intense controversies in recent neuroscience history: that is, the argument whether changes that underlie LTP are primarily pre- or postsynaptic. To address this issue, a number of laboratories applied whole cell recording techniques and methods of quantal analysis, originally developed to

study release at the neuromuscular junction, to hippocampal slices. Initial results indicated that the induction of LTP increases the probability of glutamate release and thus supported a presynaptic hypothesis for expression. However, questions soon appeared as to whether the essential conditions for quantal analysis had been satisfied in the slice studies and thus about the degree to which the results obtained actually challenged the postsynaptic hypothesis. When subsequent work on mechanisms of potentiation (see below) concurred with the conclusions from the studies on NMDA versus AMPA receptor changes, the controversy gradually subsided and a broad consensus emerged that expression is largely, and perhaps entirely, a postsynaptic phenomenon.

Active versus Structural Models of LTP Expression

What type of postsynaptic change underlies expression? One possibility considered was that synaptic potentiation arises from a change in spine resistance. However, tests of necessary predictions from this hypothesis proved negative. The alternative and favored hypothesis is that LTP expression involves another straightforward change that would lead to larger EPSPs; namely a modification involving postsynaptic AMPA receptors. Two versions of this idea have evolved over the past 5–10 years. The first, which will be referred to as the active model, posits that self-regenerating enzymatic activity acts on the AMPA receptors in such a way as to either increase their conductance or encourage their insertion into the synaptic membrane. The original version of the argument, involved calcium/calmodulin-dependent protein kinase II (CaMKII). Sacktor and colleagues subsequently advanced a second, and remarkably well-developed, active model based on protein kinase M-zeta (PKMzeta). Both of these enzymes are concentrated in the postsynaptic region, exhibit enduring activity, and influence AMPA receptor activities in ways that should increase the AMPA receptor component of the postsynaptic response. It is thus reasonable to propose that induction engages an enzyme that then (1) increases AMPA-receptor-mediated currents and (2) generates new copies of the active enzyme within the spine. The latter step ensures the maintenance of the potentiated state. Adding to the plausibility of this scenario are data indicating that activities of CaMKII and PKMzeta are increased with LTP induction and NMDA receptor stimulation. Questions naturally arise as to whether a self-regenerating system of this type could be sustained for the weeks and months over which LTP has been followed in chronic recording experiments. Positive data relating to a key prediction of the model – that inhibitors of the kinases will fully reverse established LTP without

affecting control synapses – have been reported, but additional work on this question would be helpful.

Structural models of expression hypothesize that induction increases the pool of synaptic AMPA receptors by changing the morphology of the postsynaptic region. This idea is grounded on two observations. First, early electron microscopic (EM) studies using hippocampal slices and acutely anesthetized rats obtained evidence that LTP is accompanied by changes in the postsynaptic density (PSD), the specialized anatomical region lying immediately beneath the synaptic contact zone. The mean effect of LTP on PSD sizes was small, but this is as expected given that the activated connections constituted a minority of the total synaptic population measured. These experiments also indicated that the PSD effects were associated with changes in the shape of dendritic spines. Collectively, the results led to the hypothesis that induction causes a rounding of spines and synapses and thus an increase in the area of the latter. Subsequent ultrastructural studies described other types of PSD and spine modifications, but in general terms supported the proposal that rapid structural changes are a concomitant of LTP. A second set of results pertinent to structural models came from immunogold/EM studies of the density of glutamate receptors at hippocampal synapses. Experiments of this type from different groups established that the number of AMPA (but not NMDA) receptors correlates positively with PSD size. Thus, LTP-related increases in PSD area, as found in some EM studies, would be expected to entail proportionate increases in synaptic AMPA receptor number and therefore to provide a satisfactory explanation for expression.

The advent of light microscopic techniques that allow for resolution and measurement of micron-level objects in the dense three-dimensional matrix of brain opened the way for new tests of the structural hypothesis for expression. Using these methods, convincing evidence has been obtained for the idea that the brief periods of high-frequency afferent activity used to induce LTP cause a rounding and enlargement of spines. Results of a recent, carefully executed experiment described a lasting 41% increase in spine volume following TBS along with a change in the shape of the volume–frequency distribution of the potentiated spines, an effect which is suggestive of a change in spine shape. Other work using immunocytochemical markers for potentiated synapses (see below, **Figure 2(c)**) found a 50–70% increase in PSD size following a conventional theta burst train that was again accompanied by a shift in the size–frequency distribution similar to that described for spines. Remarkably, the quantitative results for the PSD and spine studies are in good agreement with the magnitude of LTP and their congruence makes a powerful case for the hypothesis that expression of the potentiation effect is achieved by structural changes to spines and synapses.

Is there a syncretic model that incorporates both the active and structural arguments regarding LTP expression? Rapid filling of the expanded synapse with AMPA receptors presumably involves increased activity by the enzymes that promote movement of the receptors from lipid rafts in the perisynaptic membrane into the junc-tional zone. CaMKII and PKMzeta are well suited, both by their locations and known functions, to perform this role. The first step in exploring this idea would be to test if, within individual spines, activity of the two enzymes correlates with PSD size under resting conditions; positive results would constitute evidence that the machinery regulating receptor trafficking is linked to the factors controlling the area of synaptic apposition, and thus for an active/structural version of LTP expression.

LTP Expression and the Organization of Memory

Early work testing for evidence of LTP expression during behavior took advantage of several unusual features of the afferents to the olfactory cortex to substitute theta-pattern stimulation for sensory input to create electric odors, making it possible to measure EPSPs at precisely the same synapses that received inputs perceived by the animal to be a real-world cue. Learning of a two-odor discrimination, where one or both of the odors was electric, resulted in robust, synapse-specific, and long-lasting LTP. Importantly, failures to induce LTP with electric odors were invariably accompanied by failures to form memories. Recent experiments by Bear and colleagues obtained strong evidence that learning of a conditioned response enhanced synaptic responses in the hippocampus; critically, these effects occluded LTP, suggesting that they shared substrates with the potentiation effect, and involved only a portion of available synapses. The discovery that TBS increases the size of synapses made it possible to carry this line of work to the next level – to directly test, through visualization of individual synapses, whether the expression mechanisms for LTP are actually engaged by learning. The results were clear: spines in the hippocampus that were potentiated (i.e., contained a biochemical marker associated with the recent induction of LTP) by 30 min of unsupervised learning had synapses that were significantly larger than their neighbors that lacked the potentiation marker. These effects involved only a small percentage of the spine population, so they accord well with the expectation that the acquisition of substantial amounts of information (learning a complex environment) does not use up a significant fraction of the available synapses.

The parametric details of LTP expression, as was the case for induction, help explain how the biology of synaptic memory leads to one of the many possible internal representations of the external world. The approximately 50% increase in synapse size found in the imaging studies

aligns closely with the maximum amount of LTP obtained under standard conditions with naturalistic theta burst stimulation, a correspondence that seems unlikely and yet in line with the observation that synapse size scales linearly with the number of AMPA receptors (see above). What does it mean, in a computational sense, if synapses can change just this much but not more? Modeling research suggests that cortical networks incorporating LTP-based synaptic learning rules will inevitably form hierarchical categories in which learned cues are associated according to their similarity. In these models, the number of items needed to form a category is set by the magnitude of the smallest increment of LTP, while category breadth is determined by the maximum degree to which synaptic strength can be increased. According to these results, the serial learning of odors, to cite one well-studied example, results in the formation of classes (plants, animals) under which are subsumed subcategories (flowers, fruits), under which are specific cases (roses). Thus, the internal world generated by memory seems to be shaped by the ability of synapses to change size.

Consolidation

LTP Consolidation Depends on the Spine Actin Cytoskeleton

Nineteenth-century researchers were well aware that memory is unstable immediately after its encoding and then over the next 15 min becomes progressively more resistant to disruption. This reduced vulnerability to disruption is termed the consolidation of the memory trace. That LTP possesses a similar consolidation period was discovered in the early years of research on the potentiation effect, but the significance of this was not fully appreciated until several years later. Initial studies showed that LTP could be reversed by low-frequency stimulation applied within the first 5 min following LTP induction and that this erasure effect was selective to potentiated synapses (i.e., control, unpotentiated, pathways were unaffected). Later, chronic recording experiments confirmed that potentiation did not return following such erasure even after 24 h. Other studies showed that a number of manipulations (e.g., adenosine application and hypoxia) could selectively erase LTP when applied in the first minutes after induction but were without effect 10–20 min later. A sizeable number of experiments from different groups have confirmed these points.

How consolidation is achieved constitutes one of the major questions facing the field. It brings the plasticity effect face to face with one of the fundamental issues in memory research, and raises mechanistic questions that are likely related to a broad spectrum of neuropsychiatric

problems. Early attempts to explain consolidation posited that the structural modifications triggered by the induction process resulted in a lasting reorganization of the spine cytoskeleton, which then maintained the altered geometry of the synaptic junction. LTP in this reading would be a special case of the broad class of events whereby cells form specialized quasi-permanent connections with the extracellular matrix or other cells. An impressive wave of recent work suggests that this idea is largely correct. Intense stimulation of glutamate receptors in dissociated neurons or cultured hippocampal slices causes the rapid polymerization of actin within dendritic spines; evidence for activity-driven polymerization has also been reported for adult hippocampus, but in that instance it was not possible to clearly resolve individual spines. Subsequent work with novel technical modifications resolved the latter problem and showed that TBS causes a rapid (<2 min) increase in the number of spines containing high concentration of filamentous (F)-actin within the dendritic sublamina containing potentiated synapses. The effect had the same threshold (number of theta bursts) for induction as did LTP and was completely blocked, along with consolidation, by a toxin (latrunculin A) that prevents the addition of actin monomers to growing filaments.

While many lines of evidence indicate that TBS-induced F-actin assembly is essential for the production of stable potentiation, the effect by itself does not explain a defining feature of LTP consolidation: progressive development over a 15–30-min time frame. In other words, the protracted nature of consolidation points to stabilization processes that occur after TBS triggers actin polymerization (30 s to 2 min). One possibility is that the newly induced actin filaments are initially dynamic and then gradually transition into a more stable configuration. Work on growth cones shows that actin polymers engage in a treadmilling process wherein they add monomers at one end and release them at the other. Tests of whether this occurs in spines after LTP induction were made by applying latrunculin A at various times after TBS. As predicted, the toxin eliminated the several-fold increase in spines with dense concentrations of F-actin when infused at 2 min post-TBS but was without effect 10 min later. Its actions on LTP paralleled these results. These last findings provide a first candidate – F-actin stabilization – for the event that consolidates LTP.

Ongoing efforts to understand how a 1-s-long theta burst train, composed of five bursts of depolarization, can yield such dramatic changes to the spine cytoskeleton have already resulted in a novel model of synaptic function in which the junction contains adhesion and modulatory receptors along with the classical transmitter (glutamate) receptors. Integrin class adhesion receptors are known to potently influence the actin cytoskeleton across cell types. The $\beta 1$ -family integrins are

concentrated at glutamatergic, hippocampal synapses and three groups using different methods have shown that blocking their operation potently disrupts LTP consolidation. This confirms an early hypothesis that integrin engagement is a key step in producing stable LTP. The junctional zone also contains receptors for brain-derived neurotrophic factor (BDNF) and adenosine – the BDNF TrkB receptor promotes TBS-induced actin polymerization and LTP whereas the adenosine A1 receptor inhibits both processes. Paradoxically, then, theta bursts elicit the release of modulators that exert opposing effects on consolidation, an observation that will figure into a later discussion of how the synaptic chemistry of LTP not only encodes but shapes memory as well.

Do activities of glutamate receptors, integrins, and modulatory receptors coordinate the assembly and stabilization of actin networks within the confined space of the dendritic spine? The analysis of the small percentage of synapses involved in physiologically induced LTP in an adult brain was impossible prior to the very recent development of restorative deconvolution microscopic techniques for quantitative analysis of immunofluorescent labeling. These methods make it possible to ask if a subpopulation of synapses in the discrete dendritic layers targeted by TBS exhibit stimulation-induced increases in activated versions of proteins known from a vast literature on non-neuronal tissues to control actin filament assembly. Work using these methods revealed that, as predicted, TBS increases the number of synapses containing dense concentrations of phosphorylated p-21-activated kinase and cofilin, two proteins that act as intermediaries between integrins and the actin cytoskeleton. The cofilin result, as illustrated in **Figure 2**, is particularly diagnostic. The protein is constitutively active and functions to sever growing filaments; the suppression of this activity by phosphorylation, which is promoted by BDNF, is thus critical for actin-filament assembly and maintenance. These analytical techniques allow us to examine how much of the complex machinery regulating the actin networks in a diverse array of cell types is present in spines and engaged by LTP induction.

LTP Consolidation and Memory

Consolidation events described here are largely complete within 10–15 min following the induction of LTP. This time period aligns well with that first described by Ribot (see above) for the stabilization of memory. However, there is a large literature suggesting that consolidation involves multiple stages occurring over hours or even days. A long-standing question in memory research concerns the extent to which the proposed stages of consolidation are serial (where one causes the next) or parallel in the sense that different events with different latencies are activated by learning. The LTP work favors

the former idea. Specifically, studies by Vanderklish and Edelman show that the assembly of actin networks is necessary for activity-driven protein synthesis in the dendritic segments underlying spines. Sacktor independently reached this conclusion in his work on PKMzeta. Further discussion of these arguments, which would involve a survey of the vast literature on the possible roles of gene transcription and protein translation in memory and LTP, is beyond the scope of the present review.

Imaging memory consolidation. In addition to identifying actin-signaling pathways engaged by theta stimulation within spines, the quantitative immunofluorescence studies described above have provided a set of biochemical markers for recently potentiated synapses. This was a critical first step toward asking if LTP consolidation actually occurs in synapses during learning. Recent work established that unsupervised learning results in a modest, but statistically robust, increase in the number of hippocampal synapses associated with phosphorylated cofilin, one of the effects produced by TBS that is critical for generating new F-actin. This learning-induced increase was prevented by an NMDA receptor antagonist at concentrations that block both LTP and the production of long-term memory (**Figure 2(b)**). Collectively, these results constitute good evidence that memory consolidation involves the same mechanisms used to stabilize LTP. They also suggest a strategy for investigating one of the most important issues in all of behavioral neuroscience: Where in the cortical telencephalon are memories stored? The work with unsupervised learning focused on a single dendritic lamina in a subfield (CA1b) of mid-septotemporal hippocampus but, nonetheless, required significant sampling. Expanding such an analysis to include the entire hippocampus, but excluding the neocortex, using current technologies is a daunting prospect but may become realistic with further advances in computerized microscopy and automated identification and measurement of micron-sized structures.

The LTP work suggests the idea, rarely discussed in the behavioral literature, that the consolidation process affects the properties of memory. Parametric studies showed that 30-s trains of theta-frequency stimulation (i.e., single pulses, rather than bursts, delivered at 5 Hz) are sufficient to erase newly induced potentiation; this is informative because bouts of theta activity lasting this long are a routine feature of the hippocampus in freely moving animals. Possibly, then, the activity of ascending cholinergic projections and the behavior of the animal, two variables that regulate theta activity, in the post-acquisition period determine which aspects of the recently encoded information are erased or transferred into long-term memory. Results showing that the occurrence of extended periods of theta activity in behaving rats during the first few minutes after TBS eliminates LTP are in accord with this suggestion. In all, the consolidation effect

operating over several acquisition episodes may allow brain networks to actively construct a memory that highlights certain features of the learned material while omitting others.

LTP Rules Suggest Means for Enhancing Memory

Progress in explaining the induction, expression, and consolidation of LTP led to entirely new ideas about the failure of memory with aging and in neurodegenerative diseases and how it might be rescued. Closely related to this is a burgeoning body of work investigating neurobiologically grounded techniques for enhancing normal encoding. Beginning with induction, an early set of studies showed that antagonists of NMDA receptors thoroughly disrupt spatial learning, a result that first raised the idea that enhancing the triggering mechanisms for LTP might reduce the amount of training needed to acquire memory. It should be noted here that those same widely cited experiments also found that the antagonists left some forms of learning intact; the failure to recognize that LTP contributes to some but not all forms of memory added confusion to the subsequent extensive literature on the behavioral significance of the potentiation effect. In any event, the first attempts to exploit information about induction used an invented class of centrally active, allosteric modulators ('ampakines') that enhance the ionic currents passed by AMPA receptors. Since these currents provide the depolarization needed to unblock NMDA receptors, it was reasoned that they should reduce the activity threshold for inducing LTP and thereby facilitate the process. Both predictions were confirmed and ampakines were subsequently found to improve retention scores in a variety of learning paradigms in animals and humans. Moreover, these effects were obtained with ampakine dosages that produced little, if any, effect on baseline performance across multiple testing procedures.

The ampakine results lead to a conclusion with far-reaching implications: namely that the parameters for LTP induction and expression are less than optimal with regard to memory acquisition. This may be a very unlikely idea for some simply because learning is essential to survival and thus is presumably the target of strong adaptive pressures operating over tens of millions of years. In line with this suggestion, LTP-like effects have been recorded in representatives from multiple orders of mammals. If, as suggested by this, the phenomenon appeared with the earliest mammals, then it is at least 150 million years old. Note, however, that the tuning of LTP parameters would have occurred in environments that have only a passing resemblance to the settings in which memory tests are conducted – from this perspective

LTP settings that are less than ideal would not be unexpected. Acquisition is not the only learning-related variable affected by the LTP rules; as discussed, network models suggest that the categorization of information is intimately related to the induction threshold and expression ceiling for LTP. If this is correct, then experimental treatments acting on these variables so as to accelerate learning, or enhance the strength of memory, will likely affect the way in which information is organized in the cortex. Whether this would be to the benefit or detriment of cognitive operations can only be investigated using complex, real-world situations – tests of the point, which may become possible during clinical testing of LTP-related drugs, are likely to yield fascinating results.

Manipulation of consolidation offers some intriguing prospects for memory enhancement. In principle, such treatments would not affect acquisition but instead would improve the likelihood of translating the learned material into long-term storage. They could, in other words, be highly selective with regard to their impact on the organization of memory. Most of the work in this area has involved treatments directed at the synthesis of proteins thought to promote late phases of consolidation and so are beyond the scope of the present discussion. Factors that modulate activity-driven reorganization of the spine actin cytoskeleton offer obvious targets for enhancing the rapid phase of consolidation. Thus, several physiologically plausible manipulations are reported to increase the production of BDNF, which, as described, potently facilitates both TBS-induced actin polymerization and LTP consolidation. Surprisingly, there do not appear to be studies testing if, as predicted from the LTP work, elevation of brain BDNF levels improves retention scores in long-term memory paradigms. Another candidate suggested by recent experiments shows that agonists for estrogen receptor beta promote the formation of stable LTP and markedly improve performance in tests of long-term memory. Very little is known about the synaptic mechanisms responsible for these effects but estrogen

has a strong influence on actin dynamics in non-neuronal systems. In all, it appears that we are entering a period in which the growing body of knowledge about LTP will be used to design novel, mechanism-based strategies for enhancing memory.

Glossary

Hyperalgesia – This word, literally, means an increased response to a painful stimulus. The phenomenon may involve a lowering of nociceptive threshold or an increase in the magnitude of pain evoked by suprathreshold stimuli. Hyperalgesia can occur at the site of tissue damage (primary hyperalgesia) and in the surrounding undamaged zones (secondary hyperalgesia). While primary hyperalgesia can result from changes in the sensitivity of nociceptors, the basis of secondary hyperalgesia remains unclear. The spread of hyperalgesia in the periphery may occur through the sensitization of nociceptors that project collateral branches, one of which innervates the site of injury.

Neuropathic pain – This type of pain may result from disorders of the peripheral nervous system or the central nervous system. Thus, it is divided into peripheral neuropathic pain, central neuropathic pain, or mixed neuropathic pain. Central neuropathic pain is found in spinal cord injury, multiple sclerosis, and some strokes. The common causes of painful peripheral neuropathies are diabetes, herpes zoster infection, human immunodeficiency virus (HIV)-related neuropathies, nutritional deficiencies, toxins, remote manifestations of malignancies, and genetic and immune-mediated disorders. Neuropathic pain is common in cancer as a: (1) direct result of cancer on peripheral nerves, (2) side effect of some chemotherapy drugs, and (3) result of radiation injury.

Potential receptor – A potential restricted to the receptive field that propagates electronically. It is generally produced by the opening of excitatory channels selective for cations. The movement of these ions brings the membrane potential toward the threshold for triggering an action potential. An example of this is mechanotransduction. A mechanical stimulus deforms the membrane, causing the activation of mechanosensitive channels. The ion flow through these channels depolarizes the membrane, activates voltage-gated Na^+ channels, and gives rise to an action potential.

Sensory neurons – Sensory information is conveyed from the periphery to the central nervous system via sensory neurons that have their cell bodies in dorsal root ganglia and in trigeminal ganglia. Somatosensory

modalities (touch, pain, and temperature) are subserved by separate populations of sensory neurons specialized in detecting innocuous and injurious stimuli. Sensory neurons roughly fall into three categories: (1) rapidly adapting mechanotransducers, which are neurons that respond to touch and non-noxious temperatures. They conduct action potentials rapidly and make a subset of nerve fibers referred to as ' $\text{A}\beta$ fibers'; (2) proprioceptive neurons, which are neurons that indicate the position of our muscles. They also conduct action potentials rapidly and comprise $\text{A}\beta$ nerve fibers; and (3) nociceptors, which are pain-sensing neurons that respond to painful mechanical or thermal stimulation. They also comprise the class of neurons that respond to chemical irritants (like capsaicin). They are lightly myelinated ($\text{A}\delta$) or unmyelinated (C-fibers), so they conduct action potentials more slowly than $\text{A}\beta$ fibers.

Transient receptor potential channels – TRP channels were named after the near-blind *Drosophila* mutant that displays transient potentials in response to continuous light. The identification of the TRP gene and recognition of its function as a Ca^{2+} -permeable cation channel led to the cloning of many channels that bear sequence and structural similarities to the *Drosophila* TRP. On the basis of sequence homology, the TRP family is divided into seven main subfamilies: the TRP canonical (TRPC) family, the TRP vanilloid (TRPV) family, the TRP melastatin (TRPM) family, the TRP polycystin (TRPP) family, the TRP Mucolipin (TRPML) family, the TRP ankyrin (TRPA) family, and the TRP NOMPC (TRPN) family. The characterization of TRP members has grown considerably during recent years, leading to a plethora of data on the roles of TRP channels in a variety of cellular functions, tissues, and species.

Vanilloids – They comprise a group of compounds including capsaicin, which is the primary pungent principle of hot pepper. It was first isolated by LT Thresh more than a century ago, who named this compound 'capsaicin,' and predicted that the structures of capsaicin and vanillin were closely related. Despite this early discovery, it was not until 1919 that the exact chemical structure of capsaicin was determined by EK Nelson. Today, capsaicin is used as a neuropharmacological tool to identify sensory neurons and their contribution to health and disease.

Introduction

Sensory neurons enable us to sense and perceive our environment, which is a condition for triggering appropriate behavioral responses. In vertebrates, these sensations are mediated by specialized sensory neurons, whose cell bodies are located in trigeminal ganglia (TGs) and dorsal root ganglia (DRGs). These neurons project long axons to the skin and deeper body structures where they detect chemical, thermal, and mechanical cues. Therefore, detecting and transducing several types of stimuli enable us to perceive touch, body movement, spatial orientation, as well as temperature. However, if the intensity of a particular stimulus is above a certain threshold, it can evoke the sensation of pain.

Sensory neurons are functionally heterogeneous: different subpopulations of neurons are specialized to detect different sensory modalities. The stimulus, whatever its nature, is always converted into an electrical signal, the receptor potential, which eventually leads to the generation of action potentials that propagate toward the central nervous system.

The transduction mechanisms underlying temperature sensation and mechanosensation have been the subject of intense study. Recently, several transient receptor potential (TRP) channels have been identified as candidate thermo- and mechanosensors. Channels from the TRP channel superfamily were first described in *Drosophila*, deriving their name from the mutant phenotype of a TRP channel in response to prolonged light stimulation. Thereafter, several subfamilies of TRP channels have been recognized

in both invertebrates and vertebrates and this led to the discovery of their roles in transducing mechanical, chemical, and thermal stimuli. To date, more than 70 TRP channel subunits have been identified in genomes of *Caenorhabditis elegans*, *Drosophila*, and humans, and have been classified into seven subfamilies: the TRP canonical (TRPC) family, the TRP vanilloid (TRPV) family, the TRP melastatin (TRPM) family, the TRP NOMPC (TRPN) family, the TRP ankyrin (TRPA) family, the TRP polycystin (TRPP) family, and the TRP Mucolipin (TRPML) family. Of these, the members of three families, that is, the TRPV channels, the TRPM channels, and the TRPA channels are of particular interest as thermo- and mechanosensors. This article summarizes findings regarding the role that TRP channels play in thermosensation and mechanosensation in mammals.

Thermotransducers in Mammals

The demonstration that certain TRP channels can be activated by increases or decreases in temperature, along with the recognition of their heterogeneous temperature sensitivities and expression pattern, has led investigators to evaluate these proteins as candidate thermosensors. Six highly temperature-sensitive TRP channels, whose genetic ablation alters thermally driven behaviors, have been implicated to mediate temperature sensation. These channels, expressed in sensory neurons or in the skin, are active at specific temperatures ranging from noxious cold to burning heat (**Table 1**).

Table 1 Thermal- and mechanosensitive mammalian TRP channels in sensory neurons and in the skin

Channel	Sensory stimulus	Agonists	Physiopathological role
TRPV1	T ≥ 43 °C	Capsaicin Vanilloid compounds Protons Anandamide Resiniferatoxin	Thermal pain sensation Thermal hyperalgesia Stretch-evoked sensation
TRPV2	T ≥ 52 °C Cell swelling	2-APB Carvacrol	Thermal pain sensation
TRPV3	T ≥ 31 °C	Thymol Eugenol 2-APB Camphor	Thermosensation Thermal preference
TRPV4	T ≥ 27 °C Cell swelling	4- α phorbol Eicosanoid	Osmotic sensation Thermal hyperalgesia
TRPM8	T ≤ 28 °C	Icilin Menthol Eucalyptol	Thermal preference Cold thermosensation
TRPA1	T ≤ 17 °C	Icilin Garlic (allicin) Cinnamaldehyde	Inflammatory pain Mechanosensation Thermosensation Cold-induced pain

Thermo-TRP Transducers to Noxious Heat

TRP vanilloid 1

TRP vanilloid 1 (TRPV1) is both a receptor for capsaicin, the ingredient of chili peppers, and related pungent vanilloid compounds, and a heat receptor, capable of depolarizing a subset of primary afferent neurons in response to noxious temperatures ($>43^{\circ}\text{C}$). Evidence for a contribution of TRPV1 to peripheral thermosensation has come from pharmacological, physiological, and genetic approaches. TRPV1 is expressed in small- to medium-diameter sensory neurons, consistent with the selectivity of vanilloid action on C- and A δ -fibers responsible for pain and warmth perception. In heterologous expression systems, TRPV1 can be activated not only by vanilloid compounds, but also by resiniferatoxin, extracellular protons, and arachidonic acid metabolites. Mice lacking TRPV1 have altered behavioral responses to capsaicin and resiniferatoxin. In cultures of DRG neurons, TRPV1 knock-out (KO) neurons exhibit a dramatic decrease in the occurrence of capsaicin-evoked cationic currents and do not respond to heating up to 50°C . Consistent with this, TRPV1 KO mice were found to exhibit prolonged latencies for tail withdrawal in assays of acute thermal nociception. However, analysis of thermosensation in these animals has produced a mixed picture. In cultured sensory neurons and skin–nerve preparations from TRPV1 KO mice, thermal sensitivity was defective, but not absent. Therefore, other heat transduction mechanisms, in addition to TRPV1, exist that can detect noxious temperatures (see below). TRPV1 channels are sensitized by inflammatory mediators such as low pH, bradykinin, nerve growth factor, and prostaglandins. TRPV1 sensitization by inflammatory mediators typically produces decreased threshold or latencies of withdrawal from thermal stimuli. In TRPV1 KO animals, the signs of thermal hyperalgesia following inflammation are markedly reduced, demonstrating that TRPV1 contributes to the transduction of painful heat stimuli, particularly in the context of inflammation.

TRP vanilloid 2

The residual responsiveness to heat stimuli in mice lacking TRPV1 argues for the existence of an additional heat transduction mechanism. TRP vanilloid 2 (TRPV2), which shares 50% amino acid identity to TRPV1, is a candidate. TRPV2 is expressed in a subpopulation of medium- to large-diameter sensory neurons that give rise to A δ /B fibers. TRPV2 shows responsiveness to high temperatures ($>52^{\circ}\text{C}$, $\sim 10^{\circ}\text{C}$ higher than that of TRPV1), but it is unresponsive to typical activators of TRPV1, including low pH and capsaicin. TRPV2 may be the thermotransducer mediating type I heat response in A δ nociceptors because these afferent fibers are unresponsive to intradermal capsaicin administration.

TRPV2 has been shown to heteromultimerize with TRPV1. This raises the possibility that TRPV2 may contribute to thermodetection within a temperature range lower than that required to activate homomeric TRPV2 channels.

Thermo-TRP Transducers to Non-Noxious Heat

TRP vanilloid 3 and TRP vanilloid 4

TRP vanilloid 3 (TRPV3) and TRP vanilloid 4 (TRPV4) share 40–50% homology with TRPV1. TRPV3 can be activated by temperatures above 33°C , and by camphor, which causes the sensation of warmth when applied to human skin, and irritant extracts from oregano, thyme, and clove. TRPV4, although activated by warm temperatures (25 – 34°C), was first described to be activated by hypotonic stimuli, metabolites of arachidonic acid, and by phorbol esters. TRPV4 currents show marked desensitization upon repetitive thermal challenge, in contrast to TRPV3 currents that exhibit an increase in amplitude in response to repetitive heating stimulation. TRPV3 and TRPV4 are expressed at low levels in sensory neurons, but are strongly expressed within skin keratinocytes. The expression of TRPV3 and TRPV4 in skin epidermis led to the hypothesis that keratinocytes are involved in the detection of warmth stimuli. In line with this, TRPV3 KO mice have a diminished sense for warm temperatures, in that they show an increased latency in the hot-plate and tail-immersion assays at relatively high temperatures. TRPV4 KO mice also show defect in acute thermally evoked withdrawal responses in the tail-immersion assay. Compared to wild-type (WT) animals, TRPV4 KO mice show a preference for warmer innocuous temperatures, suggesting that the channel is important for dictating the precise range of preferred temperatures within the innocuous range.

Collectively, these studies demonstrate impairment of thermotaxis behavior in TRPV3 and TRPV4 KO mice. In addition, they suggest that keratinocytes, through release of paracrine factors, such as ATP, opioid peptides, and cytokines, among others, sensitize the sensory nerve endings. Evidence for the role of keratinocytes in peripheral thermosensation remains to be established *in vivo*.

Thermo-TRP Transducers to Noxious Cold

TRP ankyrin 1

The TRP ankyrin 1 (TRPA1) channel exhibits strong expression within sensory ganglion neurons and is present in a subset of small- to medium-diameter DRG neurons that expressed TRPV1. TRPA1 is unique in that it possesses a relatively long N-terminus domain with numerous ankyrin-repeat motifs. It is insensitive to capsaicin, but is activated by a variety of pungent chemical ligands, including isothiocyanates such as those found in

mustard oil, wasabi, and garlic. Intracellular calcium can directly activate TRPA1. In addition, it has been suggested that TRPA1 may act as a sensor of painfully cold temperatures. Support for a role of TRPA1 in transducing noxious cold has come from the following observations: first, TRPA1 is activated by temperatures of about 17 °C; second, antisense oligonucleotides directed against TRPA1 have been reported to reduce behavioral hyperresponsiveness to cold after peripheral inflammation, suggesting that TRPA1 may sense cold in these disease states; and third, TRPA1 KO mice have been reported to exhibit blunted behavioral responses to a cold metal surface and to acetone-mediated cooling. However, these conclusions have been challenged. In contrast to these findings, certain papers showed that TRPA1 KO mice have a normal sensitivity to cold temperatures, while DRG neurons from these animals are still sensitive to noxious cold. Thus, the involvement of TRPA1 in transducing noxious cold certainly awaits further experiments.

Thermo-TRP Transducers to Non-Noxious Cold

TRP melastatin 8

TRP melastatin 8 (TRPM8) is a member of the TRP melastatin subfamily of TRP channels expressed in a subset of small DRG neurons distinct from those that express TRPV1. The TRPM8 channel is activated by temperatures below 26 °C, consistent with a role in innocuous cooling perception. Cooling-mimetic chemicals, including menthol and eucalyptol, activate TRPM8 and shift to warmer temperatures the threshold for TRPM8 activation. Icillin, which is structurally not related to menthol or eucalyptol, activates TRPM8 and produces a sensation of cooling in humans. Additional support for the participation of TRPM8 in physiological cold transduction comes from the observation that TRPM8 KO mice show reduced sensitivity to non-noxious cold

stimuli, whereas their behavioral responses to noxious cold temperatures are only slightly altered.

Mechanotransducers in Mammals

Although all animals employ mechanical sensations to apprehend their external and internal environments, the molecular transduction mechanisms involved in the detection of mechanical stimuli remain obscure. The ability of mechanoreceptive sensory neurons to detect mechanical information relies on the presence of mechanosensitive (MS) channels that rapidly transform external mechanical forces into electrical signals. In the few past years, genetic approaches coupled to functional studies have provided insights into the basic mechanisms by which the senses of touch and pain are transduced in mammals. TRP channels have again emerged as candidate mechanosensors ([Table 1](#)).

Properties of Native MS Channels in Sensory Neurons

Recordings of mechano-gated currents under voltage clamp were first made by JD Levine and colleagues in 1999. MS currents evoked in sensory neurons have a relatively short latency, which argues against activation of a second-messenger cascade and favors direct activation of a mechanically activated channel. In response to sustained mechanical stimulation, MS currents decline or adapt, through closure of the transduction channels. Based on these adapting kinetics, three main classes of MS currents have been identified and loosely classified as either rapidly adapting (RA), intermediately adapting (IA), or slowly adapting (SA) ([Figure 1](#)). An MS current that does not adapt within the testing range has been occasionally observed in sensory neurons. This nonadapting MS current exhibits the particularity to peak during

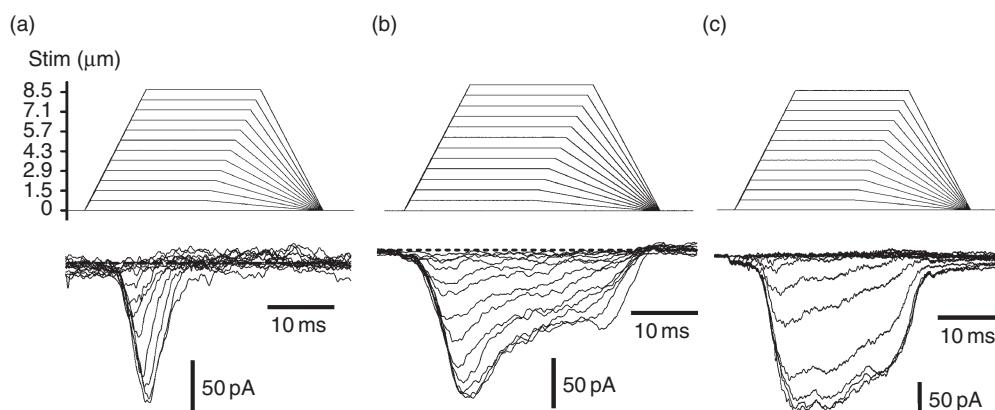

Figure 1 Families of mechanosensitive current traces evoked by a series of mechanical steps in 0.7- μm increments. Mechanosensitive currents showing (a) rapid-, (b) intermediate-, and (c) slow-adapting kinetics recorded in sensory neurons. Mechanical ramp stimulations (top traces) were applied at a holding potential of -60 mV ; the probe velocity was $850\text{ }\mu\text{m s}^{-1}$.

the stationary part of the mechanical stimulus. The majority of large-diameter sensory neurons express RA MS currents, whereas small- to medium-diameter sensory neurons preferentially display SA/nonadapting MS currents. The differences in properties of MS currents among sensory neuron subpopulations *in vitro* are consistent with the *in vivo* physiological properties of low-threshold mechanoreceptors (LTMs) and nociceptors.

RA and SA MS currents in sensory neurons exhibit reversal potentials at about 0 mV and are carried by channels nonselective for cations and impermeable to anions. The similarity in the ionic selectivity of these MS currents among different populations of sensory neurons suggests that closely related ion channel subunits mediate these currents. The ability of RA MS currents to pass large organic molecules, such as TEA, choline, and Tris, strongly favors the view that the pore of the underlying MS channels is relatively large.

While MS currents show the ability to be carried by Ca^{2+} and, to a lesser extent, by Mg^{2+} , both Ca^{2+} and Mg^{2+} at physiological concentrations produce a partial block of MS currents. Although the mechanism of the block is still unknown, it may be due to a Ca^{2+} -binding site within the pore causing reduced permeation to Na^+ .

Pharmacological studies of MS channels have been dominated by the use of unselective blockers such as metal cations. Not surprisingly, gadolinium (Gd^{3+}), a widely used blocker of various cationic conductances, blocked all MS currents in sensory neurons. Amiloride, another nonselective drug that blocks many epithelial Na^+ channels and TRPP-like channels, inhibited most MS currents at relatively high concentrations. These properties are shared by many mechano-gated cationic channels in other systems, including spider mechanoreceptor neurons, *Xenopus* oocytes, and mammalian hair cells. Recently, it has been shown that a conopeptide analog termed 'NMB-1' (for noxious mechanosensation blocker 1) preferentially blocks SA MS currents in sensory neurons. Indeed, NMB-1 has an approximate 30-fold selectivity for MS channels mediating SA currents over those carrying RA currents. Biotynylated NMB-1 principally binds to peripherin-containing sensory neurons, which are typically considered as nociceptors. Consistently, animals show reduced mechanically evoked behavioral responses to high-intensity mechanical stimuli in the presence of NMB-1. Collectively, these data reinforce the view that SA and RA MS currents are expressed in functionally distinct sensory neuron populations and are carried by different molecular entities.

Non-TRP Mechanotransducers

Acid-sensing ion channels

Acid-sensing ion channels (ASICs) belong to an H^+ -gated subgroup of the DEG/ENaC channel family of cation

channels. Four ASIC genes have been cloned and encode seven channel subunits. Although all ASIC channel subunits are expressed in the peripheral nervous system, only ASIC2a, b and ASIC3 are specifically expressed in mechanosensory neurons. They are expressed in DRGs and transported from the cell bodies to specialized mechanosensory structures, such as Meissner corpuscles and Merkel cells, as well as to penicillate and lanceolate nerve endings surrounding hair follicles. Both channel subunits are also expressed in unmyelinated free nerve endings of the skin, suggesting a role in the transduction of mechanonociceptive stimuli.

Recombinant ASIC channels failed to demonstrate any mechanosensitivity. Furthermore, the biophysical properties and pharmacology of these heterologously expressed ASIC channels differ from MS cation channels recorded in native sensory neurons, suggesting that ASIC subunits may not contribute to the pore-forming subunit of the mechanosensory apparatus. In line with this, no differences in the current amplitude or kinetics of MS currents were seen in ASIC2/ASIC3-null mutant mice.

The role of ASIC channels has been also investigated in behavioral studies using mice with targeted deletion of ASIC channel genes. ASIC2 KO mice exhibit a decreased sensitivity of both RA and SA LTMs. By contrast, ASIC3 KO mice show an increase in sensitivity of RA LTMs, no change in SA LTMs, and reduced responses of myelinated high-threshold mechanoreceptors (HTMs) to noxious stimuli. Although these data argue for the involvement of ASIC subunits in mechanotransduction, the definite demonstration that ASIC subunits carry MS currents in mammalian sensory neurons awaits further experiments.

Stomatin

In *C. elegans*, MEC-2 encodes an integral membrane protein with a stomatin homology domain involved in touch receptor function. MEC-2 exhibits a central sequence of 247 amino acids that possess 64% homology with the mammalian protein stomatin. The use of mutant mice lacking stomatin-like protein 3 ($Slp3^{-/-}$) provided evidence to suggest that SLP3 is an important determinant of skin mechanoreceptor functions. About 36% of sensory neurons recorded *in vitro* show no responses to mechanical stimuli in $Slp3^{-/-}$ mice, compared with less than 5% in WT sensory neurons. Because the proportion of cells that normally display RA and SA MS currents decreased conjointly, it can be hypothesized that SLP3 is necessary for both types of underlying MS channels. At the behavioral level, the loss of SLP3 impairs tactile discrimination capability and touch-evoked pain following neuropathic injury. Therefore, SLP3 appears as an essential element of the mechanosensory apparatus in mammalian mechanoreceptors. Although its precise function is still unknown, SLP3 may be envisioned as a

putative linker between MS channel subunits and the underlying microtubules, as proposed for its *C. elegans* homolog MEC-2.

TRP Mechanotransducers

TRPV channels

TRPV channels are best known for sensing heat and mediating neurogenic inflammation; however, some have also been implicated in mechanosensation. TRPV1, which is activated by capsaicin and heat, is also required for normal stretch-evoked reflexes in the bladder and for osmosensation in circumventricular neurons. However, it cannot directly sense and respond to mechanical stimuli and *Trpv1*-null mutant mice exhibit normal acute mechanical sensitivity and mechanical hyperalgesic responses following tissue inflammation.

Some evidence has implicated TRPV2 in aortic myocyte responses to membrane stretch and hypotonic stimulation and in the constriction of blood vessels under increasing pressure. Although TRPV2 is preferentially expressed in large-diameter somatosensory neurons, its role in mechanotransduction remains to be tested.

TRPV4 has been proposed to act as an osmosensor because, in addition to warm temperature and acidic pH, it is activated by cell swelling through an indirect mechanism requiring fatty acid metabolites. In that sense, TRPV4 cannot be considered as a real mechanosensor and there must be an upstream element to fulfill this function. It is a crucial determinant in shaping the response of nociceptive neurons to osmotic stress. Disrupting *Trpv4* expression in mice has only modest effects on acute mechanosensory thresholds, but strongly reduces sensitivity to noxious mechanical stimuli. In addition, TRPV4 has been implicated in mechanical hypersensitivity during inflammation.

TRPC1 channels

Known as a store- and receptor-operated channel, the canonical TRP channel TRPC1 has been recently proposed to form the stretch-activated cation channel constitutively expressed in *Xenopus* oocytes. TRPC1 antisense reduces the endogenous stretch-activated current in oocytes, whereas overexpression of TRPC1 increases the current. Moreover, TRPC1 expression in Chinese hamster ovary, clone K1 (CHO-K1) cells results in a fivefold increase in MS cation current density. Against the presumed role of TRPC1 in mechanotransduction, however, is the observation that this channel is widely expressed in mammalian cells, most being devoid of mechanosensory functions. Perhaps, the MS signaling properties of TRPC1 rely on its interaction with other MS TRP subunits. Evidence has appeared to suggest that TRPC1 can interact with the putative MS TRPP2, a channel involved

in the mechanical detection of laminar fluid flow in renal epithelial cells. Whether TRPC1/TRPP2 heteromers form functional channels that sense mechanical stimuli remains to be tested.

TRPA1 channels

No mechanoreceptor potential C (NomPc), a member of the TRPN cation channel subfamily in *Drosophila*, together with its homologs in *C. elegans* and vertebrates, has been consistently implicated to play critical roles in mechanotransduction. A unique feature of these TRPN-related channels is their large N-terminal domains harboring numerous ankyrin repeats. This prompted the suggestion that these N-terminal domains may serve as tension transmission structures to the pore-forming region.

TRPN channels are not present in the genome of reptiles, birds, and mammals. The only mammalian TRP subunit with an extended domain of ankyrin repeats is TRPA1. This subunit was suggested to form the main mechanotransducing channel of the inner ear, but this proposal was not corroborated by knock-out strategies since *Trpa1*^{-/-} mice showed normal auditory responses and hair-cell transduction currents. Recently, the *C. elegans* ortholog of mouse TRPA1 has been shown to be expressed in mechanosensory neurons and contributes to neural responses of these cells to touch. In addition, mechanical pressure can activate *C. elegans* TRPA1 heterologously expressed in mammalian cells. These data demonstrate for the first time that *C. elegans* TRPA1 encodes an ion channel that can be activated in response to mechanical pressure.

The expression of TRPA1 in small-diameter neurons of DRGs and TGs in mammals led to the suggestion of its possible implication in mechanical pain sensation. Consistent with TRPA1's expression pattern in sensory neurons, mice lacking TRPA1 are deficient in the detection of acute high-threshold mechanical stimuli applied to the extremities. However, contrary to these findings, the Julius group did not report deficit in responses to noxious mechanical stimuli in *Trpa1*^{-/-} mice. Kwan and co-workers in 2006 went on to further demonstrate a role of TRPA1 in mechanical hyperalgesia by showing that the mechanical pain threshold after bradykinin-induced inflammation is significantly higher in *Trpa1*^{-/-} mice compared to WT. Taken together, these data provide substantial evidence suggesting that TRPA1 mediates responses to high-threshold mechanical stimuli in nociceptive neurons. However, further investigations are clearly needed to determine whether TRPA1 is a real mechanotransducing channel and to clarify the existing discrepancies regarding its role in mammalian mechanosensation.

Conclusions

Emerging features of the TRP channels include their physiological roles in sensory functions. Some TRP channels, especially TRPM and TRPV, are equipped to detect thermal changes from noxious cold to noxious heat. TRPM8 and TRPV3/TRPV4 encode cool and warm, respectively, and TRPV1 and TRPV2 sense noxious heat. TRPV4 and TRPV1 respond to thermal, chemical, and mechanical stimuli as well. Others, including TRPA1, are probably involved in mechanosensation and cold transduction. Typically, TRP channels are activated by a plethora of chemical and physical stimuli. Such gating promiscuity allows TRP channels to play a key role in a wide range of sensory processes, including osmoregulation, thermal, and chemical signaling. Importantly, some of these TRP channels are involved in life-threatening human diseases such as mucolipidosis IV, polycystic kidney disease, hypomagnesemia, glomerulosclerosis, and many others. TRPV1 has been linked to chronic pain, neuropathies, bladder disorders, irritable bowel syndrome, and gastroesophageal reflux disease, among others.

While the discovery of thermosensitive TRP candidates has greatly enhanced our understanding of transduction mechanisms of thermal stimuli, findings in selective KO animals indicate that additional, yet unknown, transduction mechanisms contribute to thermal sensation. In addition, some important channels involved in touch and painful mechanical stimuli have not been unequivocally identified, and the exact role of TRP channels in mechanotransduction remains to be investigated in depth. Future studies will undoubtedly be focused on gaining insight into thermal and mechanical activation and the role of TRP channels in disease pathophysiology.

Hormonal Contributions to Arousal and Motivation

D Pfaff, The Rockefeller University, New York, NY, USA

Glossary

Appetitive behavior – A word with many meanings, including the variable behavior impelled by internal deficits or any behavior that increases the probability of satisfaction of a need.

Arousal – It determines an organism's responsiveness to sensory stimuli, level of voluntary motor activity, and emotional reactivity.

Consummatory behavior – Any stereotyped behavior pattern supposed to end a sequence of behavior or causes the fulfillment of a need.

Lordosis – Female mating posture consisting of immobility with back arched downward, extended hindlegs, and the tail deflected to the side. In many mammals, this behavior pattern is absolutely dependent on estrogens.

Motivation – A concept referring to the ease by which a behavior is activated as well as the specific direction of behavior and its persistence.

Hormones link the brain with the rest of the body and help to render behavior concordant with the state of the body and with the environment. One of the ways they accomplish this is through changes in specific motivational states such as sexual desire, hunger, or fear. However, they also work through changes in the underlying states of arousal, global central nervous system (CNS) functions that provide for the activation of behavior. This article deals both with specific motivational forces and with generalized CNS arousal.

Motivation

The ability of sex hormones to increase the performance of sexual behaviors, when all other aspects of the experiment are held constant, is proof of the ability of these sex hormones to increase sexual motivation. That is, in the quantitative relations between environmental stimuli and biologically important responses, changes in motivation account for changes in behavioral response when the environment is held constant. For both experimental animals and human behavior, motivational states are subdivided into their specific aspects (e.g., sex, hunger,

thirst, and fear) and their general aspects (accounting for the activation of any behavior). These general aspects usually go under the name 'arousal,' which in turn can be subdivided into specific forms (leading to alertness, attention, etc.) and general forms (including but not limited to the sleep/wake cycle).

The general features of hormonal actions on motivation have been summarized in the form of several principles:

1. Hormones can either increase or decrease motivational states.
2. A single hormone can have many effects.
3. Combinations of hormones may be required for motivational change.
4. Hormonal metabolites may be the motivationally active compounds.
5. There may be optimal hormone concentrations; too much or too little can be damaging.
6. In molecular terms, both membrane-initiated and genomic actions of hormones may be necessary and may synergize with each other.
7. Hormonal effects on motivation may depend on the environmental context.
8. Hormonal mechanisms have been largely conserved from the animal brain into the human brain.

Arousal

It is clear that sex hormones heighten CNS arousal. In female four-footed animals, estrogens cause greatly increased muscular tension and increased locomotion. In male animals, androgenic hormones cause the male to fight for territory and mates, to explore to seek out females, and then to mount them.

Sex hormones are certainly not the only types of hormones that can influence CNS arousal. Consider thyroid hormones, including the chemical form in which the thyroid secretes the hormone, thyroxine (T4), and the chemical form most active at thyroid hormone receptors, triiodothyronine (T3). High levels of these hormones in the human produce nervous, jittery, hyper-aroused individuals. Abnormally low levels produce a sluggish, underaroused patient, a form of disease called myxedema.

The most primitive, elementary form of arousal is called ‘generalized arousal,’ and has been given the following operational definition: a more aroused animal or human being

1. is more responsive to sensory stimuli in all modalities.
2. emits more voluntary motor activity, and
3. is more reactive, emotionally.

Ascending neuroanatomical systems supporting generalized CNS arousal are well known, and include noradrenergic, dopaminergic, histaminergic, serotonergic, and cholinergic systems, augmented by the actions of orexin/hypocretin. All of these systems are influenced by hormones.

A Specific Hormone-Influenced Motivated Behavior, and How Hormone-Influenced Generalized Arousal Influences It

The most complete analysis of a motivated behavior is the estrogen-driven mating behavior of female four-footed mammals. It is called lordosis behavior and constitutes a dorsiflexion of the vertebral column – a sway-backed posture by which the female permits fertilization. Successful analysis of this behavior shows how steroid hormone effects on nerve cells can direct natural, instinctive behaviors.

First, discovering exact cellular targets for steroid hormones in the brain. A system of hypothalamic and limbic forebrain neurons with sex hormone receptors, discovered in rodents, was later found to be present in species ranging from fish through to primates. This hormone-sensitive system is apparently a general feature of the vertebrate brain. *In situ* hybridization studies to distinguish gene expression for estrogen receptor alpha (ER- α) from estrogen receptor beta (ER- β) revealed remarkably different distributions for the two and showed the estrogenic-feedback sensitivity of ER- α gene expression. We have visualized these ER- α -producing cells using modern transgenic techniques: in the ventromedial nucleus (VMN) of the hypothalamus, not only ER- α but also ER- β mRNA can be downregulated by estradiol administration. Use of an adeno-associated viral (AAV) vector encoding a small interfering RNA (siRNA) directed against the mRNA for ER- α allowed us to microinject it into the VMN with the result that proceptive and lordosis behaviors were abolished.

Second, working out the neural circuitry for hormone-dependent female reproductive behavior, the first behavior circuit elucidated for any mammal. Electrical activity in neurons at the top of this circuit, the VMN of the hypothalamus predicts a chemical compound’s ability to influence lordosis. Third, involves the demonstration of several genes that are turned on by estrogens in the forebrain.

Fourth, showing that these gene products facilitate reproductive behavior. For example, the induction of one of them – the gene for the progesterone receptor – showed that the hormone estrogen could activate another transcription factor important, in turn, for behavioral control.

Taken together, these four sets of studies have proved for the first time how specific chemicals acting in specific parts of the brain could determine individual behavioral responses.

How do generalized arousal forces influence hormone-responsive hypothalamic neurons to increase sexual arousal and sexual behaviors? For the female, we have four mechanisms, discovered by biophysical techniques, that work in parallel: histamine and norepinephrine, generalized arousal transmitters, increase the electrical excitability of neurons in the hypothalamic cell group that drive estrogen-dependent sexual behavior. The other two routes are inhibitory. μ -Opioid peptides and prostaglandin D reduce generalized arousal and reduce female sexual behavior.

Lessons

A series of surprising lessons in gene–behavior relations has emerged from a long series of studies using knockouts of ER- α and ER- β genes. (1) The effect of a given gene on a given type of behavior depends on where in the brain and exactly when that gene is expressed. (2) The effect of the ER- α gene on aggressive behavior in males is the opposite of that in females. (3) The effects of ER genes on aggressive and locomotor behaviors can depend upon the age at which the behavioral assay is conducted. (4) The effect of a specific gene on aggressive behavior can depend on the type of aggression tested and the nature of the opponent.

Finally, comparisons of the causal influences of the genes encoding ER- α and ER- β on the reproductive and aggressive behaviors of female and male mice led to the principle that, for the mammalian CNS, we have moved beyond the classical ‘one gene–one enzyme’ concept of George Beadle and Edward Tatum derived from the classical, Nobel-recognized work with *Neurospora*. Instead, for mammalian CNS and behavior we have ‘patterns’ of gene expression governing ‘patterns’ of behavior.

The ‘Appetitive versus Consummatory’ Distinction in Motivated Behaviors

Progress in understanding the hormonal, neuroanatomical, biophysical, and molecular underpinnings of hormone-regulated motivation has been so remarkable that we now can turn back to certain classical intellectual problems in the field and look at them with a new view.

Perhaps the most important is the distinction between appetitive behaviors (ABs) and consummatory behaviors (CBs). Clearly, the CNS arousal systems described above serve both. Because generalized arousal is essential for the activation of any behavior, it is easy to see, for example, in the case of male mating behavior, that a high level of CNS arousal is required for the male to search for and find a female; but then, of course, it is also required to support mounting, erection, and ejaculation.

One of the present authors (DP) subscribes to the AB/CB distinction for three reasons. (1) From a common sense point of view it is intellectually, intuitively appealing. (2) It was useful in the work of the classical ethologists such as Konrad Lorenz and Niko Tinbergen for the description of natural behaviors in the home environments of the animals. (3) From a neuroscientific point of view, it may provide a terminology to help separate out different stages in the production of a motivated behavior and analyze those stages individually. For example, it is clear that preoptic neurons regulate both AB and CB for male sexuality. In some animals, more rostral preoptic region cell groups affect AB, and more caudal, CB. It is a sign of high accomplishment in this field that scientists can turn to this type of question with considerable cellular and molecular data that bear on the issue. Some previous authors have criticized the distinction (1) because they find it difficult to identify a clear boundary between AB and CB; and (2) because in a long chain of behaviors an individual response might be the CB of a preceding behavior and the AB of a subsequent behavior.

The other author (AA) does not think the ‘appetitive/consummatory’ distinction is useful. The reasoning behind this rejection is straightforward, but it needs to be put into a context in order to be comprehensible. Basically, we need to accept that behavior is a sequence of motor patterns. These motor patterns are frequently classified in categories based on prominent and/or stereotyped actions. Motor patterns characteristic of food ingestion can be grouped under the label eating, while motor patterns typical of copulation can be grouped under the label sexual behavior, for example. However, before executing the stereotyped movements associated with food consumption or copulation, an animal needs to detect and approach food or a mate. The motor patterns displayed while approaching food or a mate are highly variable. In fact, they are determined by the context. Furthermore, identical motor patterns may be employed for approaching different kinds of stimuli. Thus, while the motor patterns displayed during actual commerce with a stimulus like food or a mate are highly specific for that particular stimulus, motor patterns leading to approach are independent of the stimulus activating them.

It might intuitively appear convenient to label the variable approach behaviors appetitive and the ensuing stereotyped behaviors consummatory. However, the

common use of the terms appetitive and consummatory rarely coincides with this distinction. In the case of female rat sexual behavior, some stereotyped patterns like ear wiggling and hop-darting, behaviors specifically activated by proximate stimuli from the male, are frequently considered appetitive, while another stereotyped motor pattern, lordosis, equally activated by proximate stimuli provided by the male, is considered consummatory. The logic behind that distinction is impenetrable unless we accept that the term consummatory means fulfillment. Lordosis is a motor pattern making vaginal penetration possible, thereby eventually allowing the male to deposit sperm which would represent the fulfillment of the biological purpose of copulation. However, a female rat will display lordosis in response to a male’s mount during the entire period of proestrus, essentially irrespective of how many ejaculations she might have received. Thus, the purported fulfillment associated with lordosis resides in the eyes of the beholder and not in the female rat’s brain.

Furthermore, the fact that the female continues to display lordosis as long as her brain is exposed to adequate amounts of ovarian hormones excludes another use of the term consummatory, namely acts that bring a behavior sequence to an end. The display of one lordosis does not reduce the likelihood for the display of a second or third, and so on. Likewise, the attainment of one ejaculation in a male rat does not reduce the likelihood of attaining a second or third in rapid succession. The inevitable conclusion is that it is no exaggeration to maintain that the concept of consummatory behavior is arbitrary, in the same way as appetitive behavior.

A most illustrative example of this arbitrariness would be an animal walking from a very hot place to a place with a temperature close to the thermoneutral zone. Whether the behavior of walking is appetitive or consummatory is impossible to determine. It is appetitive because it brings the subject into contact with a desirable end-state, and it is consummatory because it fulfills the biological purpose of behavioral thermoregulation (and, coincidentally, ends the behavioral sequence). How we decide to label the walking behavior becomes a matter of personal inclination, which is an undesirable situation in science.

Terms with many simultaneous meanings are always a source of confusion, and they probably obscure the understanding of basic behavioral processes. Consequently, if we wish to persist in the habit of subdividing the continuous flow of behavior into categories, this division should at least not be based on the empirically void distinction between appetitive and consummatory. It could be based upon the distinction between arbitrary approach behaviors – independent of the stimulus being approached – and specific stereotyped behaviors activated by the stimulus, as already suggested. Such a distinction coincides with current knowledge of brain function. There are several examples of experimental manipulations affecting the stereotyped

behaviors activated by a specific stimulus while leaving the variable approach behaviors to that same stimulus intact. Although both kinds of behaviors ultimately depend on adequate motivation and general arousal, approach is controlled by distant stimuli while the stereotyped behaviors are activated when the stimulus source is in close proximity.

It is even likely that the variable approach behaviors are controlled by stimulus modalities different from those controlling the stereotyped motor patterns displayed when in direct contact with the stimulus. In the female rat, for example, olfaction is essential for approach to a mate, while tactile stimuli control lordosis. No wonder, then, that the central nervous circuits controlling approach are partly different from those controlling lordosis. However, when a behavior is influenced by hormones, both the variable approach behaviors and the stimulus-specific stereotyped behaviors seem to be affected by the same hormone, and it is possible that hormone action at a single brain site controls both.

Incentive Motivation and Incentive Salience

Glossary

Hedonic impact ('liking') – Hedonic impact or 'liking' corresponds to activation of brain mechanisms that generate the pleasure of a reward. Hedonic generating mechanisms are sometimes called 'hedonic hotspots,' and include cubic-millimeter sites in the nucleus accumbens and ventral pallidum where opioid and endocannabinoid signals can amplify 'liking' for sweet tastes and related sensory pleasures.

Incentive salience ('wanting') – Incentive salience is a form of motivation, sometimes called 'wanting,' that is generated by brain mesolimbic systems involving dopamine. Incentive salience is actively attributed to brain representations of reward stimuli and their associated cues. Attribution makes those stimuli and cues become attention grabbing and perceived as attractive or 'wanted,' and able to elicit behavioral approach and pursuit. Under some circumstances, incentive salience can occur without conscious desire, resulting in unconscious 'wanting.'

Incentive sensitization – A brain-based theory of addiction, which posits that drugs produce long-term sensitization changes in brain mesolimbic dopamine-related systems that mediate 'wanting' or incentive salience for rewards. Sensitization produces increases in 'wanting' to take drugs, without necessarily increasing 'liking' for the same drugs. Sensitization may last years after drug use is stopped. Sensitized 'wanting' may thus cause relapse back into drug taking, even for drugs that will not cause much pleasure, and even if the addict no longer suffers from withdrawal.

Many types of evidence combined against reduction concepts, but perhaps the single most important line of evidence against drive reduction concepts, came in the 1960s from studies of brain stimulation reward and related studies of motivated behavior elicited by "free" brain stimulation. A single electrode in the lateral hypothalamus could both elicit motivated behavior (if just turned on freely) and have reward or punishment effects (if given contingent on the animal's response). Many behavioral neuroscientists of the time believed in drive reduction theory. So, at first, they expected to find that brain sites where stimulation would reduce eating (presumably by reducing drive) would also be the sites where stimulation was rewarding (again, presumably by reducing drive). Conversely, they believed the opposite would be true too. They expected to find that punishing electrodes would sometimes activate drives such as hunger.

Surprisingly to most behavioral neuroscientists of the era, the theory was not true, and many of the predictions based on it turned out to be wrong for explaining natural motivations such as hunger, thirst, or sex. In most cases, the opposite results were found instead. The brain sites where the stimulation caused eating behavior were almost always the same sites where stimulation was rewarding. Eating electrodes were not punishing electrodes. Instead, the eating electrodes were reward electrodes. Stimulation-induced reward and stimulation-induced hunger drive appeared identical or, at least, had identical causes in the activation of the same electrode. This meant that the reward of the lateral hypothalamic electrode could not be due to drive reduction from the same electrode. Instead, the reward electrode increased the motivation to eat; it did not reduce that drive. In other words, the reward must be understood as a motivational phenomenon of its own independent from drive reduction, involving its own active brain mechanisms.

Today, the active brain mechanisms of incentive motivation for reward are the topic of much research in affective neuroscience. Incentive motivation concepts rose as drive concepts fell beginning in the 1960s. One of the most useful incentive concepts is the Bolles-Bindra-Toates theory of incentive motivation. The theory posits that individuals want and like the cues that predict pleasant rewards (pavlovian conditioned stimuli), much as they ant and like the rewards themselves (food, drink, sex, drugs, etc.; pavlovian unconditioned stimuli).

This incentive motivation concept was the psychological forerunner of the incentive salience concept. The

Incentive Motivation Concepts: From the Ashes of Drive Reduction

Up until the 1960s, drive reduction reigned as the chief concept for explaining motivation. It posited that brain mechanisms of motivation acted chiefly to reduce aversive drives. However, to a large extent today drive reduction concepts have been largely replaced by incentive motivation concepts for natural motivations such as hunger, thirst, and sex. In several ways, incentive motivation explains more of the data from more experiments than drive reduction.

neurobiological forerunners of incentive salience were hypotheses that brain mesolimbic dopamine systems mediated the pleasure of rewards and the appetitive motivation to obtain them. The incentive salience concept essentially adopted the Bolles–Bindra–Toates formulation for how incentive motivation worked but split it into separate ‘liking’ and ‘wanting’ concepts, stripped the pleasure ‘liking’ role from dopamine, and assigned dopamine to a specific ‘wanting’ role.

Incentive Salience as a ‘Wanting’ Module

Incentive salience is a ‘wanting’ module: it is a particular subcomponent of what is ordinarily meant by the word, wanting. Incentive salience has evolved to add a visceral ‘oomph’ to mental desires. This is part of what makes ‘wanting’ a unique module and quite different from wanting (no quotation marks) in the usual sense of the word as a conscious, cognitive desire. That is why the author and his colleagues have put quotation marks around ‘wanting’ when writing about incentive salience. Ordinarily, incentive salience ‘wanting’ is congruent with other forms of desire such as cognitive wanting, and is also congruent with the hedonic pleasure or ‘liking’ of the outcome. But dissociations can occur among all of these utility forms, and when they do incentive salience is revealed as a distinct module of desire.

Comparison to Ordinary Meaning of the Word Wanting

How does ordinary wanting in the usual sense of desires differ from ‘wanting’? Ordinary cognitive desires involve explicit thoughts of the target or reward. In cognitive desires, or wanting in the ordinary sense without quotation marks, you know what you want, or at least think you do, you expect to like the wanted target, and you may have some idea of how you intend to get it. Such desires are guided by explicit memories of how nice the target was in the past, or if never before experienced then at least on imagination of what it would be like to experience.

By contrast, none of this cognition needs to be part of incentive salience ‘wants.’ Incentive salience is a percept-bound type of ‘wanting,’ which typically occurs as relatively brief peaks upon encountering a reward or a physical reminder of the reward (a cue). Incentive salience does not require a clear cognition of what is wanted, and does not even need to be consciously experienced as a feeling of wanting, at least in some cases (though when it is brought into consciousness, it can considerably intensify feelings of desire). Perhaps a reason for the difference is that incentive salience is mediated chiefly by mesolimbic dopamine-related brain mechanisms which are largely

subcortical, whereas cognitive forms of desire are more dependent on higher cortex-based brain systems. Incentive salience may have evolved using ‘early’ brain systems as a distinct ‘wanting’ module to pursue particular innate incentives. Possibly, it gave an elementary form of goal directedness, which could guide behavior in the right direction in advance of experiencing the goals. Later in evolution ‘wanting’ may have become harnessed to serve ‘liking’ and learned features of reward, so that most incentive salience in our lives today is probably attributed to learned reward cues.

Incentive salience as a module is only one type of wanting. It is not the one we are most aware of in daily life, because our awareness or consciousness of desire focuses on our cognitive representations of potential rewards. Cognitive representations of reward can be different from more basic incentive salience (as when you cognitively believe a reward will be bad for you, but you still ‘want’ it). However, incentive salience is important in daily life, needed to color conscious desires with motivational power, to make them compelling spurs to action. It may be a crucial component of our most intense and visceral desires, and especially important in the pathological intensity of some addictions and compulsive desires.

Incentive salience can be viewed as a motivational transform of a brain signal corresponding to the perceived object of desire or its mental. When attributed to a stimulus representation, incentive salience transforms the mere sensory shape, smell, or sound into an attractive and attention-riveting incentive. Once attributed, the incentive percept becomes difficult to avoid noticing, the eyes naturally move toward the incentive, it captures the gaze and becomes motivationally attractive, and the rest of the body may well follow to obtain it.

Signature Psychological Features of ‘Wanting’

How can incentive salience be recognized? There are several distinguishing psychological features that help it be recognized even in animal experiments as well as in human daily life. Incentive salience gives a ‘motivational magnet’ property to stimuli it is attributed to, and makes those stimuli attractive, ‘wanted,’ and potently able to elicit approach. Incentive salience also triggers momentary peaks of intense motivation to obtain a cued reward. Such features (reward cues becoming motivational magnets, cues as objects of desire, peaks of cue-triggered ‘wanting’ for the actual reward) allow us to recognize incentive salience in behavioral neuroscience experiments with animals as well as in people.

In many relevant neuroscience experiments, the brains of rats or mice are manipulated in painless ways that alter the operation of underlying substrates for ‘wanting.’ For

example, microinjection of tiny quantities (a two-thousandth of a milliliter) of amphetamine solution is directed into a targeted brain structure, such as the nucleus accumbens, or into its major target, the ventral pallidum. The drug stimulates dopamine release by neurons in the target brain site.

When activated by a brain microinjection, the chief features of incentive salience that become enhanced are cue-triggered ‘wanting’ for rewards, the potency of reward cues as motivational magnet, and their potency as conditioned reinforcers. These features are described below.

Cue-Triggered ‘Wanting’: Temporary Peaks of Desire

One feature of incentive salience is to endow reward-related cues (in experiments these are pavlovian conditioned stimuli or CSs) with ability to trigger powerful peaks of ‘wanting’ for their own associated reward. For example, the scent of food may suddenly make you ravenous as lunchtime approaches even if you were not feeling particularly hungry moments before that cue occurred. The tinkling sound of an email arriving in your computer inbox may trigger a sudden urge to check the message. In all such cases, cue-triggered ‘wanting’ occurs as a temporary peak, bound to a particular encounter with a cue or to a vivid mental image of the reward. Peaks of cue-triggered ‘wanting’ are sudden, intense, temporary, reversible, and repeatable.

Behavioral neuroscience experiments have dramatically amplified cue-triggered ‘wanting’ by stimulating brain mesolimbic dopamine systems. The most specific way to do that is by placing a tiny droplet of amphetamine drug in the nucleus accumbens. Amphetamine causes the ends of dopamine-containing neurons to release extra amounts of dopamine onto their target neurons. The psychological result is typically to increase the incentive salience that cues trigger for their reward without altering other components of desire or reward. In such experiments, a rat’s brain would have been constantly flooded with dopamine after an amphetamine microinjection, yet its ‘wanting’ came and went with the coming and going of the physical cue for sugar. Incentive salience thus reflects a synergy between brain states of mesolimbic activation and particular events happening in the world. Both must be present to trigger the ‘want.’ These constraints of operation help show the psychological boundaries of the ‘wanting’ module and reveal it as just one among several psychological mechanisms of desire – albeit a powerful one when present.

Cues as Motivational Magnets: Good Enough to Eat

A second feature of incentive salience is that its attribution to a reward-related stimulus may make that stimulus ‘wanted,’ even if the stimulus is just the cue. The pavlovian

CS stimulus becomes an attractive ‘motivational magnet’ itself, in addition to triggering ‘wanting’ for its hedonic reward, although the CS cue is only a learned predictor for the reward that has little to no intrinsic value of its own. In a sense, a cue can even become ‘good enough to eat.’ For example, incentive salience may make a rat try to ‘consume’ a metal object whose presence predicts sugar, with nibbles and sniffs of the metal cue that are similar to movements used in eating actual sugar. Cues for other rewards become attractive in their own ways. Crack cocaine addicts, for instance, have been reported to compulsively ‘chase ghosts’ when they have no cocaine, that is, to scrabble around on the floor after tiny whitish specks under the table, even if they know the specks are more likely to be sugar. They are chasing a visual cue for cocaine: white specks. Such motivational magnet features of attractive cues are made much more potent by activation of mesolimbic systems, such as the amygdala or nucleus accumbens. Motivational magnet features of reward cues may account for a host of phenomena in which individuals become pulled toward reward cues acting as beacons to guide brain motivation systems.

Conditioned Reinforcers: Working to Obtain the Cue

A related mark of a motivational magnet cue is that individuals may ‘want’ to possess that cue, just as they ‘want’ its hedonic reward. Animals in an activated brain state will work harder to obtain a CS or cue that is attributed with incentive salience, just as they would work to obtain the actual reward. This is sometimes called conditioned reinforcement.

Unconscious Aspects of Incentive Salience ‘Wants’

Another way in which incentive salience diverges from intentionality, as well as from the ordinary sense of explicit desire that one is aware of, is that it need not always be conscious. Examples of unconscious core ‘wanting’ have been demonstrated people ranging from drug addicts to ordinary college students.

Brain Bases of Incentive Salience

Incentive salience is generated chiefly by subcortical brain circuits, especially the mesocorticolimbic dopamine system. Other neurotransmitters important to incentive salience include opioids (natural brain neurochemicals similar to poppy-derived opiate drugs such as opium, heroin, or morphine) which can also cause ‘liking’ as well as ‘wanting’ when delivered into cubic-millimeter

hedonic hot spots in nucleus accumbens or ventral pallidum, glutamate from the brain cortex and from amygdala, thalamus and hippocampus, and gamma aminobutyric acid (GABA) from many sources. We have often used dopamine and opioid activations in mesolimbic structures to turn on incentive salience in our laboratory. The dopamine neurons project from the midbrain where their neuronal cell bodies are sending axon fibers upwards to nucleus accumbens, other parts of striatum, amygdala, and prefrontal neocortex. Opioid enkephalin neurons exist within these structures themselves, and other opioid neurons enter as beta-endorphin neurons from the arcuate nucleus of the hypothalamus. Amygdala and cortex neurons project down to nucleus accumbens, forming a common interchange there. Nucleus accumbens in turn projects downwards to ventral pallidum and eventually up again into prefrontal cortex, and also again back down to midbrain, where the process can start over, forming recursive loops for reward-related signals.

Manipulations of dopamine neurotransmission have proven especially useful in manipulating and isolating incentive salience to reveal its psychological features. Elevations in dopamine, more than other neurotransmitters in this system, appear to selectively activate ‘wanting’ as a psychological function. Manipulations that selectively boost brain mesolimbic dopamine signals tend to specifically increase ‘wanting,’ without necessarily increasing other reward aspects such as ‘liking’ or hedonic pleasure, or other motivation aspects such as cognitive desires. In addition to activating dopamine systems by direct drug administration, it is also possible to make them permanently hyper-reactive by inducing what is called neural sensitization via a repeated series of binges with addictive drugs. Neural sensitization of mesolimbic systems by drugs causes a similarly selective but enduring enhancement of cue-triggered ‘wanting.’ Thus, it is a useful shorthand to think of brain dopamine systems as powerfully controlling ‘wanting’ (though other neural stages of the mesocorticolimbic circuit are involved too).

Addiction and Incentive Sensitization

Human drug addiction may be a special illustration of intense “wanting” that results from permanent sensitization of mesocorticolimbic. Sensitized ‘wanting’ may rise to quite irrational levels. That is, the intensity of cue-triggered ‘wanting’ to take drugs for brain-sensitized addicts could outstrip their ‘liking’ even for pleasant drugs, outstrip their expectation of how much they will like the drugs, and outlast any feelings of withdrawal if they stop. Brain-sensitized addicts may be unable to give a reason for their drug taking in such a case. Indeed, there is no reason; there is only a cause for why they ‘want’ so much. Sensitization is a second reason besides withdrawal

escape for why addicts are so prone to relapse. Sensitization also lasts much longer, and may possibly be permanent, and so it may especially contribute to relapse in ‘recovered’ addicts who have already succeeded through detoxification therapy. Even though a sensitized addict may no longer experience strong withdrawal symptoms, they will be vulnerable to intense peaks of cue-triggered ‘wanting’ to take drugs again.

Sensitization of mesolimbic systems arises as a permanent change that addictive drugs can produce in the brains of susceptible individuals. Sensitization increases the neurochemical responsiveness of these neurons and can even change their physical shapes. Individual susceptibility is determined by genetic factors, hormonal factors, previous drug experiences, and previous experiences with major stresses in life. Sensitization is also influenced by drug dose and the speed with which it reaches the brain, and is facilitated most when the drugs are taken in binges. Neural sensitization of mesolimbic dopamine systems means that the brain system becomes hyper-reactive to drugs. The system is not constantly hyperactive in a stable fashion, but it can be put temporarily into a hyperactive state by reaction to the drug again or to related cues: it is hyper-reactive to particular stimuli. Sensitization of mesolimbic systems may create compulsive levels of ‘wanting’ for drugs or other addictive incentives. A sensitized brain responds with extra incentive salience to reward cues just as a brain that has been drugged with amphetamine does – even if the sensitized brain has no drug on board at that moment. A sensitized addict’s brain, on encountering the right drug cue, would irrationally “want” the cued reward at that moment because of excessive incentive salience – even if the person cognitively expected not to like it very much and eventually did not like it much in the end. Crucially, sensitization may last years after an individual stops taking any drugs.

‘Liking’: Hedonic Hot Spots for Generating Pleasure

Different from ‘wanting’ is ‘liking’ or the core process of hedonic pleasure. A much more restricted brain circuit appears to mediate hedonic ‘liking’ than incentive ‘wanting.’ The generation of pleasure ‘liking’ is more restricted neurochemically: opioid stimulation but not dopamine stimulation (whereas ‘wanting’ is enhanced by both). ‘Liking’ is also more restricted anatomically: enhanced by opioid ‘hot spots,’ which are about a cubic millimeter in the brains of rats and probably about a cubic centimeter in human brains, but not by the rest of the same limbic structure that contains the hot spot (even if the entire structure can enhance ‘wanting’). ‘Liking’ generation is also more restricted as a brain circuit, requiring unanimous activation of multiple hot spots simultaneously

(whereas ‘wanting’ can be enhanced by a single hot spot). In short, enhancement of pleasure ‘liking’ is fragile, and brain pleasure systems are relatively recalcitrant to activation compared to ‘wanting’ systems. Consequently, our limbic mechanisms may consign us more often to states of desire than of pleasure.

Conclusion

‘Wanting’ a reward is distinct from ‘liking’ the same reward. The two can sometimes diverge, and notably, ‘wanting’ can become unjustifiably high in certain circumstances. The identity of incentive salience as a distinct module within desire creates conditions under which in some cases, such as addiction, incentive salience ‘wanting’ to persist in the face of a fully sincere cognitive intention to do the opposite.

Motor Function and Motivation

J D Salamone, University of Connecticut, Storrs, CT, USA

Glossary

Effort – The conscious exertion of power; work done to achieve a particular end.

Energy – The capacity of acting or being active; vigorous exertion of power: i.e., effort.

Motivation – The set of processes through which organisms regulate the probability, proximity and availability of stimuli; motivation has both directional and activational aspects.

Work – The sustained physical or mental effort to overcome obstacles and achieve an objective or result.

Thus, when discussing motivation it is useful, even necessary, to understand the relation between motivational processes and other important concepts such as homeostasis, allostasis, emotion, cognition, learning, reinforcement, and sensation. For this article, the primary focus is upon the fundamental relation between motivational and motor functions.

Psychological constructs persist in the literature because they are useful; the main utility of the construct of motivation is that it provides a convenient summary and organizational structure for observable features of behavior. It is often said that behavior is directed in relation to particular stimuli, many of which can be referred to as goals. More broadly, the behavior of organisms is directed toward or away from particular stimuli, as well as activities that involve interacting with those stimuli. Organisms seek some stimulus conditions (i.e., food, water, and sex) and avoid others (i.e., pain, stress, and discomfort), both actively and passively. Another important feature of motivated behavior is that it typically takes place in phases. The terminal stage of motivated behavior, which reflects the direct interaction with the goal stimulus, is commonly referred to as the consummatory phase. The word consummatory, which often is associated with Craig, does not refer to consumption, but instead to consummation, a word of French/Latin origin; to consummate means to complete or to finish. In view of the fact that motivational stimuli usually are available at some physical or psychological distance from the organism, the only way to gain access to these stimuli is to engage in a pattern of behavior that brings them closer, or makes their occurrence more probable. This phase of motivated behavior often is referred to as appetitive, preparatory, or instrumental. The word instrumental was suggested for this specific purpose because it is equally applicable for both approach and avoidance behavior, and also because the term already is widely used in psychology (i.e., instrumental behavior or conditioning).

In addition to directional aspects of motivation, another fundamental feature of motivated behavior is that it has activational aspects. Because organisms are usually separated from motivationally relevant stimuli by a long distance, or by various obstacles or work-related response costs, engaging in instrumental behavior to obtain access to these stimuli typically involves work. Whether it is foraging in the wild or running in a maze, whether it is a rat pressing a lever in an operant chamber, or a human walking several blocks to reach a soda

Motivation is a term that is widely employed in psychology and neuroscience, which has been discussed in many different contexts and defined in several different ways. Like many psychological concepts, the discussion of motivation had its origins in philosophy. For example, in describing motivational causation, the German philosopher Schopenhauer considered how organisms must be in a position to “choose, seize, and even seek out the means of satisfaction.” Since the emergence of modern psychological sciences, motivation has been a core area of interest. Early psychologists such as Wundt and James included motivation as a subject in their texts. Although Skinner did not place much emphasis on motivation, viewing the concept as largely unnecessary, neobehaviorists such as Hull and Spence readily applied motivational concepts such as drive and incentive. In his book *Motivation and Emotion*, P.T. Young defined motivation as “the process of arousing actions, sustaining the activity in progress, and regulating the pattern of activity.” According to a more recent definition, motivation is “the set of processes through which organisms regulate the probability, proximity and availability of stimuli.” Broadly speaking, the modern psychological construct of motivation refers to the behaviorally relevant processes that enable organisms to regulate both their external and internal environment. Although we can define motivation in terms that make it distinct from other concepts or constructs, it should be recognized that, in fully discussing either the behavioral characteristics or neural basis of motivation, one must also consider related functions. The brain does not have little dotted lines or box-and-arrow diagrams that neatly separate core psychological functions into discrete, nonoverlapping neural systems.

machine, an animal must allocate resources toward stimulus-seeking behavior. Motivated behavior is therefore characterized by considerable effort, that is, speed, vigor, persistence, and high levels of work output. Although the exertion of this effort can at times be relatively brief (e.g., a predator pouncing on its prey), under many circumstances it must be sustained over long periods of time (combing over large areas while foraging, maintaining operant behavior across long sessions). These effort-related capabilities are highly adaptive, because in the natural environment survival value can depend upon the extent to which an organism can overcome work-related response costs. For these reasons, the notion that behavioral activation is a fundamental aspect of motivation has been a persistent feature of the literature in psychology and animal behavior for several decades. Early studies of the neural basis of emotion and motivation highlighted the importance of arousal and energy mobilization. Hull and Spence used the concepts of drive and incentive to emphasize the energizing effects of motivational conditions on measures of instrumental behavior, such as run speed in a maze. Cofer and Apley suggested that there was an anticipation–invigoration mechanism that could be activated by conditioned stimuli, and which functioned to invigorate instrumental behavior. Scheduled noncontingent presentation of primary motivational stimuli such as food can induce various activities, including drinking, licking, locomotion, and wheel running. Several researchers have studied the impact of work requirements on the performance of an instrumental task, which ultimately helped to lay the groundwork for the development of economic models of operant behavior. Ethologists also have employed similar concepts. Animals foraging in the wild sometimes need to exert considerable energy in order to obtain access to food, water, or nesting material, and optimal foraging theory was proposed to account for the fact that the amount of effort or time expended to obtain these stimuli was an important determinant of choice behavior. In humans, pathological aspects of behavioral activation processes also have considerable significance for clinical psychologists and psychiatrists. Fatigue, anergia, and psychomotor slowing are common symptoms of depression, and can also be present in a number of other psychiatric or neurological disorders.

As noted above, motivational processes do not stand alone, but instead should ultimately be viewed in the overall context of related psychological functions. For example, instrumental behavior is not only influenced by the motivational properties of reinforcing stimuli. Learning obviously is extremely important as well. Animals learn to engage in specific instrumental responses that are associated with particular reinforcing or punishing outcomes; effectively, organisms must learn which responses lead to which stimuli. Furthermore,

behavioral activation often is instigated by conditioned stimuli that predict motivational outcomes. In various ways, motivational functions are intertwined with cognitive, emotional, and other functions. A thorough review of all these diverse features of motivation is beyond the scope of this article. Instead, the primary focus is on the relation between motivational and motor functions. Of course, in some basic sense, every behavioral activity is fundamentally related to motor control. Consummatory activities such as food intake involve organized patterns of motor activity, such as food handling, chewing, and swallowing. However, it is particularly evident that activational aspects of motivation directly reflect features of motor output. Indeed, there is a considerable degree of conceptual overlap between motor control and activational aspects of motivation, as well as functional overlap in terms of the behavioral parameters measured and the neural systems involved.

Illustrative examples of the relation between activational aspects of motivation and motor control processes can be seen in numerous behavioral tasks. Food deprivation can make a rat run faster in a maze. Is the fundamental process in operation under these conditions motivational, motoric, or some combination of both? Locomotor activity clearly involves actions of the neural systems that regulate movement. Nevertheless, locomotor activity also is very sensitive to the impact of motivational conditions. Enhanced locomotor activity in rats can be induced by novelty or food deprivation. Furthermore, scheduled presentation of small food pellets to a food-deprived rat can generate excessive wheel running, or levels of locomotor activity comparable to those seen after administration of amphetamine. In addition, if an organism is presented with a work-related challenge during instrumental performance, it often responds to that challenge by exerting greater effort. When a rat that has been trained to lever press on a continuous or fixed ratio, 1 reinforcement schedule (1 lever press yields 1 food pellet) is then shifted to a schedule with a higher ratio requirement (e.g., fixed ratio 5; 5 lever presses yield 1 food pellet), this increased work requirement creates a substantial upward pressure on response rates. Indeed, if over multiple sessions the ratio requirement were to continue to get increase, up to levels such as fixed ratio 60 or more, the rat would eventually display a radical shift in its response speed, emitting thousands of lever presses per half hour, with the vast majority of responses occurring at local rates considerably faster than once every 500 ms. Similarly, if a rat trained to run in a maze for food reinforcement is suddenly confronted with a barrier that blocks the maze arm, it quickly adjusts its behavior and leaps over the barrier to obtain the food. If, over subsequent sessions, the barrier gets larger and larger, the rat continues to adjust to the challenge and climb the barrier. It is as though portions of the neural systems that regulate

motor output operate at the behest of those neural systems that direct behavior toward or away from particular stimuli.

The examples listed above illustrate precisely why scholars in this field have found it to be useful and important to emphasize the activational components of motivation. This is why Young defined motivation in terms of arousing actions and sustaining activity, and why Cofer thought it so necessary to posit that there was a mechanism allowing for the ability of conditioned stimuli to invigorate instrumental behavior. Conceptually, the examples listed above highlight the necessity of recognizing that there is a basic overlap between motor control and motivational processes. Of course, the terms motor control and motivation do not have exactly the same meaning. Moreover, one can easily find points of nonoverlap. For example, parkinsonian tremor is clearly more in the realm of movement control, while initiation of osmotic thirst by activation of osmoreceptive cells is more related to directional aspects of motivation. Nevertheless, it is also evident that there is a fundamental overlap as well. For that reason, it is illuminating to consider that the English words motivation and movement both are ultimately derived from the Latin word *move*, to move (i.e., *moti* is the past participle of *move*).

Over the last several decades, behavioral neuroscientists have intensively studied the brain mechanisms thought to be involved in various aspects of motivation. Considerable research and scholarship in this area has come to place emphasis on the role of nucleus accumbens as a point of functional overlap between brains systems involved in aspects of motivation and those involved in motor control. In a seminal paper aptly entitled "From motivation to action: functional interface between limbic system and the motor system," Mogenson and colleagues identified the nucleus accumbens as a point of functional interaction between limbic brain areas involved in motivation, emotion, and cognition and basal ganglia regions involved in generating behavioral output. In particular, nucleus accumbens dopamine (DA) has been strongly implicated in activational aspects of motivation and effort-related processes. As described above, scheduled presentation of food pellets to food deprived animals can induce high levels of various activities, including wheel running, drinking, and locomotion. Evidence indicates that these environmental conditions are associated with substantial increases in accumbens DA release, and also demonstrates that low doses of DA antagonists and accumbens DA depletions can block these schedule-induced activities. In contrast, interference with nucleus accumbens DA transmission, even at a level that can impair spontaneous or schedule-induced locomotor activity, generally has no effect on food consumption, little effect upon food-reinforced fixed ratio 1 performance, and minimal actions upon the discrimination of reinforcement magnitude in maze choice tasks. It has also

been reported repeatedly that the effects of accumbens DA depletions on various operant procedures are substantially different from those of pre-feeding and appetite suppressant drugs. Taken together, this evidence of fundamental aspects of food motivation being preserved after interference with accumbens DA transmission has been used to support the hypothesis that nucleus accumbens DA depletion or antagonism can impair activational aspects of motivation while leaving directional aspects largely intact.

Furthermore, the effects of nucleus accumbens DA depletions on food-reinforced operant behavior depend greatly upon the requirements of the instrumental response. Accumbens DA depletions have little effect on total response output with rats responding on a fixed ratio 1 schedule; their main impact is to produce an initial slowing of responding that does not closely resemble extinction. Similarly, nucleus accumbens DA depletions exert little influence upon performance of variable interval schedules, such as variable interval 30, 60, or 120 s. Overall, the primary pattern of effects that has been observed is that nucleus accumbens DA depletions affect food-reinforced operant responding in a manner that is directly related to the ratio requirement of the schedule. Although fixed ratio 1 performance shows little sensitivity to the effects of accumbens DA depletions, schedules with higher ratio requirements (fixed ratios of 16 and 64 in one study, or up to 200 to 300 in another) are substantially impaired by interference with accumbens DA transmission. Essentially, nucleus accumbens DA depletions produce two effects on food-reinforced ratio performance: they reduce responding on schedules that have moderately high ratio requirements, and they dramatically suppress responding on schedules with very high ratio requirements, a phenomenon known as ratio strain. In other words, nucleus accumbens DA depletions suppress the response enhancing effects of moderate size ratio requirements, and enhance the response suppressing effects of large ratios.

There are several noteworthy features of the effects of accumbens DA depletions on ratio lever pressing performance. First of all, the reduction of overall responding that occurs when there are low-to-moderate size ratio requirements is directly related to the baseline rate of responding; the higher the response rates, the greater the diminution of responding. Second, the reduction in responding appears to have two major components: there is a slight decrease in the local rate of responding as reflected by alterations in the interresponse times, and a very substantial increase in the number and duration of pauses in responding. Thus, lever pressing becomes more fragmented or disengaged. Another feature of the effects of accumbens DA depletions on ratio performance is that the overall pattern of effects of DA depletion is completely different from the overall pattern of effects observed

after pre-feeding to reduce food motivation. Finally, the ratio strain that develops with very high ratios (i.e., fixed ratio 200–300) appears to be relatively independent of the rate of responding, and more dependent upon the sheer size of the ratios.

In addition to being involved in the exertion of effort in response to work-related obstacles or challenges, nucleus accumbens DA is also involved in effort-related choice behavior. An animal in a complex environment can select from alternative sources of food and other motivational stimuli. There are diverse paths for obtaining each of these stimuli, and each distinct trajectory can entail different response requirements related to time, work, and other parameters. Several behavioral paradigms have been developed that assess how animals allocate resources based upon analyses of reinforcement value and response cost. In some studies, a concurrent lever pressing chow feeding procedure is employed. With this task, animals can choose between lever pressing for a more preferred food reward (e.g., high carbohydrate operant pellets) versus approaching and consuming a less preferred food, such as common laboratory chow. Performance on this task is affected by the ratio requirements on the lever pressing component, thus demonstrating some degree of sensitivity to the work load placed on the operant schedule. Importantly, with rats responding on a fixed ratio 5 schedule for the preferred reward, untreated animals generally get most of their food from lever pressing. Several studies have shown that accumbens DA depletions or antagonism shift the choice behavior of these animals, decreasing lever pressing and substantially increasing chow intake. This pattern of effects is not produced by prefeeding or appetite suppressant drugs. Another commonly used procedure is a T-maze task; the two arms of the maze can have different reinforcement densities (e.g., 4 vs. 2 food pellets, or 4 vs. 0), and under some conditions a 44 cm barrier can be placed in the arm with the higher reward density to present a work-related challenge to the animals. When there is no barrier present in the arm with the high reinforcement density, untreated rats generally prefer that arm, and neither haloperidol nor accumbens DA depletions affect preference of the arm with the higher reward density. In contrast, DA antagonism and accumbens DA depletions dramatically alter choice behavior when the high density arm (four pellets) has the barrier in place, and the arm without the barrier contains an alternative food source (two pellets); rats with impaired DA transmission show decreased choice of the high density arm (i.e., reduced barrier climbing), and increased choice of the low density arm without the barrier. Researchers also have developed lever pressing and T-maze versions of effort discounting tasks, and the results all point in the same direction, that is, interference with DA transmission alters effort-related choice behavior across a wide variety of tasks. These findings indicate that manipulations that affect nucleus

accumbens DA transmission set constraints on effort-related choice behavior, biasing animals toward low cost alternatives.

The effects of nucleus accumbens DA depletions on exertion of effort and effort-related choice behavior in food-motivated tasks do not appear to be dependent upon a general reduction of appetite for food, or an incapacity to respond, or the induction of severe motor impairments. Nucleus accumbens DA depletions alter response output across different ratio schedules in a manner that does not closely resemble the effects of prefeeding. Similarly, the effects of accumbens DA antagonism and DA depletion on effort-related response allocation in the concurrent lever pressing/chow feeding procedure do not mimic the actions of prefeeding or appetite suppressant drugs. Rats with nucleus accumbens DA depletions show normal levels of food intake, and also show normal patterns of reaching, grasping, and food handling. Furthermore, injections of DA antagonists into nucleus accumbens core or shell subregions, which alter choice behavior in the concurrent lever pressing chow feeding task, do not affect the form of lever pressing by increasing lever press duration. The shift from lever pressing to chow intake observed in the concurrent fixed ratio 5/chow feeding choice task can be observed in animals with mild DA depletions that do not show impaired lever pressing on the fixed ratio 5 schedule, indicating that these DA depleted rats are capable of responding, and are therefore choosing to select lab chow over lever pressing, when both are concurrently available. Similarly, the ratio strain induced by accumbens DA depletions is not just occurring because of a ceiling on response rates, DA depleted rats responding on a fixed ratio 64 schedule actually press less than DA depleted rats responding on a fixed ratio 16. In a variant of the T-maze choice task in which the barrier arm contained four pellets, but the other arm contained no pellets (i.e., the only way to get food was to climb the barrier), rats with accumbens DA depletions still chose the high density arm, climbed the barrier, and consumed the pellets. Taken together, this pattern of results does not appear to resemble the characteristics of either a reduction in directional aspects of food motivation (i.e., appetite), or a severe impairment in motor execution. Granted, there are brain areas at which dopaminergic manipulations can produce such effects; for example, hypothalamic DA is involved in appetite, and ventrolateral neostriatal DA depletions can produce motor impairments in reaching, grasping, forepaw usage during feeding, feeding rate, and lever press duration. Nevertheless, nucleus accumbens DA depletions produce more subtle, context-dependent effects that are at the very cusp of motivation and motor control functions, but not solely in either realm.

Of course, nucleus accumbens DA does not participate in behavioral activation and effort-related processes in isolation. Rather, it is a nodal point imbedded into a larger

forebrain circuitry that includes other neurotransmitters and brain regions. Basolateral amygdala and prefrontal/anterior cingulate cortex also participate in effort-related choice behavior. Within the accumbens, evidence indicates that DA interacts with the neuromodulator adenosine to regulate behavioral activity. Stimulation of adenosine A_{2A} receptors in nucleus accumbens can mimic the effects of DA depletions, and blockade of A_{2A} receptors can reverse the effects of DA antagonism. The gamma aminobutyric acid (GABAergic) ventral striatopallidal pathway, the major output pathway from nucleus accumbens to ventral pallidum, also participates in behavioral activation and effort-related functions. Within the last few years, researchers have begun to sketch the outline of the brain circuitry involved in motivational aspects of motivation and related decision-making processes.

Research in this area has shed considerable light on the neural mechanisms underlying motivational aspects of motivation for natural reinforcers. However, it also has considerable clinical significance. Exertion of effort is not only important for natural motivation; excessively focused exertion of effort is a hallmark of drug abuse and addiction. Drug addicts show a radically altered preference structure for motivational stimuli, with drug selection taking a distorted position atop the hierarchy of motivational stimuli. Addicts can show markedly reduced behavioral activation in response to natural reinforcers, and can display psychomotor slowing during drug withdrawal, while also being able to allocate a disproportionate and extreme amount of behavioral (and financial) resources into drug seeking. This exaggerated effort invested in drug seeking in addicts may involve DA, though it is also possible that it is relatively DA independent, relying upon the recruitment of other components of the circuitry. Nevertheless, these patterns of behavior suggest that the addiction process is characterized by a dramatic restructuring of both directional and motivational aspects of motivation. Another clinical manifestation of the role of behavioral activation is related to psychomotor dysfunctions in depression, mania, and other disorders. Energy-related symptoms such as anergia, fatigue, and psychomotor slowing are common symptoms of depression. Clinical research has shown that these symptoms are strongly related to outcome measures in depressed people. In terms of the neural systems involved, evidence indicates that there is a striking similarity between the brain areas implicated in psychomotor dysfunction in depression and the circuitry that is involved in regulating behavioral activation in animals. To a certain extent, psychomotor slowing in depression shares some characteristics with parkinsonism, which is consistent with the use of antiparkinsonian drugs for the treatment of anergia or fatigue. In stark contrast to depression, mania is accompanied by dramatically heightened levels of behavioral activation. People in the manic phase of bipolar disorder often work

copiously, and have an exaggerated sense of self-efficacy, capability, and power.

Several decades of behavioral neuroscience research has shown us that the conceptual structure inherited from psychology is useful, even necessary, for understanding brain function, but also that it can be somewhat limiting. In addition to considering the neural systems that perform the operations related to core psychological functions, we also must recognize that the borders between these functions are not always distinct, that they do not map neatly onto brain systems, and that there can be considerable overlap and integration of function. For example, a particular behavioral function can be sensory/motor, or cognitive/affective. So it is with the relation between motor function and motivation. Clearly, motivational aspects of motivation represent an area of overlap between motivational and motor processes, and the neural systems involved in behavioral activation, such as nucleus accumbens DA, display the characteristics of involvement in this type of functional integration. Continued research on behavioral activation and effort-related processes will help elucidate how brain mechanisms participate in the regulation of both natural and pathological features of motivation, and also how the selection of paths toward specific motivational stimuli can ultimately be translated into action.

Glossary

- Cloninger's novelty seeking** – One of three dimensions measured by the Tridimensional Personality Questionnaire (TPQ); the other two dimensions are harm avoidance and reward dependence.
- Habituation** – Nonassociative loss of responsiveness in a neural or psychological process over time when a constant stimulus is applied.
- Mesocorticolimbic dopamine reward system** – Neural system that projects from ventral tegmental area (VTA) to nucleus accumbens (NAcc), medial prefrontal cortex (mPFC), and associated limbic structures subserving the rewarding effect of novelty, drugs of abuse, and other reinforcers.
- Novelty detection** – Identification of a new or unknown stimulus based on past experience.
- Novelty-induced place preference** – Free-choice preference displayed for a novel context over a familiar context.
- Novelty seeking** – Approach to or preference for a new stimulus relative to a familiar stimulus.
- Sensory adaptation** – Loss of responsiveness in a sensory transducer over time when a constant stimulus is applied.
- Zuckerman's sensation seeking** – Personality trait measured by the Zuckerman–Kuhlman Personality Questionnaire (ZKPQ) that is characterized by a need for novel, complex, and ambiguous stimuli and a willingness to take a risk for obtaining these stimuli.

Background

From a historical perspective, one of the most interesting set of psychological experiments conducted during the 1950s involved the use of extreme sensory deprivation in human subjects. Volunteer subjects were instructed to lie on a bed in a sound-attenuated cubicle and sensory information was restricted by having the subjects wear goggles and gloves. After several hours, the prolonged sensory deprivation had a debilitating effect on normal functions, often producing hallucinatory experiences and unpleasant emotional feelings. Immediately upon termination of the sensory deprivation period, significant deficits in performance on various cognitive tasks were also noted.

However, not all individuals suffered deleterious effects, and there were large individual differences in the reaction to the sensory deprivation.

These early sensory deprivation experiments were important because they helped to usher in the modern view that organisms are not merely passive sensory neural systems, but rather that they are built to require a virtually continuous stream of sensory experience. Repetitive sensory stimulation is not sufficient to maintain the organism, but instead there is a need for varied experience. When faced with a lack of sensory input or a lack of varied input, the organism must become active to seek out the needed stimulation. Thus, novelty engages not merely sensory detection properties, but also incentive motivational neural systems. Both sensory and motivational neural systems are tuned exquisitely to process novel information because attending to and approaching new stimuli leads to potential sources of food, water, and sexual partners, while providing information about potential sources of danger.

A corollary idea is that individuals differ in the degree to which they need varied experience, with some individuals having a high need for novelty and others having a low need. This can be demonstrated by presenting a novel visual stimulus to two different individuals. One individual may habituate rapidly to the stimulus and thus turn away relatively quickly, whereas another individual may habituate slowly and thus attend to the stimulus for a longer period of time. Even though both individuals are attracted initially to the stimulus (novelty detection), the first individual who turns away more quickly to find other sources of stimulation may have a higher need for novelty (novelty seeking). Such individual differences may have important clinical implications for the expression of risk-related behaviors, as discussed below.

Before proceeding, it is important to point out that the term novelty is difficult to define precisely because any discrete stimulus or situation is experienced in the context of other stimuli or situations. In an absolute sense, a novel stimulus is one that has never been experienced before. However, a never-experienced stimulus may be relatively more novel when viewed within a familiar context, as opposed to being viewed in a novel context. Conversely, a previously experienced stimulus may be novel when it occurs unexpectedly in a different context. Hence, novelty is not an absolute attribute of any stimulus or situation, but rather it reflects the relative difference compared to a background.

Mechanisms of Novelty Seeking

Adaptation and Habituation

A general principle of neuroscience is that sensory and integrative systems are tuned to attend to changes in environmental events, as opposed to repetitive monotonous events. In the sensory transduction process, the visual system provides a good example of this general principle. Continuous stimulation of a specific retinal region of the eye with light will fatigue the photoreceptive transduction that occurs at the level of the rods and cones. Such fatigue leads to a temporary loss of visual acuity because the photo pigments of the sensory cells become depleted, a process that is known as sensory adaptation. This adaptive process is partially offset by the saccadic or jerky movements of the eyes, which varies slightly the location of a visual stimulus on the retina.

Within the peripheral and the central nervous systems, constant repetitive stimulation also leads to a loss of function. This process is called habituation, and it represents a primitive form of learning that is important in the context of understanding novelty detection. For example, an auditory stimulus (tone) that is presented for the first time may elicit orienting responses. However, when the same stimulus is presented repeatedly at regular intervals, these orienting responses weaken and may dissipate completely. However, with the passage of time, some of the weakened response may return, a process referred to as spontaneous recovery. Behaviorally, this process is illustrated by placing a rat into the same stimulus environment on repeated occasions. When a rat is first placed into a novel context, it is highly active due to exploratory behavior and this exploratory behavior diminishes across the exposure sessions. Following a rest period, there is some return of the exploratory behavior, although it is somewhat weakened relative to the first exposure. Without this habituation process, an organism would be unable to detect a novel stimulus because the background in which they occur would also be novel.

Motivational Aspects

Not only does novelty engage attention systems, it elicits active exploratory behaviors that engage incentive motivational neural systems. This phenomenon is illustrated in rats by spontaneous alternation in a T-maze. In this test, even when both arms of a T-maze are reinforced with food, rats tend to alternate their choice between the two arms, a behavior that is thought to reflect novelty preference. Rats will also interact more with a novel object than a familiar object and will choose a novel environmental context over a familiar context, suggesting further that novelty engenders positive incentive motivation.

Perhaps the most cogent evidence that novelty has positive incentive value comes from operant conditioning experiments in which novelty is used as a reinforcer. Rhesus monkeys will solve complex discrimination tasks when novel visual and auditory stimuli are presented contingent on correct lever-press responding. Rats will also exert effort (lever pressing) to earn novel visual and auditory stimuli. In contrast to other types of reinforcers such as food, water, or sex, novelty does not necessarily reduce a drive state (hunger, thirst, or sexual drive), and there is no consummatory response that leads to satiation. In this regard, novelty is somewhat analogous to the phenomena of brain stimulation reward, a motivated behavior that can be maintained for prolonged periods with little diminution in intensity.

Development

Novelty seeking represents an important functional aspect of the nervous system across the life span. Prelingual human infants are attracted to complex visual patterns. This preference can be demonstrated by exposing infants to a pattern on a computer screen repeatedly, followed by presentation of a novel stimulus. Using an eye-tracking system, it has been shown that infants spend more time viewing novel stimuli than familiar stimuli. If a discrete novel stimulus is presented as a feature against a background of familiar stimuli, infants are readily able to detect the stimulus, a phenomenon that is sometimes referred to as the pop-out effect.

Adolescence is a developmental period that is characterized by an especially heightened expression of novelty seeking. This is a period in which mammals become fully capable of moving away from parental protection into an environment where potential mate selection will be available. In many mammals, including humans, activity levels and risk taking increase at the same time as the onset of puberty. While this is a period of heightened risk, it should be emphasized that this is generally an adaptive strategy for species survival. Moreover, novel stimulation plays a critical role in promoting normal development, as well as maintaining an optimal level of arousal for information processing.

Neural Mechanisms

While there are undoubtedly multiple brain regions and neurotransmitters involved in novelty seeking (see **Table 1**), one critical part of the neural circuitry is the mesocorticolimbic dopamine (DA) system. Many studies have shown that exposure to novelty (either forced exposure or free-choice exposure) activates the mesocorticolimbic DA system. Similar to the effects of many drugs of abuse, rats exposed to novel environmental stimuli display an increase in locomotor activity. Rats also

Table 1 Some of the various brain systems activated following exposure to novelty

show a conditioned place preference when novel objects are paired with one compartment of a place preference apparatus. When entering a novel compartment from a familiar compartment, there is a transient and rapid surge in DA activity in the nucleus accumbens (NAcc) recorded by *in vivo* voltammetry. This rapid increase in voltammetric signal is not obtained when the rat re-enters the now familiar compartment, and thus it is not an artifact of locomotor activity or a general stimulus change. Further, injection of the neurotoxin 6-hydroxydopamine (6-OHDA) into the mesocorticolimbic DA system disrupts the increase in locomotion and rearing normally elicited by novel stimuli. Novelty-induced place preference is also blocked by DA antagonist drugs (both D1 and D2 antagonists) and by lesioning the NAcc. Even though the 6-OHDA-induced blockade of novelty-induced place preference is reversed after several weeks, a deficit in exploratory behavior persists.

In recent reports using electrophysiological techniques in nonhuman primates, novelty signal detection has been observed in the ventral tegmental area (VTA) of behaving animals. VTA neurons show tonic impulse activity, but respond with short-latency, short-duration bursts of activity to novel stimuli, unpredictable positive rewards, and conditioned stimuli that reliably predict positive rewards. VTA neuron burst firing is thought to occur when the stimulus input is sufficiently novel to warrant a change in behavior. Similarly, in human subjects, anticipation of novelty reward activates the ventral striatum and this activation is correlated positively with scores on the novelty-seeking subscale of Cloninger's Tridimensional Personality Questionnaire.

Monoamines other than DA also play a role in novelty detection and seeking. For example, accumulating evidence indicates that norepinephrine activity in the

hippocampus is also involved in novelty signal detection. Although no direct neural connections have been found between the VTA and the hippocampus, most hippocampal targets send efferent projections to the VTA. For example, the hippocampus sends efferents to the medial prefrontal cortex (mPFC), which sends excitatory input stimuli to VTA. Similarly to the novelty-induced increase in mesocorticolimbic DA, exposure to novel environmental stimuli increases the concentration of extracellular norepinephrine in the frontal cortex assessed by *in vivo* microdialysis, which presumably reflects an increased response of neurons in the locus ceruleus. In any case, these results indicate that the VTA acquires information about stimulus novelty through circuitry involving the prefrontal cortex and hippocampus, sites for memory storage, and novelty detection.

Serotonin and glutamate systems have also been implicated in novelty seeking. The 5-HT_{1A} agonist 8-OHDPAT produces a dose-dependent decrease in novel object exploration in rats, whereas the 5-HT_{1A} antagonist WAY-100635 produces an increase in novel object exploration. Importantly, these serotonin-mediated effects are obtained without any change in locomotor activity, thus demonstrating that the effects are specific for approach to novelty rather than general exploratory behavior. Similarly, a role for glutamate has been illustrated in rats conditioned to approach an environmental context paired previously with a novel object. The noncompetitive *N*-methyl-D-aspartic acid (NMDA) antagonist MK-801 given during the conditioning phase blocks this effect, thus implicating a role of NMDA receptors in learning produced by stimulus novelty.

Individual Differences in Novelty Seeking

Genetic Influences

There is considerable evidence that novelty seeking is, at least in part, under genetic control. For example, different inbred strains of mice display a different level of locomotor activity in a novel apparatus, as well as a different rate of contact with novel objects. Along with these behavioral differences, strain differences have been observed in a number of DA neurochemical markers, including the density of DA striatal D₂ receptors, metabolism of DA in the NAcc, and drug-stimulated DA release.

Recently, Akil and colleagues at the University of Michigan have initiated a selective breeding study in rats based on the novelty-seeking phenotype. Based on the level of locomotor activity in an inescapable novel environment, selectively bred high responders show decreased anxiety-like behaviors compared with low responders. In addition to alterations in DA systems, phenotype differences between high and low responders are observed in mRNA signal for serotonin receptor

transcripts in the olfactory tubercle, dentate gyrus, dorsal hippocampus, and thalamo-cortical projection areas, implicating a contribution of 5-HT systems to novelty seeking.

In humans, both twin-pair and family history approaches have revealed a genetic influence on the expression of novelty seeking. While there is some variability in published results across different population samples, genetic factors alone generally account for about 50% or more of the variance in novelty-seeking scores measured by either Zuckerman's sensation seeking scale or Cloninger's novelty seeking scale. Some evidence also suggests that the degree of inheritance may be greater in males than in females.

Novelty seeking was reported initially in 1996 to be associated with a polymorphism of the DA D₄ receptor (DRD4) gene. Subsequent reports using independent populations have either refuted or confirmed a role of the DRD4 gene in novelty seeking, thus generating considerable debate in this area. In another line of work, high novelty seekers have been shown to have low monoamine oxidase (MAO) activity in blood platelets. Since MAO is the major enzyme that metabolizes monoamine neurotransmitters such as DA, these results suggest that the activity of monoamine brain systems, and DA in particular, may differ between high and low novelty seekers. However, this conclusion is speculative presently, since platelet MAO activity is not a reliable index of MAO activity in the brain.

Environmental Influences

While individual differences in novelty seeking are under some genetic control, they are also influenced by environmental factors. One important environmental factor that alters novelty seeking is the amount of novel sensory experience that an individual encounters during development. One paradigm that has been used widely is the environmental enrichment paradigm. In this paradigm, rats are housed for several weeks in either an enriched condition (EC) with novel objects and social cohorts or an isolated condition (IC) without objects or cohorts; rats can also be raised in a social condition (SC) in which cohorts are available, but no novel objects. A host of studies has shown that EC rats display a wide range of neurobehavioral changes relative to IC rats. In general, EC rats find novelty to be less stressful than IC rats, and they will approach novel stimuli more rapidly than IC rats. For example, while EC rats display less activity than IC rats in an inescapable novel environment, in a free-choice situation, they enter a novel compartment and manipulate novel objects more than IC counterparts do. While they approach novelty more readily, EC rats also habituate to novel stimuli more rapidly than IC rats. EC rats are less motivated than IC rats to make an operant response for a

weak auditory or visual reinforcer, suggesting that the incentive value of novelty is reduced by enrichment.

The enrichment-induced alterations in novelty seeking may be mediated by various neural substrates. Studies have shown that environmental enrichment produces profound neuroanatomical and neurochemical changes in the neocortex, particularly in the visual cortex, which likely explains the enhanced visual acuity by EC rats. Environmental enrichment increases dendritic arborization, as well as increasing neocortical weight and thickness, primarily due to an increased density of glial and capillary endothelial cells. These enrichment-induced anatomical changes are initiated by the expression of various gene-encoded transcription factors, some of which are involved in inducing neurotrophic factors. Similar to environmental enrichment, repeated exposure to stimulant drugs such as amphetamine and cocaine increases dendritic branching in NAcc and mPFC.

As regards specific neurotransmitter systems, relatively little is known about the effect of environmental enrichment on subcortical neurotransmitter systems, and on NAcc activity in particular. In one study, no difference in DA D1 or D2 receptor levels in NAcc (core, shell, and rostral subregions) was found between EC and IC rats. However, it has been shown that EC rats have greater glucose utilization in NAcc following exposure to a novel environment relative to IC rats, but it is not known if this increase in metabolic activity reflects a specific activation of DA neurons. In cortex, environmental enrichment increases cholinesterase activity and increases levels of norepinephrine and DA. In mPFC, environmental enrichment decreases the density of DA D1 receptors and the number of cell-surface DA transporter proteins, indicating that the repeated exposure to novelty during development downregulates both pre- and postsynaptic proteins involved in DA transmission. It remains to be determined if this change in mPFC underlies the enrichment-induced alterations in novelty seeking.

Risk-Related Novelty Seeking

Drug Abuse

Laboratory animal studies

Similar to novelty-seeking behavior, there is ample evidence that drug-abuse-related behaviors also involve ascending mesocorticolimbic DA projections. While a full review of that literature is beyond the scope of the current article, Piazza and colleagues at the University of Bordeaux have shown that individual differences in locomotor activity within an inescapable novel environment predict stimulant self-administration, with high-responder rats self-administering more cocaine and amphetamine than low-responder rats. Compared with low responders, high responders also exhibit greater

neuronal firing in VTA, greater levels of extracellular DA in NAcc following exposure to novelty or stimulant drugs, greater velocity of DA uptake in NAcc, and greater mRNA levels for tyrosine hydroxylase and DA D1 receptor proteins. In addition, high responders have fewer DA D2 receptors in NAcc, suggesting a decreased number of release-regulating autoreceptors or a compensatory downregulation of postsynaptic receptors in response to increased presynaptic DA release. Despite the wide use of this model, it is not clear to what extent it reflects individual differences in novelty exploration (novelty seeking), as opposed to individual differences in stress reactivity within the inescapable novel environment. Stress reactivity likely plays some role, since high and low responders differ in levels of the stress hormone corticosterone.

Other rat models have examined free-choice approach to a novel context or novel objects as a more direct measure of novelty seeking. Individual differences in novelty place preference have been shown to predict amphetamine reward, and this relation is probably not due to individual differences in stress hormones because free-choice novelty does not elevate levels of corticosterone. Instead, approach to novelty likely activates directly the reward-relevant mesocorticolimbic DA circuitry.

Evidence from inbred rat strains also supports the importance of genetics in the control of novelty-seeking and drug-seeking behaviors. The Lewis (LEW) and Fischer (F344) rat strains have received considerable attention. Relative to F344 rats, LEW rats display increased locomotor activity in an inescapable novel environment and increased sensitivity to the locomotor-stimulant effect of methamphetamine. LEW rats also display greater intake of various drugs of abuse and more rapid acquisition of intravenous cocaine self-administration. The greater drug intake in LEW relative to F344 rats likely reflects an enhanced sensitivity to the reinforcing effect, as LEW rats also show greater cocaine conditioned place preference. At the neurochemical level, although DA receptor levels are similar between LEW and F344 rats, LEW rats display greater tyrosine hydroxylase activity in VTA and greater cocaine- and methamphetamine-induced DA release in NAcc.

More recently, selective breeding of rats that are either high or low on activity in an inescapable novel environment indicates that high responders self-administer more cocaine than low responders do. Interestingly, while both male and females show these heritable differences, high-responder females show the most dramatic increase in acquisition of cocaine self-administration, suggesting that female novelty seekers may be especially vulnerable to stimulant abuse. However, this conclusion is tempered somewhat by other work showing that mice selectively bred for differences in exploratory head dipping do not consume differential amounts of ethanol or methamphetamine.

As for environmental influences, just as environmental enrichment alters mesocorticolimbic DA neurocircuitry, it also alters the neurobehavioral effects of drugs of abuse such as amphetamine. EC rats are more sensitive than IC rats to the locomotor stimulant effect of acute amphetamine and are more sensitive to amphetamine conditioned place preference. These behavioral differences are accompanied by an enrichment-induced increase in amphetamine-stimulated DA release and metabolism in NAcc. With repeated amphetamine injections, however, EC rats show an attenuation of locomotor sensitization relative to IC rats, as well as a reduction in the discriminative stimulus effects of amphetamine. EC rats also exhibit a reduction in amphetamine self-administration across repeated sessions. Thus, although some of the initial effects of amphetamine may be enhanced, environmental enrichment reduces the psychostimulant effects of repeated amphetamine treatment.

Human studies

In humans, numerous studies indicate that individual differences in novelty or sensation seeking, measured by either the Cloninger or Zuckerman questionnaires, reliably predict drug use and abuse, with high novelty seekers being at increased risk. Recent meta-analytic reviews have found small-to-moderate effect sizes between novelty seeking scores and alcohol use, with the effect size tending to be greater among studies that include higher percentages of male subjects. Individual differences in response to stimulant drugs are also related to novelty seeking. For example, in controlled human laboratory studies, high novelty seekers show greater amphetamine-induced subjective stimulation and elevated mood compared to low novelty seekers. High novelty seekers have been shown to be more sensitive than low novelty seekers to the rewarding effects of drugs of abuse as measured by self-administration. The relation between novelty seeking and positive response to amphetamine in healthy volunteers is consistent with the idea that common neural mechanisms underlie both measures, and that such mechanisms may be in part responsible for the increased vulnerability to psychostimulant use and abuse among high novelty seekers.

It is generally assumed that novelty seeking is an antecedent trait that increases risk for abuse; however, much of this work has involved cross-sectional analyses, which does not allow for determining the exact relation between novelty seeking and drug use. While longitudinal studies have confirmed that novelty seeking early in life does predict later drug use, there is also evidence that drug use can increase novelty seeking. This latter finding suggests that drug use may predict later novelty seeking due to a third variable (e.g., common deviant peer influence) or due to a direct effect of the drug on brain function. In any case, it appears that there is a reciprocal relationship between novelty seeking and drug use.

Other Risk-Related Behaviors

In addition to increased drug-abuse vulnerability, individual differences in novelty seeking predict other negative health outcomes in humans. Novelty or sensation seeking is associated with aggressive and criminal antisocial behaviors. High novelty seekers are also more likely to engage in sexual risk taking, including having multiple sex partners, causing or becoming pregnant, and having unwanted sex while drunk. Further, high novelty seekers are more likely to gamble, drive fast, and suffer from physical injuries. In survey studies, high novelty seekers report a greater likelihood than low novelty seekers to not wear seatbelts, beat other drivers at the getaway, weave through traffic, enjoy passing other vehicles, and driving at high speeds. Extreme and dangerous sports, such as skydiving, hang gliding, motorcycle racing, ocean kayaking, rock climbing, and scuba diving, have also been correlated with high novelty seeking. Finally, novelty seeking has also been associated with various eating disorders; in particular, individuals with bulimia nervosa or anorexia nervosa characterized by binge eating and purging have higher novelty seeking scores than controls.

In conclusion, research in the field indicates that novelty seeking is a phenotypic behavior that is highly adaptive and conserved within the species. It serves to direct attention toward unexpected events that may have important biobehavioral relevance for survival and, thus, novelty has an affective positive incentive value. However, unbridled novelty seeking can be maladaptive, consistent with the evidence linking it to risk-related negative health outcomes. Thus, the most adaptive individual may be one who not only has the ability to attend to and approach novelty, but also has that ability to counterbalance that propensity with appropriate behavioral inhibitory control when needed.

Glossary

Incentive sexual stimuli – Primary or conditioned stimuli that stimulate sexual arousal and desire. Conditioned sexual incentives appear to require both opioid and dopaminergic activation for their salience, whereas primary (unconditioned) sexual incentives do not appear to require dopamine. **Sexual arousal** – It refers to increased activation of the autonomic nervous system that prepares the body for sexual responding. This includes increased parasympathetic actions that control genital blood flow and increased sympathetic actions that increase heart rate and breathing rate. It is typically divided into physiological arousal (reflecting blood flow into or out of tissues) and subjective arousal (reflecting a conscious awareness of one's physiological state). Key neurochemical activators include noradrenaline and acetylcholine both in the brain and the periphery to modulate the arousability of the organism, and dopamine, oxytocin, and vasopressin in the hypothalamus and pituitary to direct autonomic outflow.

Sexual desire – It refers to wanting or craving sexual activity, along with behaviors aimed at acquiring sex partners or sexual reward, including operant responses for conditioned sexual incentives. It is synonymous with sexual excitation and most obviously reflective of sexual motivation. It is altered by hormonal actions and the effect of priming stimuli on neural systems for incentive motivation in general and sexual responding in particular, but also by the degree of sexual inhibition present at any given time. Sexual desire is typically viewed as conscious, although it can be expressed as an ability to be distracted by primary or conditioned sexual incentive stimuli, or as an inability to be distracted away from such stimuli. Key neurochemical activators include central actions of dopamine, melanocortins, and oxytocin, to modulate incentive sexual responding and partner preference.

Sexual inhibition – It refers to a dampening of sexual arousal and desire. This occurs in varying degrees as a function of sexual reward and satiety, as occurs during sexual refractoriness or exhaustion, or as a function of stress, fear, or punishment, as might occur in situations in which having sex would be dangerous for the

organism. Key neurochemical activators of the inhibitory state appear to be central opioid transmission that gives rise to a sexual reward state or that is activated by stress or fear, and central serotonin transmission that gives rise to a state of satiety that inhibits both incentive sexual responses and genital blood flow.

Sexual reward – It refers to the pleasure derived from sexual gratification. This occurs most typically as a function of the reward state induced by orgasm, but may also include the intimacy, bonding, and control inherent in sexual activity with one or more partners. A key neurochemical activator appears to be central opioid transmission, most notably in the medial preoptic area of the hypothalamus and ventral tegmental area of the midbrain.

Sexual satiety – A state of refractoriness in which sexual responding is inhibited and in which further sexual stimulation may be aversive or painful.

What Is Sexual Motivation?

Definitions

Sexual motivation can be defined as the energizing force that generates one's level of sexual interest at any given time. It drives our sexual fantasies, compels us to seek out, attend to, and determine the quality of sexual incentives, regulates our levels of sexual arousal and desire, and enables us to masturbate, copulate, or engage in other forms of sex play. It seems like a straightforward concept, yet it runs into trouble at several important levels. As a concept of something internal, it is often circular, being inferred from the strength of a behavior or content of a fantasy. Of course, people can be highly motivated sexually but suffer from an arousal disorder, such as erectile dysfunction. The concept also runs into problems of definition when it is presented as a fuzzy dichotomy, like "physiological versus subjective arousal," or when it is used to define a set of internal motivational processes that are somehow distinct from the outward expression of sexual performance (as if any sexual performance is not also sexually motivated). Defining the goal of sexual behavior – a necessity if we are to understand what the

motivation is driving the organism to do – is often tricky because it ranges from reward to reproduction.

The value of a concept like sexual motivation lies in its ability to provide a framework, or ‘heuristic,’ within which sexual behaviors and their neural correlates can be more easily organized and understood. It should be able to handle animal and human sexual behaviors at different levels of analysis, and despite their outward dissimilarities. General models of sexual behavior are almost always conceptual in nature, and try to distill the behavioral components down to core variables that can be applied across species or situations.

Common Components of Sexual Behavior

All organisms that engage in sexual behavior share a common set of principles and endpoints that define the behavior. First, they must be able to respond to hormonal and neurochemical changes that signal sexual arousal and desire. This ability underlies a moment-to-moment level of sexual arousability and contributes to the internal state that is commonly referred to as sex drive. Organisms must be able to identify external stimuli that predict where potential sex partners can be found, to seek out, solicit, court, or otherwise work to obtain sex partners, distinguish external cues and behavioral patterns of potential sex partners from those that are not sexually receptive, and to pursue sexual partners once sexual contact has been made. Neural mechanisms exist that allow the stimulation received during sexual contact to be perceived as rewarding. Such reward alters subsequent behavior, for example, by contributing to the formation of preferences for salient stimuli associated with positive sexual reinforcement, and also leads to a state of sexual satiety in which inhibitory neural systems are activated.

For all animals, sexual behavior occurs as a sequence or cascade of behavioral events. Researchers have recognized the heuristic value of separating sexual behavior into respective appetitive and consummatory phases. Appetitive behaviors bring an animal from distal to proximal and into contact with goal objects or incentives. Consummatory behaviors are performed once an animal is in direct contact with the incentive (i.e., to consummate the goal). Consummatory behaviors tend to be species specific, sexually differentiated, and stereotyped, whereas appetitive behaviors are more flexible. Indeed, survival often depends on an animal’s ability to learn a variety of strategies to obtain goals in different appetitive circumstances. Heuristically, it is useful to conceive of appetitive and consummatory behaviors as two overlapping Venn diagrams (**Figure 1**) in which the behavioral stream moves from appetitive to consummatory incentive sequences. The intersection of the diagrams defines pre-copulatory behaviors made once animals come into contact with potential sex partners. The diagrams are

overlapping, rather than discontinuous, because the division between the two phases is rarely fixed. Some responses, such as solicitation, can be placed into both phases, especially if sexual interaction comes in bouts. Solicitation would, therefore, be defined as a precopulatory behavior that acts as a transition from appetitive to consummatory.

It is also useful to describe sexual motivation in terms of components of sexual behavior displayed across species, including sexual arousal, desire, reward, and inhibition. In turn, the neural substrates that control those aspects of sexual function can be studied in terms of how they are altered by hormones, sensory stimulation, conditioned cues, drugs, and lesions or stimulation of different brain regions.

Sexual Arousal

Sexual arousal in the humans and other animals can be defined as increased autonomic activation that prepares the body for sexual activity. This includes both parasympathetic blood flow that keeps blood in genital tissues such as the clitoris, labia, vaginal epithelium, and penis, and sympathetic blood flow from the heart to striated and smooth muscle that participate in sexual responses. Sexual arousal also includes a central component that increases neural tone or preparedness to respond to sexual incentives. Both peripheral and central arousal may be detected as part of the perception of subjective sexual arousal, and both clearly lead to changes in responsiveness in genital tissues and control certain copulatory responses, such as the latency to orgasm or ejaculation.

Both in males and females, removal of the gonads or conditions in which gonadal output is depressed or inhibited (rendering the individual hypogonadal, as happens to women after menopause) lead to decreases in sexual arousal. Penile, clitoral, and vaginal tissues shrink in such conditions and blood flow to those tissues is compromised. Those effects can be counteracted by hormone-replacement therapy (e.g., exogenous administration of androgens in males and females, and/or androgens and estrogens in females). Hypothalamic and, possibly, limbic structures are key targets for steroid hormones in the stimulation of autonomic outflow and in the processing of sexually arousing cues that lead to autonomic outflow. Many treatments that enhance genital blood flow in men and women enhance penile erection and vaginal vasocongestion in rats and rabbits (e.g., phosphodiesterase (PDE)-5 inhibitors such as sildenafil, dopamine (DA) agonists such as apomorphine, melanocortin agonists such as melanotan-II (MT-II) and its active metabolite bremelanotide, prostaglandin E₁, oxytocin, α_2 -adrenergic receptor antagonists like yohimbine, idazoxan, or imiloxan, vasodilators that act through nitric oxide substrates, such as nitroglycerine, sodium nitroprusside, and linsidomine).

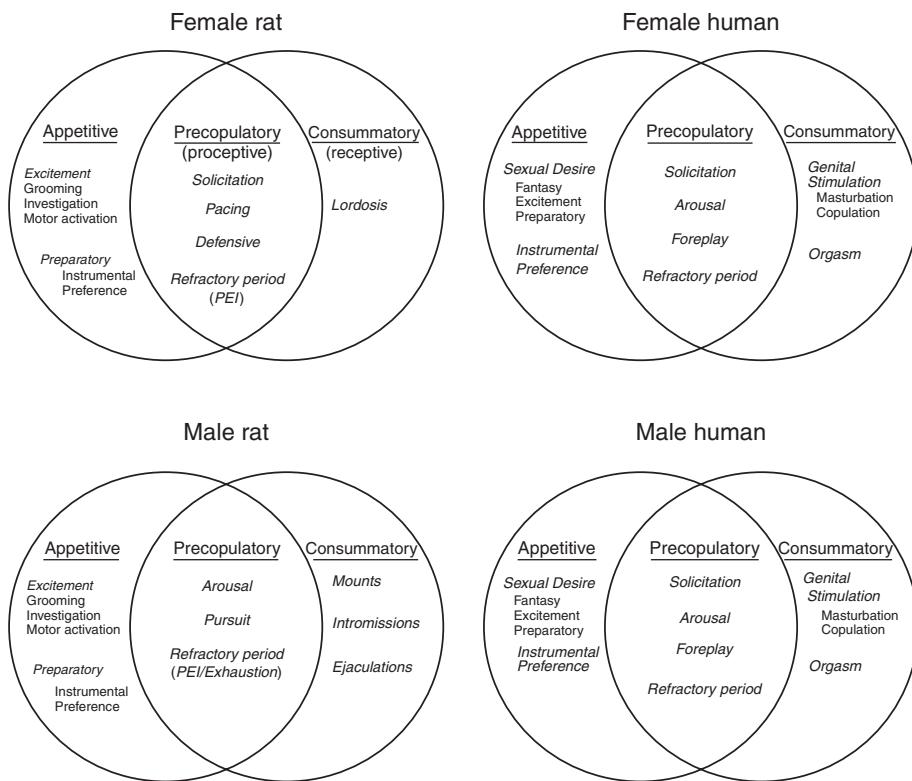

Figure 1 Incentive sequences for human and rat sexual behavior. The behavioral stream moves from left to right, through appetitive, precopulatory, and consummatory phases of behavior. This conforms to the movement of animals from distal to proximal to interactive with respect to the sexual incentive. Three types of appetitive responding reflect relative degrees of learning and necessity. ‘Preparatory’ behaviors are learned responses that animals must make in order to acquire the incentive (e.g., operant behaviors, pursuit). ‘Anticipatory’ behaviors are learned responses that occur in anticipation of an incentive, but are not necessary to obtain it (e.g., conditioned psychomotor stimulation that characterizes behavioral excitement). Unlearned appetitive responses also exist that are innate (e.g., unconditioned anogenital investigation). These aspects of behavior also occur once copulatory contact has been made, especially if copulation occurs in bouts (as it does in rats). Adapted with permission from Pfau JG (1999) Revisiting the concept of sexual motivation. *Annual Review of Sex Research* 10: 120–157

Selective activation of DA receptors in the medial preoptic area (mPOA) of the anterior hypothalamus alters autonomic arousal, with selective agonist actions on D1 receptors facilitating erections and inhibiting seminal emissions in male rats, and selective actions on D2 receptors doing the opposite. This suggests that the erectogenic actions of the DA agonist apomorphine in rats occur through its binding to D1 receptors in this or other brain regions, such as the paraventricular nucleus of the hypothalamus (PVN) – another region that controls erection through the release of oxytocin. A similar mechanism may exist in the control of female vaginal blood flow, as melanocortin agonists increase vaginal blood flow in women and stimulate DA release selectively in the mPOA in both male and female rats.

Sexual Desire and Reward

Perhaps the most obvious examples of sexual motivation are found in behaviors that denote sexual desire. Clinicians and motivational theorists alike view sexual

desire as distinct from sexual arousal both in animals and the humans, a distinction that generally reflects blood flow to the genitals and erectile tissues versus a psychological sexual interest in which individuals want or crave sex. When an individual expresses sexual desire, attention and behavior focus on obtaining some form of positive sexual reinforcement. This can occur alone in fantasies or together with others in goal-directed social and sexual behaviors. Thus, in addition to people stating colloquially that they feel horny (with or without corresponding arousal), desire encompasses the work people will perform to obtain sexual rewards, the excitement displayed in anticipation of such rewards, and the strength of the incentive value ascribed to a particular sexual stimulus. It must be noted that sexual desire and sexual reward go hand-in-hand, and the strength of desire is usually directed by the anticipation of reward. Many behaviors that reflect the reward state, for example, conditioned place or partner preferences, are typically tested using measures of sexual desire (e.g., movements into the

preferred place, solicitations of the partner associated with greater sexual reward, and choice of partner for ejaculation).

Similar to the humans, animals increase their motor output in anticipation of copulation and work for the opportunity to copulate or to obtain primary or secondary (conditioned) sexual rewards associated with copulation. Animals will also choose among two or more sexual incentives based on the strength of the incentive cues and the animal's own internal drive state. What characterizes these behaviors is that they occur before copulation: Solicitation, courtship, operant responses, conditioned locomotion in anticipation of sex, time spent near a particular sexual incentive, or choices made between two or more incentives can all be considered analogies of anticipatory sexual desire. Desire can also be inferred from certain appetitive behaviors that occur during copulation. Those aspects of sexual behavior are altered in a relatively selective fashion by certain drugs that are known to alter desire in the humans.

It is generally agreed that sexual reward in the humans reflects the pleasure obtained during or after genital stimulation (e.g., the pleasure inherent in genital stimulation during copulation and/or orgasm, and intimacy during the delicious afterglow). In male rats, the reward state induced by ejaculation supports the development of conditioned place and partner preferences. However, the sexual reward state also depends on the level of sexual arousal experienced prior to ejaculation. Both conditioned place and partner preferences in male rats can be abolished by treatment with the opioid antagonist drug naloxone during conditioning, indicating that the release of endogenous opioids during copulation and/or ejaculation are a critical feature of the reward state. Female rats also form conditioned place and partner preferences if they are allowed to control or pace the initiation and rate of copulation. This can be accomplished in open fields and bilevel chambers (in which the female can enforce her preferred copulatory interval by running from the male, forcing the male to chase her), or in pacing chambers bisected by a barrier with holes that allow only the female to cross into and out of the male's side. Similar to males, treatment with the opioid antagonist naloxone during conditioning abolishes the development of both conditioned place and partner preferences. Moreover, female rats given their primary sexual experiences under the influence of naloxone display significantly fewer solicitations and other sexual interactions with males when taken off the drug, indicating that the lack of opioid-induced reward during their formative sexual experiences lead to a decrease in measures of sexual desire. It thus appears that opioid turnover during copulation, particularly in hypothalamic and/or limbic regions of the brain, constitutes a critical feature of sexual reward.

Instrumental Responding for Primary or Conditioned Sexual Rewards

Sexual rewards may come in the form of primary reinforcers (e.g., orgasm in the humans; ejaculation in male rats or the ability to regulate or 'pace' copulation in female rats), or secondary reinforcers, such as stimuli associated with sexual gratification (e.g., certain facial features, clothes, or smells in the humans; certain odors or place cues in rats). All animals work to obtain such rewards. In male rats, those behaviors have included performance in obstruction boxes, straight-alley running, maze learning, crossing of electrified grids, nose-pokes through a wire-mesh screen that prevents contact with a sexually receptive female, digging through sand, bar-pressing for a sex partner or for second-order cues such as light associated with the arrival of a sex partner. Indeed, to gain access to receptive females, male guinea pigs will learn to run an alley, male pigeons will learn to peck keys, and male stickleback fish will learn to swim through rings.
